the products are acetic acid and water. It is found that the presence of acetic acid causes rusting and corrosion, and that the addition of a considerable quantity of benzol to the alcohol serves as a safeguard against such corrosion. In France a mixture of equal parts of denatured alcohol and benzol has been used as an engine fuel. The analysis of the fuel was as follows: C, 0.690; H, 0.095; O, 0.146; H_2O, 0.069; higher heating value by test, 14,180 B.t.u. Table 12 gives combustion data for the various alcohol fuels. Approximate heats of combustion for American commercial alcohol in B.t.u. are as follows: Wood alcohol, 8140; 95 per cent. ethyl alcohol, low value 10,500, high value 11,900; denatured alcohol, 10,350.

Blast-furnace Gas. Plottings of gas analyses from a group of 11 furnaces in operation during a continuous period of 2 years yield the following formulæ, in which R = lb. of dry coke per ton of pig iron:

Per cent. by volume of methane = constant = 0.2
Per cent. by volume of hydrogen = $0.000276\,R + 2.944$
Per cent. by volume of CO_2 = $24.67 - 0.0054R$
Per cent. by volume of CO = $16.15 + 0.00476R$

Using a coke containing approximately 88 per cent. carbon, and assuming that the carbon charged as coke reappears in the gas and that the carbon in the limestone is offset by the carbon in the pig iron and flue-dust produced, the following formulæ have been derived, in which T = tons of iron per 24 hr., the calorific values of CO, H and CH_4 in B.t.u. per cu. ft. being taken respectively as 324, 275 and 915:

B.t.u. per cu. ft. of gas = $0.016R + 62.5$
Cu. ft. gas per ton of iron = $71.4R$
B.t.u. in gas per ton of iron = $1.143R^2 + 4462.5R$
Cu. ft. of air at tuyères per ton of iron = $51.4R$
Cu. ft. of air per min. = $0.0357RT$.

Acetylene (92.3 C + 7.7 H by composition) see Table 48, p. 365, is a colorless gas having a specific gravity of 0.91. It liquefies under a pressure of 700 lb. per sq. in. at 70 deg. fahr. Acetylene as a fuel is confined to the oxy-acetylene blowpipe for cutting and welding metals, in which the combustion of a mixture consisting of 1 volume of acetylene and 1.7 volumes of oxygen produce a flame having a temperature of 6300 deg. fahr. Acetylene is obtained by bringing water into contact with calcium carbide, 1 lb. of chemically pure carbide yielding (at 70 deg. fahr. and 30 in. of mercury) 5.83 cu. ft. of the gas and precipitating slaked lime. The commercial carbide, containing impurities, yields around 5 cu. ft. per lb. Calcium carbide, CaC_2(62.5 Ca + 37.5 C by composition), is made by the reduction of an intimate mixture of quicklime (100 parts by weight) and powdered coke (68 parts) in an electric arc furnace, about 1.8 lb. of the mixture being required to produce 1 lb. of carbide. It is a crystalline, semi-metallic solid having a specific gravity of 2.22.

MISCELLANEOUS NON-METALLIC MATERIALS

BY

CARL F. WOODS

ABRASIVES

REFERENCES: Printed matter issued by the Norton Company and the Carborundum Company; "The Relative Efficiency of Different Abrasives in Common Use," *Sc. Am. Supp.*, Dec. 8, 1894.

Abrasives are of two general types, those used for removing metal or other stock and those used for burnishing or polishing. In leather or wood-working, for instance, the abrasive must be sufficiently hard to maintain its sharpness, while in cutting steel and other metals the cutting quality is maintained by the particles of the abrasive breaking away and constantly presenting new cutting surfaces.

Natural Abrasives

Corundum, the best of the natural abrasives, is a mineral composed of nearly pure alumina with a hardness of 9, in Mohs's scale, namely, next to that of the diamond. The artificial product, however, is much harder.

Emery, an impure form of corundum, has been extensively used for grinding wheels and abrasive paper on account of its cheapness. It is now used to some extent to mix with corundum and artificial abrasives, but has been largely superseded by the artificial products. Corundum and emery are graded according to the mesh of the screen through which they pass. These screens run 4, 6, 8, 10, 12, 14, 16, 20, 24, 30, 36, 40, 46, 54, 60, 70, 80, 90, 100, 120, 150, 180, and 200 to the inch. The flour, which is obtained by settling the overflow from the washers, is graded as 1F, 2F, 3F, 4F, 5F, and 6F.

The abrasive action of emery depends upon its corundum content; but chemical analysis is not a reliable guide as physical characteristics are more important. The amount of attrition produced by rubbing the powder between two weighed pieces of plate glass for a definite time as compared with that produced by a powder of known quality, is a good indication of the abrasive quality. Corundum is used mainly for the manufacture of vitrified wheels. For polishing, emery flour is better than corundum, as it does not scratch so much.

Garnet. Certain deposits of garnet having a hardness between quartz and corundum are used in the manufacture of abrasive paper. Quartz is also largely used for this purpose. In the electrical trades, quartz colored to imitate garnet is sometimes substituted. Garnet costs about twice as much as quartz and generally lasts proportionately longer. It is better for wood-working than the artificial abrasives, as the grains do not break down. Corundum is superior to garnet for leather working. A small quantity of feldspar is also used as an abrasive, but is much inferior.

Grindstones and Pulpstones are quarried directly and generally made from sandstone.

Buhrstones and Millstones are generally made from cellular quartz. **Chasers** (or stones running on edge) are also made from same mineral.

Oilstones. The great majority of oilstones are quarried in Arkansas and are known as "Arkansas" and "Washita" stones. The **Arkansas stone** is a true novaculite, homogeneous, gritty, and of a fine, siliceous composition. The hard variety is used for sharpening tools requiring a very fine edge, such as those of surgeons, engravers, dentists, etc. The soft variety is more porous and coarser and is used for less careful work.

Of same hardness as quartz, but very brittle. **Washita stone** is less dense, more porous and of the same general composition. The chief use is for whetstones and for coarser tools.

Pumice, of volcanic origin, is extensively used in leather, felt, and woolen industries, and in the manufacture of polish for wood, metal, and stone. An artificial pumice is made from sand and clay in five grades of hardness, grain, and fineness.

Infusorial Earth or Tripoli resembles chalk or clay in physical properties; it can be distinguished by absence of effervescence with acid; is generally white or gray in color, may be brown or even black. Owing to its porosity it is very absorptive. It is used extensively in polishing powders, scouring soaps, etc.; and on account of its porous structure, in the manufacture of dynamite as a holder of nitroglycerine; also as a non-conductor for steam pipes and as a filtering medium. Also known as **kieselguhr.**

Artificial Abrasives

Artificial abrasives, although more expensive than the natural, are rapidly superseding them owing to the absolute uniformity which it is possible to impart to the coarseness or fineness of the grade, thus enabling a perfect stone to be made with either a coarse, medium, or fine grain. It is also possible to produce a stone of unvarying hardness or mixture throughout, thus avoiding soft or hard spots, coarseness, and other defects in natural abrasives.

Aluminum Oxide. The artificial aluminum oxide products are best adapted as abrasives for high-tensile-strength metals such as steel. **Alundum** is made by the Norton Company from bauxite in the electric furnace. The physical formation of the grain of alundum is such that when it is broken or fractured it leaves sharp cutting corners or edges, but the material is very tough and stands up under the hardest service. It is also used in the manufacture of refractories and electric furnace parts. **Aloxite** and **corubin** are trade names of similar products. Melting point, around 3720 deg. fahr. Coefficient of expansion, 0.00000328 per deg. fahr.

Carbide of Silicon. Two products known as **carborundum** (Carborundum Co.) and **crystolon** (Norton Co.) are available. They are made by fusing together in an electric furnace, coke, sand, sawdust and salt. The abrasive so produced is characterized by great brittleness, the grains readily separating and breaking, thus presenting new cutting surfaces and preventing glazing. Carbide of silicon can be used for grinding most materials, but is generally employed for grinding metals of low tensile strength such as cast iron, brass, and aluminum, also marble, granite, etc. It is found uneconomical on high-tensile-strength metal, such as steel, on account of its rapid wear.

Grinding Wheels

Vitrified Wheels. In these the abrasive grains are bonded with clay and, after drying, are fired at a temperature sufficiently high to melt the bonding material (3000 deg. fahr. approx.). The majority of smaller abrasive wheels are made by this process, but wheels over 30 in. in diam. are not, as they are liable to warp in the firing. The hardness or grade of vitrified wheels is controlled by the composition of the bonding compound and by the firing temperature. The grade cannot always be exactly predetermined, so each wheel is tested and assigned to its proper grade. A common method for **testing for grade** is to dig into the wheel with a hard steel tool, the resistance of the grain to being dug out and removed determining the hardness of grain. In the larger works special instruments are used which are designed to make the grading more exact and to prevent the liability of error due to personal judgment. Vitrified wheels are most satisfactory for general grinding operations.

Silicate Wheels are made with a bond of sodium silicate, the grains and the liquid silicate of sodium being mixed and tamped while plastic in iron molds. They are then baked at a low temperature for a few days. The hardness or grade is determined largely by the amount of tamping the wheel received, but the tamping must be uniform to avoid hard and soft spots. These wheels are **used** largely **for tool and knife sharpening** and are usually **run wet.** They are made either with or without a wire web, opinions differing as to the added strength so obtained. Silicate wheels should be specified for large sizes; in cases of emergency where a wheel not in stock is required for immediate use; in places where low wheel wear and tool cutting are required; and for grinding tools requiring keen cutting edges. The same grades and grains are obtainable in both silicate and vitrified wheels.

Elastic Wheels. In making these the grains are mixed with shellac, heated, and allowed to cool; the mass is then broken up and poured into molds which are heated until the shellac melts, the surface being rolled with hot rollers by hand. Very large sizes are formed under heavy pressure. These wheels are very elastic and can be used as thin as 1/32 in. thick in sizes as large as 12 in. in diameter. Very fine wheels of small diameter can be used as thin as 1/64 in. They are **used for slotting** and cutting metals, and for **gumming saws** and sharpening shaping cutters, where, in backing off, much sidewise strain is applied to the wheels; and for certain classes of work, such as roll grinding, to give a special finish. They are supplied in eight to twelve grades, the grade being determined largely by the amount of bonding material.

The ordinary abrasive wheel is operated at **speeds** of from 4000 to 6000 surface ft. per min.; wheels below 6 in. in diam. are frequently operated at higher speeds. The retail **prices** of silicate and vitrified wheels are the same; elastic wheels are slightly higher in price. Carbide of silicon wheels, whether made by the silicate or elastic processes, cost more than aluminum oxide wheels. Abrasive wheels are **trued** up by a diamond set in the end of a soft metal rod and held against the face of the wheel while revolving. Diamond dust, rolled into a soft copper disk, is also used.

The following information is furnished by the Norton Company.

The **grain** of a wheel is determined by the size or number of the abrasive grain used. The numbers employed are 10, 12, 14, 16, 20, 24, 30, 36, 46, 50, 60, 70, 80, 90, 100, 120, 150, 180, and 200. By No. 10 grain is meant a size that will pass through a grading sieve having ten meshes to the linear inch. The finer grades of alundum and crystolon known as **flour** are designated as F, FF, FFF, and XF.

The **grade** is determined by the degree of hardness of the wheel, or the resistance of the cutting particles under grinding pressure. The wheel from which the particles are easily broken, causing it to wear away rapidly, is called soft, while one which is able to retain its particles longer is called hard.

The following table gives the grade designations and letters for abrasive wheels.

Grade designation	Very soft		Soft	Medium soft	Medium	Medium hard	Hard	Very hard
Norton Co.	A	BC	DEFG	HIJK	LMNO	PQRS	TUVWX	YZ
Carborundum Co.	V	UT	SRQ	PO	NML	KJIH	GFE	D

The intermediate letters between those designated as soft, medium-soft, etc., indicate so many degrees harder or softer; *e.g.*, L is one grade or degree softer than medium for a Norton wheel.

Elastic wheels are graded as follows: 1, 1½, 2, 2½, 3, 4, 5, and 6. Grade 1 is the softest and grade 6 the hardest.

See also pp. 1448 to 1450.

Abrasive Paper

Flint, Garnet, Emery, Corundum, and the artificial abrasives are all used on paper and cloth, fastened by glue or some special adhesive. The abrasive papers are used mostly for soft materials, such as wood, while the abrasive cloths are used for metal work. They are furnished in a great variety of grain **sizes,** as follows:

	Sand	Emery	Alundum	Carborundum	Aloxite
Paper, No.	4-0 to 4	3-0 to 3½	180 to 20	180 to 20	180 to 20
Cloth, No.	....	FF to 3½	180 to 40	FF to 3½	FF to 3½

Crushed Steel is made by heating high-grade crucible steel to nearly white heat and then quenching in a bath of cold water. The fragments thus produced are crushed to particles varying from fine powder up to 1/16 in. in diameter, and are classified as diamond crushed steel, diamond steel, emery, and steelite. The chief use of crushed steel is in the stone, brick, glass and metal trades, the size of the steel used depending on the character of the stone to be cut, rubbed, ground, or polished.

ADHESIVES

REFERENCES: J. A. Taggart, "The Glue Book." Fernback, "Glues and Gelatine." Sherer, "Casein."

Glue is made by boiling out hides, skins, bones, and sinews of various animals and drying the resulting liquor. Fish glue is produced from the heads, bones, and sinews of fish. It is obtainable commercially in sheets, strips and flakes, or ground. There is no uniform method of testing and grading glues. The grades originally used by Peter Cooper, known as "Cooper Standards," are widely employed and, in order of their strength, are as follows: A Extra, No. 1, 1X, 1¼, 1⅜, 1½, 1⅝, 1¾, 1⅞. These terms are commonly accepted as designating the various commercial grades.

In grading glues, chemical **tests** are of little value, viscosity and jelly strength being the most important tests. Generally, the greater the tenacity of the glue the greater its cohesiveness and the higher its viscosity. Viscosity is generally determined in a pipette as compared with water. Jelly strength is of great importance; by making up jellies of standard glues and the glue to be tested, a very close idea of strength can be determined by pressing each with the tip of the finger.

Ground glue is frequently **adulterated** and should be carefully examined for foreign substances. **Decay** is evidenced by white bubbles on the surface of the glue, also by sour odor. Bubbles inside the glue do not indicate putrefaction. Bone glues are usually darker than hide glues, but some cheap glues are clarified to give the appearance of a higher grade. The best glues should be neutral to litmus paper. Excess of acid should be avoided. A thin piece of good glue should bend without breaking, and when broken should show a splintery edge. A clean **fracture** indicates brittle, low-grade glue. Glues containing much grease or which foam on beating the solution, should be avoided.

In **dissolving,** glue should always be soaked in cold water first and then warmed. It is of great importance to employ no more heat than is necessary to reduce the glue to a proper consistency. It should never be heated higher than 150 deg. fahr. and heat should never be applied by live steam but always indirectly. The "Glue Book," by J. A. Taggart, Toledo, Ohio, gives the following valuable suggestions regarding **selection:**

Wood Joints: High-test hide glues. Veneers: A moderately high-test mixture of bone and sinew or bone and hide. Sizing: Glue free from grease and foam and that flows freely. Paper Boxes: Quick-setting hide glue for setting up; lower-test bone glue for covering. Belting and Other Leathers: High-test glues preferred. Bookbinding: For pasting covers, a low-grade bone glue; for rounding and backing, a high-grade hide glue. For Emery Purposes: Very high-grade and pure glue.

After soaking in water for 48 hours, there should be no discoloration of the water or disagreeable odor. In general, the high-test glues, although more expensive, go farther and do better work. For some purposes their quick setting is an objection.

To prepare **waterproof glue**, about 1 per cent. of ammonium or potassium bichromate may be added to the glue liquid, or a small amount of formaldehyde.

A very strong but expensive adhesive is **isinglass**, prepared chiefly from the swimming bladder of the sturgeon. Fish glues other than isinglass are always in the form of heavy solutions or pastes. **Imitation liquid glues** are made by treating animal glues, but are deficient in adhesiveness and binding properties. Certain "liquid glues" are made entirely of dextrines and flour paste. **Flexible glue** is a mixture of glue, glycerine, and water. Marine glues contain no glue but are used for calking vessels. **Jeffrey's marine glue** is a mixture of shellac and India rubber in benzine. Others are mixtures of asphaltum and rubber in petroleum solvents.

Starch Pastes are made from wheat, corn, tapioca, sago, and potato starches, each having different properties. Potato-starch paste is of heavy body with little adhesiveness; tapioca is fluid and sticky; sago yields a dark, sticky paste; corn is not so suitable for paste-making. All starch pastes must be preserved with chemicals such as bichloride of mercury, formaldehyde, or carbolic acid. They may be rendered more adhesive if treated with a hydrolizing agent, such as dilute acids or calcium chloride. In preparing starch and flour pastes, the starch or flour should always be emulsified in cold water and then added to the balance of boiling water.

Dextrines are produced by treating starches with acids. Potato dextrines are best, tapioca, corn, and sago following in order of serviceability. They are excellent substitutes for glue but do not have the same binding strength, are easily decomposed and must be preserved. Extensively used in the textile industries for filling, sizing, and as a cheap adhesive. Photo-library paste is generally made from white dextrine, preferably potato dextrine known in the market as "White E. S." or "H. White." These pastes are generally composed of dextrine and water with a small amount of glycerine and a proper preservative. Essential oils are generally added to cover the odor of the preservative.

Gum Arabic is a natural gum soluble in water with considerable adhesiveness. Although cheaper than glue, a large quantity must be used to equal the adhesiveness. Used extensively with dextrine in the manufacture of **mucilage**. Glycerine is generally added to increase flexibility and prevent cracking in the dried mucilages. Envelope gums are generally prepared from tapioca or potato dextrines.

Water-glass is a solution of sodium or potassium silicate made by fusing quartz sand with potash or sodium hydrate. It is a heavy, oily liquid containing from 33 to 60 per cent. of sodium silicate, and must be protected from the air to prevent decomposition. It is important to ascertain the actual content of silicate, as the commercial solutions vary widely in strength. It is used extensively as a cheap adhesive and as a protective coating, producing a hard surface, resistant to moisture and fireproof; also as a fireproofing agent on cloth and wood. An ingredient in many putties and in the preparation of artificial stones.

Putty. Ordinary putty is made from whiting and pure raw linseed oil. **Glazier's putty** generally contains some varnish in addition. Linseed-oil varnishes mixed with litharge or red lead and ochre are extensively used as a **hard-drying putty**. **Mastic cement** is composed of powdered limestone, sand, and litharge, mixed with linseed-oil varnish. Litharge and glycerine produce a very hard-drying cement, resistant to alkalies, acids, and petroleum solvents. Water-glass and chalk produce a hard waterproof mass, as do also water-glass and Portland cement. **Magnesia cement** consists of calcined magnesia in a 30-per cent. solution of chloride of magnesium, and hardens to a stone-like mass.

Cements for Special Uses

Pipe Joints. Use a mixture of red lead with linseed oil in a thick paste. **Diamond cement** may be prepared by slowly stirring into 40 parts of linseed oil the following ingredients in the order given: litharge, 30 parts; slaked lime, 10 parts; whiting, 20 parts; graphite, 100 parts. It should be applied hot to the slightly roughened surface of the metal. A strong cement may be made by mixing whiting in a 40-deg. Baumé water-glass solution to a plastic mass.

Porcelain and Crockery. Mix equal parts of gutta-percha and shellac at a gentle heat, and apply hot to edges previously warmed. An effective cement consists of 10 parts of casein dissolved in 100 parts of silicate of soda.

Glass. Water-glass is the best cement, provided glassware is not to be heated. For cementing glass upon glass, a mixture of Russia isinglass and acetic acid may be used.

Leather. Glue is the best adhesive for use with leather. A mixture of gutta percha, asphaltum, and turpentine gives very good results, or a solution of rubber in carbon tetrachloride, the latter being advantageous as a solvent and non-inflammable.

Wood. Glue is the best cement; shellac dissolved in alcohol is very satisfactory.

Bone. Use equal parts of paraffin wax and rosin dissolved in turpentine.

ALCOHOL

(See also pp. 298 and 612)

Grain Alcohol (Ethyl Alcohol) is made by the distillation of fermented sugar solutions derived either from grain, molasses, or fruit syrups, or by the treatment of wood with sulphurous acid. It is sold in the United States by "degree proof" or "proof," the figure representing twice the percentage of alcohol by volume; thus, 100 deg. proof spirit at 60 deg. fahr. contains 50 per cent. of absolute alcohol. Common custom in the United States expresses the percentage of alcohol "by volume." Grain alcohol is miscible in all proportions with most liquids except fatty oils, which it dissolves very slightly.

Wood Alcohol (Methyl Alcohol) is produced by the destructive distillation of wood. It is a colorless, mobile liquid with a spirituous odor, the odor of commercial wood spirit being due to impurities. Its specific gravity at 32 deg. fahr. is 0.8142, and its boiling point 151.7 deg. fahr. It burns with a non-luminous flame, is miscible in all proportions with water, ethyl alcohol, and ether, and dissolves certain resins, fats, and volatile oils. It is frequently adulterated by the addition of water, which raises the specific gravity.

Denatured Alcohol. The object of denaturing alcohol is to permit the use of ethyl alcohol for purposes other than drinking free from the heavy excise tax. The common denatured alcohol of commerce is made under Government regulation by adding a small quantity of wood alcohol and benzine to grain alcohol. Such a mixture is unfit for consumption as a beverage, but for most industrial purposes it serves equally as well as the pure product. For special industries where such a denaturing would be objectionable, the Government has permitted the use of special denaturing materials, such as pyridine, nicotine, and cadmium and ammonium iodides.

BELTING

(See also p. 743)

Leather Belts. Cut from the proper hide, belts cut along the spine have almost equal lateral stretching qualities, and consequently run the straightest and quietest, and are best for high speeds. They can only be obtained up to about 7/32 in. in thickness. Double belts can be made for greater thicknesses. For wide belts great care in selection is necessary. Very wide belts are also made as double belts, laterally.

For slow speeds and large pulleys belts may be made from side leather, as the tensions on the fibers have more time to equalize each other. Such belts should not exceed 8 in. in width. Belts cut transversely across the shoulder may be used for slow-speed machinery.

Permanent elasticity is the most important characteristic, tensile strength being less decisive in judging quality, and weight and thickness of even less importance. Thickness is often increased by artificial means, such as filling the leather. In making the belt, the ends are joined with a mixture of sinew glue and fish glue, after tapering by using a leather plane. Sewed belts are not as good as properly glued belts.

The United States Navy specifications require oak-tanned leather cut entirely from the center or back of the hide and free from any loading. Single belts must show an average tensile **strength** of 4000 lb. per sq in.; double belts a tensile strength of 3600 lb. When subjected to a stress of 2250 lb. per sq. in. for 1 hr., single belts should show not more than 13.5 per cent. elongation and double belts not more than 12.5 per cent. The modulus of elasticity in tension varies from 17,800 lb. per sq. in. for new belts to 32,000 lb. for old. The proportional elastic limit is about 2300 lb. per sq. in. The strength of chrome leather varies from 8500 to 12,900 lb. per sq. in.

Leather belts should be cleaned with warm water and dressings only applied when the belt becomes dry and husky. Melted beef tallow is an excellent dressing, also prepared castor-oil dressings. Mixtures of tallow and beeswax are stated to be of service on belts used in damp places. Resinous substances should never be used, as they cause the fibers to adhere and wear each other out by friction. A little neatsfoot oil can be used on very dry belts, but frequent application of penetrating oils makes the leather soft and flabby and causes it to stretch.

Commercial **sizes** of leather belting as adopted by the Leather Belting Association range from ½ in. to 72 in. in width, the width increasing by ⅛ in. up to 1 in., by ¼ in. up to 4 in., then by ½ in. to 7 in., and above that by inches.

Rubber Belts are made by saturating a strong woven duck belt with rubber and subsequently vulcanizing. Their advantages over leather belts are claimed to be uniformity in width and thickness, durability when exposed to steam and dampness, great tensile **strength** and grip on pulley. With proper weight of duck, a three- or four-ply rubber belt is claimed to equal a single, and a five- or six-ply a double, leather belt. Balata is extensively employed for this purpose as it is very little affected by dampness or change of temperature and does not stretch readily. Rubber belts are cheaper than leather or other belts suitable for the same kind of work and are of particular value in damp locations or under unusual temperature conditions.

Rubber belts should never be treated with animal oils or greases, as these substances rapidly destroy their life. Good results are said to be obtained by painting with a mixture of equal parts of red lead, black lead, French yellow and litharge mixed with boiled linseed oil and sufficient japan to cause quick drying. This produces a smooth, polished surface and if the belt should slip the side next the pulley can be slightly moistened with boiled linseed oil. Commercial **sizes** run from 1 in. to 60 in., increasing by ¼ in. up to 2 in., by ½ in. to 4 in., and then by inches. Special seamless and endless belts can be obtained. See also p. 744.

Cotton Belts, when woven, have a tensile strength of about 5000 lb. per sq. in.; when sewed, from 6500 to 7500 lb. per sq. in. See also p. 744.

BRICK

REFERENCES: E. Bourry, "Ceramic Industries." A. B. Searle, "Modern Brickmaking." Wahl-Henius, "American Handy-book."

Commercial brick may be divided into two main classes: building brick and refractory brick.

Building Brick includes ordinary clay brick, shale brick and sand-lime brick. The **ordinary clay brick** is most extensively used, particularly the common red brick, the color being dependent upon the composition of the clay and nature of burning. Yellow, blue, black and gray bricks are also made. Perfectly white bricks are only made by surface treatment as in glazed brick. Whitish bricks are produced from mixtures of clays and chalk or from certain marls. Good bricks should be regular in shape, texture and color, equally burned throughout and free from cracks or flaws. They should give out a clear, ringing sound when struck. Soft or unburned bricks are of no value. Bricks which have been too heavily pressed or highly burned may have too smooth a face to adhere readily to mortar. For many purposes it is unnecessary to insist upon all these qualities, a hard, well-burned brick sufficing. The characteristics of these bricks are dependent upon the clay used and are commonly classified as follows:

1. Method of Molding: Soft mud brick, stiff mud brick, pressed brick, re-pressed brick, slop brick, sanded brick, machine-made brick.

2. Position in Kiln: Arch or clinker brick form the top and sides of arches; they are very hard, brittle and weak. Body, cherry or hard brick are taken from interior, and are the best bricks in the kiln. Salmon, pale or soft brick are from the exterior of the mass; they are too soft for general purposes, and are usually employed for filling.

3. Form or Use: Compass, feather-edge brick, face brick, sewer brick, paving brick, vitrified brick. Vitrified clay blocks much larger than ordinary brick are sometimes called paving brick, but are more correctly brick paving blocks.

For average values of the strength of brick, see Table 4, p. 385.

The following values of the **compressive strength of building brick** are taken from "Tests of Metals, Etc.," 1894, pp. 456–468:

	Compressive strength, lb. per sq. in.		
	Min.	Max.	Mean
Face Brick:			
Stiff-mud	8,930	15,330	12,766
Dry-pressed	8,930	17,990	11,190
Re-pressed soft-mud	5,770	7,560	6,780
Common Brick:			
Hard-burned, soft-mud, Cambridge	9,140	14,750	11,340
Hard-burned, soft-mud, Brookfield	4,340	4,580	4,475
Hard-burned, soft-mud, Mechanicsville	5,110	6,730	5,808
Medium-burned, soft-mud, Cambridge	4,610	8,590	6,590
Medium-burned, soft-mud, Brookfield	4,200	6,850	5,248

Shale brick is similar to the ordinary clay brick, but is made from shale.

Sand-lime brick (see *Bulletin* No. 18, Ill. State Geol. Survey) consists of sand particles bound together by a network of calcium silicate, calcium-magnesium silicate, or calcium hydrosilicate formed by the action of steam under pressure upon a mixture of sand or granular silicate and lime; the lime may be either a high-calcium lime or a magnesium lime. The formation of this calcium-silicate bond results in the production of a mass in many ways similar to that produced in dry-pressed brick when they are burned.

Among the important claims made in favor of the sand-lime brick over the common clay brick are its increased strength, fire-resistant properties and the general uniformity in size and shape of each brick. Sand-lime brick will withstand a heat test of 3000 deg. fahr., the only apparent damage after 96 hr. in a kiln being a slight discoloration. Sand-lime brick are waterproof, frostproof, possess good bonding properties, and can be produced in any color desired.

A consular report from Germany states that in 255 tests on **sand-lime brick** the compressive strength varied greatly, the average, however, being 2175 lb. per sq. in., deviations from the average being less than in clay brick, a result of the greatest symmetry in shape and structure.

Refractory Brick may be divided into the following classes, based on the materials used. (For further details regarding fire brick see pp. 914 and 915):

1. FIRE-CLAY BRICKS are made by fusing certain clays to such a temperature that partial vitrification occurs, together with a plastic clay usually known as "grog" which serves as a skeleton for the formation of the brick. **Paving brick** is a lower grade of fire-clay brick which is hard but not brittle. The common **requirements** in this country for paving brick are as follows: Standard size, $8\frac{1}{2} \times 3\frac{1}{2} \times 4$ in.; not over 14 per cent. loss on standard rattler test; modulus of rupture, not less than 2700 lb.; absorption of water, not more than 2 per cent.; specific gravity, not less than 2.35; hardness, not less than 6.5 on Mohs's scale; crushing resistance, not less than 8500 lb. per sq. in.

Another class of fire-clay bricks are **acid-proof bricks.** The best bricks of this kind are made from ball or stoneware clay. The **standard test** for acid-proof bricks is to ascertain their crushing strength before and after they have been soaked for 7 days in concentrated sulphuric acid maintained at a temperature of 90 deg. fahr. The best bricks should be unaffected by this treatment. **Glazed bricks** are chiefly made of second-grade fire clay, the clay being composed of feldspar, flint, whiting, etc., fired at a high temperature.

2. SILICA BRICKS are made by heating to vitrification practically pure silica with about $\frac{1}{50}$ of its weight of lime, forming a true calcium silicate. Fire clays are commercially obtainable which fuse at a temperature corresponding to Seger cone 36. The chief disadvantages of silica bricks are brittleness and liability to "spall" when exposed to sudden changes of temperature. As silica bricks expand when heated, twice-burned bricks should be insisted upon.

3. GANISTER BRICKS are intermediate between fire-clay and silica bricks and are made in a manner similar to the silica bricks but without the addition of lime.

4. BASIC BRICKS—usually made of magnesite or bauxite—are weak in resistance to pressure but extremely resistant to heat. **Bauxite bricks** are used in metallurgical furnaces and rotary cement kilns. **Magnesia bricks** are made from calcined magnesite, a mineral containing from 90 to 96 per cent. of carbonate of magnesia and found in Styria and Greece. This material is plastic under heavy pressure and the Styrian material may be molded for brick or furnace bottoms without using a binder. Magnesia brick are remarkably resistant to slag and limestone and are particularly suitable for certain types of metallurgical furnaces. They are, however, very sensitive to the action of silica and, owing to their tendency to expand on repeated heating, cannot be used in arches. The mortar used in laying magnesia bricks should consist of powdered magnesia mixed with $\frac{1}{6}$ of its weight of tar.

5. NEUTRAL FIRE BRICKS OR CHROME BRICKS are usually made of chromite mixed with fire clay or bauxite. They are practically infusible, dense in structure and are used in basic open-hearth steel furnaces as a neutral course between fire-clay brick and magnesia brick; they are not affected by sudden changes in temperature, but are not very resistant to crushing when hot.

Melting Points of Fire Bricks and Clays. The U. S. Bureau of Standards has determined the melting points of fire bricks and other refractories. The results are given below.

	Number of samples tested	Melting point, deg. fahr.		Number of samples tested	Melting point, deg. fahr.
Fire-clay brick........	41	2831–3137	Bauxite clay........	1	3308
Bauxite brick.........	8	2849–3245	Bauxite............	1	3263
Silica brick..........	3	3092–3101	Chromite...........	1	3956
Chromite brick.......	1	3732	Pure alumina.......	1	3650
Magnesia brick.......	1	3929	Pure silica..........	1	3182
Kaolin...............	3	3155–3164	Carborundum.......	1	4892

The value of 3182 deg. given for silica is not the true melting point, but represents the temperature at which the silica flows distinctly. It was found that silicon carbide does not melt below 4892 deg. but becomes unstable at much lower temperatures.

Standard Sizes and Shapes of Brick

Common brick..........................	8¼ × 4 × 2¼ in.
Paving brick...........................	8½ × 4 × 2½ in.
Pressed brick..........................	8⅜ × 4 × 2⅜ in.
Roman brick...........................	12 × 4 × 1½ in.
Norman brick..........................	12 × 4 × 2⅜ in.
Fire and silica brick...................	9 × 4½ × 2½ in.
Paving block...........................	from 9 × 4 × 3 in. to 9 × 5 × 4 in.

The following **shapes** are also standard:

Small 9-in............................	9 × 3½ × 2½ in.
Large 9-in............................	9 × 6¾ × 2½ in.

	Bricks per circle	Circle Diameters Inside	Outside	Dimensions of Brick, in.
No. 1 Arch...........	76	4 ft. 3 in.	......	9 × 4½ × (2½ − 2⅛)
No. 2 Arch...........	38	1 ft. 9 in.	......	9 × 4½ × (2½ − 1¾)
No. 1 Wedge.........	91	4 ft. 6 in.	6 ft.	9 × 4½ × (2½ − 1⅞)
No. 2 Wedge.........	57	2 ft. 3 in.	3 ft. 9 in.	9 × 4½ × (2½ − 1½)
No. 3 Wedge.........	57	3 ft.	4 ft. 6 in.	9 × 4½ × (3 − 2)
No. 1 Key............	113	12 ft.	13 ft. 6 in.	9 × 4½ × (4 − 2½)
No. 2 Key............	57	5 ft. 3 in.	6 ft. 9 in.	9 × 4½ × (3½ − 2½)
No. 3 Key............	38	3 ft.	4 ft. 6 in.	9 × 4½ × (3 − 2½)
No. 4 Key............	25	1 ft. 6 in.	3 ft.	9 × 4½ × (2¾ − 2½)
No. 1 Circle..........	12	24 in.	33 in.	(9 − 6 9/16) × 4½ × 2½
No. 2 Circle..........	14	36 in.	45 in.	(9 − 7 3/16) × 4½ × 2½
No. 3 Circle..........	18	42 in.	51 in.	(9 − 7 7/16) × 4½ × 2½
No. 1 Cupola.........	15	30 in.	42 in.	(9 − 6 7/16) × 6 × 3 or 4
No. 2 Cupola.........	17	36 in.	48 in.	(9 − 6¾) × 6 × 3 or 4
No. 3 Cupola.........	21	48 in.	60 in.	(9 − 7 3/16) × 6 × 3 or 4
No. 4 Cupola.........	25	60 in.	72 in.	(9 − 7½) × 6 × 3 or 4

The general practice in **measuring brickwork** is to compute the superficial area of the walls and multiply by the number of brick in the wall in 1 sq. ft. of surface, depending of course on the thickness of the wall. A fair average of the practice in the eastern states for a 4-in. wall, or ½ brick in thickness, is 7½ bricks per superficial foot. In the western states the usual average is 7 bricks per superficial foot for a 4½-in. wall.

Hollow Tile. Safe loads per sq. in. of effective bearing parts are as follows: For hard fire-clay tiles, 80 lb.; for ordinary clay tiles 60 lb.; for porous terra cotta tiles, 40 lb.

CLEANSING MATERIALS

Soap is made by chemically combining fats with alkalies. Toilet and washing soaps should be entirely free from caustic alkali, and uncombined fat, and as free as possible from carbonated alkali. Bar soaps may contain excessive quantities of moisture, which should be avoided in purchasing. Soft soaps are made by combining potash with fat. Liquid soaps are potash soaps with large quantities of water and considerable glycerine. Excessive quantities of common salt should be avoided in ordinary soaps which are made by salting the soap out of solution. For cleaning paint and varnish, care should be taken that no free caustic alkali is contained in the soap and that the carbonated alkali be as low as possible; cleaning powders composed of soap and very fine infusorial earth or pulverized pumice, are excellent, provided the mineral substances do not contain hard particles which will scratch varnish. Floor-washing soaps generally contain large quantities of free sodium carbonate, which is very effective in cutting oil and dirt.

Soda Ash, which is practically pure sodium carbonate, is extensively used for cleaning purposes, and in solution as a lubricant for grinding steel dies and cutting steel and as a preventive of rust on steel tools. For the latter purpose, the strength of solution should be kept low. **Sal soda** is a crystalline form of sodium carbonate containing about 63 per cent. of water by weight. Although extensively used, it can generally be replaced to advantage by soda ash—which should be at least 97 per cent. pure. **Caustic soda** (sodium hydrate) is extensively used in textile mills for scouring, cleaning, etc., and for cleansing metals from oil and dirt. A good grade should contain not less than 94 per cent. of caustic soda. It is very hygroscopic.

Caustic Potash, used for cleansing, should contain not less than 75 per cent. of caustic potash; a crude variety, however, containing 65 per cent. together with considerable caustic soda, is frequently employed. **Carbonate of potash** should contain not less than 75 per cent. of potassium carbonate.

ELECTRICAL INSULATING MATERIALS

REFERENCE: Turner and Hobart, "The Insulation of Electric Machines." See also pp. 1596 and 1597.

The insulating properties of any material are dependent upon two factors: first, **dielectric strength,** or the ability to withstand high voltages, and, second, **ohmic resistance,** or the ability to prevent small currents from leaking through it. Materials may have one of these qualities to a far greater extent than the other, for example, air has a very high specific resistance but very little dielectric strength; glass has great dielectric strength but much lower resistance than air. The **ideal insulator** is one having the maximum dielectric strength and resistance and also mechanical strength and chemical stability. Moisture is by far the greatest enemy of insulation, consequently the absence of hygroscopic quality is desirable.

The common insulating materials are described below. For their electrical properties, see p. 1597.

Rubber. See "Rubber, Gutta Percha and Balata," p. 641.

Mica and Mica Compounds. Mica is a natural mineral varying widely in color and composition, and occurs in sheets which can be subdivided down to a thickness of 0.00025 in. White mica is best for electrical purposes, the green shades are the softest varieties, and the white amber from Canada the most flexible. Mica has high insulating qualities, the best grades having a disruptive strength of 12,000 R.M.S. volts per tenth of a millimeter. Its lack of flexibility and non-uniformity and its surface leakage are disadvantages. To offset these, several mica products have been developed, in which small pieces of mica are built up into finished shapes by means of binders such as shellac, gum, bakelite, etc.

Micanite consists of thin sheets of mica built into finished forms with insulating cement. It can be bent when hot and machined when cold, and is obtainable in thicknesses of from 0.01 in. to 0.12 in. Flexible micanite plates, cloth and paper are also obtainable in various thicknesses. **Megohmit** is similar to micanite except that it is claimed not to contain adhesive matter, which is objectionable in the latter product. It can be obtained in plates, paper, linen, and finished shapes. **Megotalc**, built up from mica and shellac, is similar to the above-named products and obtainable in similar forms.

Insulating Varnishes. Two general types of insulating varnish are used: those consisting of hydrocarbons such as asphalt, paraffin, etc., dissolved in benzine, and those consisting essentially of linseed oil with and without asphalt and other bitumens. The former are cheaper and if baked produce a fairly hard coating. They are apt to distill under working temperatures, however, with rapid crumbling and deterioration. Properly made linseed-oil varnishes are more satisfactory, as they do not deteriorate as rapidly.

Impregnating Compounds. Bitumens of various kinds are used to impregnate motor coils, the melted bitumens being forced into the coil in a vacuum tank, forming a solid insulation when cooled. Brittle compounds, which gradually pulverize due to vibration in service, and soft compounds, which melt and run out under service temperatures, should be avoided as far as possible.

Oil. Refined grades of petroleum oils are extensively used for the insulation of transformers, switches, and lightning arresters. The following specification covers the essential points:

Specific gravity, 0.860; flash test, not less than 335 deg. fahr.; cold test, not more than 14 deg. fahr.; viscosity (Saybolt) at 100 deg. fahr., not more than 120 seconds; loss on evaporation (8 hr. at at 200 deg. fahr.), not more than 0.5 per cent.; dielectric strength, not less than 35,000 volts; freedom from water, acids, alkalies, saponifiable matter, mineral matter, or free sulphur. Moisture is particularly dangerous in oil. Skinner claims that 0.06 per cent. H_2O will reduce the dielectric strength approximately 50 per cent. See p. 648.

Paraffin is used to impregnate paper and cloth. Specific inductive capacity, about 2; dielectric strength, 8,000 volts per mm.; specific resistance, 240,000,000 to 3,900,000,000 megohms per cu. cm.

Impregnated Fabrics. Fabrics serve as a framework to hold a film of insulating material, and must therefore be of proper thickness, texture, and mechanical strength, and free from nap or acidity. Cambric, muslin, lonsdale, and batiste are commonly used.

Empire Cloth is cambric treated with linseed oil by a special process. Similar products are oiled linen, oiled canvas, varnished cambric.

Insulating Tape, also known as **friction tape** or **binding tape**, consists of a flat, woven braid or tape impregnated with an adhesive and insulating compound adhering firmly to the braid. ¾-in. tape should have a breaking strength of not less than 33 lb. and run not less than 150 ft. per lb.; other widths in proportion.

Ambroin is an insulating material made from fossil copal and silicates by a special process, and is claimed to be strong, firm, uniform, resistant to high temperatures, and non-hygroscopic. It is used for commutator rings, spools, and other molded insulation, and is cheaper than ebonite. It is obtainable in various grades. Tensile strength, about 2140 lb. per sq. in.; compressive strength, 2680 lb. per sq. in.

Bakelite is a plastic substance produced by condensing phenols with formaldehyde. It is used in electrical insulation, in making imitation amber, and as a covering to resist the action of chemicals and solvents. It is also produced in liquid form for use as a wood-impregnating medium and lacquer.

Paper. The present tendency is to use paper only as a backing or framework for an insulating film or compound, owing to hygroscopic qualities. **Manila, express** and **bond** papers possess the best dielectric and mechanical strength, and when coated with good insulating varnish are excellent insulators. **Japanese paper** is extremely thin and strong, and is used in tubular insulation and also as a backing for mica paper.

Vulcanized Fiber, also known as **hard fiber,** is prepared by treating paper pulp or a textile material with a saturated solution of zinc chloride and afterward consolidating it under heavy pressure. It has a consistency like horn, but is generally found in commerce treated with glycerine or glucose, which makes it very pliable. In the hard form it can be planed, sawed and worked like wood, and in the soft form can be readily molded. It is claimed to be an efficient non-conductor of heat and an excellent insulator. The soft varieties are used in making artificial leather and rubber products. Its **specific gravity** is about 1.3; **specific resistance,** 53 megohms per cu. cm. Furnished in 42 × 66-in. **sheets** from 0.010 to 1⅛-in. thick, and in **tubes** from 3⁄16 in. to 2½ in. in diam. by 22 to 36 in. long. It must be thoroughly seasoned, tough and flexible, and must stand, when unbaked, bending around a circle having a radius of 10 times its thickness without cracking or splitting. After 12 hours' baking at 250 deg. fahr. it must bend around a circle of radius 50 times its thickness. **Tensile strength** of sheets, lb. per sq. in.: Less than 1⁄16 in. in thickness and over ⅝ in., 5000; 1⁄16 in. to ¼ in., 8000; ¼ in. to ⅝ in., 7000. **Electrical strength,** about 1200 volts per 0.01 in. of thickness.

Presspahn or Fuller Board is a specially prepared paper board which, when impregnated with oil, is an excellent insulator. Insulated presspahn is very hygroscopic. The material is mechanically strong but its dielectric strength is greatly injured by creasing. **Pergamyn** is cellulose beaten into fine fibrillæ and consolidated under pressure without gelatinization or chemical treament. Its uses are similar to those of vulcanized fiber. **Cellulith** is produced by grinding wood pulp to a homogeneous mass and then drying. It is very hard, can be worked like wood, and is claimed to be a substitute for horn or ebonite. **Isolit** is a form of papier maché impregnated and covered with special insulating compound. **Adit** is a variety of isolit claimed to have great tensile strength and toughness and to ignite with difficulty. **Litholite** is a paper product used for insulation. It has high disruptive strength, good insulation resistance, and is stated to be inflammable but tough. **Psychiloid** is a chemically treated paper pulp obtainable in sheets from 1⁄16 in. to 1½ in. in thickness. It is very strong and rigid, and stated to have high disruptive strength and insulation resistance.

Porcelain is made from the purest white clay agglutinized by some substance such as powdered feldspar which softens and fuses at the temperature at which the ware is fired, rendering the mass semi-transparent. The material possesses great solidity, strength and ability to resist sudden changes of temperature. It is used extensively for electrical purposes on account of its strength, durability and electrical resistance. External glaze is of importance in protecting porcelain. A simple test for quality consists in chipping off the glaze and noting whether ink produces a flowing stain, which it will do on poor grades. **Properties:** The Locke Insulator Mfg. Co. gives the following average values: Specific gravity, 2.427; specific inductive capacity, 4.4; tensile strength, lb. per sq. in., 1800; compressive strength lb. per sq. in., 15,000; dielectric strength, volts per mm., 16,350. J. E. Boyd (A.S.M.E., Dec., 1915) gives the compressive strength of porcelain and high-grade stoneware as 20,000 lb. per sq. in.; the tensile strength of porcelain >3000 lb. per sq. in., of stoneware 1100–2200 lb.; the modulus of elasticity in tension and compression of porcelain, 10,000,000 lb. per sq. in., of stoneware, 6,000,000 to 9,000,000.

FIBERS

REFERENCES: Matthews, "The Textile Fibers." Hannan, "The Textile Fibers of Commerce." Mitchell and Prideaux, "Fibers Used in Textile and Allied Industries." Griffin and Little, "The Chemistry of Paper-making." Worden, "Nitrocellulose Industry."

Fibers for industrial purposes are either mineral, animal, or vegetable. The principal mineral fiber of importance is asbestos (see p. 634). Finely spun glass, slag wool and metal threads are also used. The animal fibers of commercial importance are either animal hairs or the silk of the silkworm and the larvæ of other moths. Sheep, goats and camels supply the principal hair fibers. Cotton, wool, linen, jute and hemp are the principal vegetable fibers.

Fibers may readily be distinguished under the microscope. Animal and vegetable fibers may be distinguished by their odor on burning, and by the fact that vegetable fibers burn off sharply while animal fibers fuse to a rounded bead-like end.

Animal Fibers

Silk fiber consists of a continuous thread spun by the mulberry silkworm. Inferior silks are obtained from other varieties of caterpillars and are known as "wild" silk.

Silk fiber possesses great tensile strength, the average breaking strength being approximately 64,000 lb. per sq. in., and the elongation 15 to 20 per cent.

Wool. The wool of the sheep is that principally employed. The tensile strength and elasticity of wool fibers vary widely; the average strength being about half that of cotton. The length of the fiber varies between 1 and 8 in. and the diam. between 0.0018 and 0.004 in. Wool is graded according to the length of staple into "tops" and "noils," the former being used for worsted yarns and the latter for making woolen and carded yarns.

Vegetable Fibers

All vegetable fibers consist mainly of cellulose and may be classified as follows: Seed hairs, such as cotton; bast fibers, such as flax, hemp, jute, and ramie; and vascular fibers. Cotton and ramie are nearly white; linen, grayish brown; jute and hemp have a decided brown color. Those containing large proportions of cellulose are flexible and elastic, while those which are highly lignified or woody are stiff and brittle. The tensile strength varies considerably, but the relative strength of the fibers is in the following order: Hemp, jute, manila, linen, cotton, ramie. Vegetable fibers are much less hygroscopic than wool or silk, the latter averaging from 12 to 16 per cent. of moisture normally, while cotton and linen average but from 6 to 8 per cent.

Cotton fiber is obtained from the seed hair of the cotton plant, the seeds being separated from the fiber by a process known as "ginning." The small hairs left on the seed after the first ginning, known as "linters," are used in the manufacture of cotton batting, guncotton, etc. The best quality of cotton fiber is known as "Sea Island" cotton, as it is raised on islands off the coast of Carolina.

The natural spiral-like twist of the fiber makes it specially adapted to spinning. The spinning quality is also dependent upon the length and fineness of the staple. Sea Island cotton is spun into very fine yarns, up to 300, *i.e.*, 300 hanks of 840 yd. each weigh 1 lb. The **tensile strength** of cotton is between that of silk and wool. For cotton rope, see p. 748.

Mercerized Cotton. When cotton is treated with strong caustic alkali and simultaneously subjected to mechanical tension to prevent contraction, the fiber is greatly changed, taking on a high luster and an increase in tensile strength of from 30 to 50 per cent. The mercerized fiber also has a greater power of absorption for dyestuffs.

Linen is obtained from the flax plant by "retting." The linen fiber consists of nearly pure cellulose. Natural linen varies from pale yellowish-white to gray. It may be bleached with chloride of lime, but the fiber suffers considerable deterioration. It is of pronounced luster, silky in appearance, stronger than cotton and a better conductor of heat. Its hygroscopic moisture is about the same as cotton. It does not withstand the action of boiling alkalies, bleaching powders, and other oxidizing agents, as well as cotton, nor does it dye so readily. Linen can be mercerized in the same manner as cotton.

Jute is obtained from the stalks of the jute plant by steeping in water. The fiber so obtained is free from woody fiber and generally has a length of from 4 to 7 ft. It is of pale yellowish-brown color, the best qualities showing a yellowish-white or silver-gray, and having considerable luster and tensile strength. The short fibers are employed as a raw material for paper-making. The fiber is smooth and lustrous and has no jointed ridges or transverse markings, such as in linen or other bast fibers. It cannot be readily bleached owing to the disintegration of the fiber. Its valuable qualities are fineness, silk-like luster, and adaptability for spinning. Its strength is less than that of most other bast fibers. Its chief defect is lack of durability, dampness causing rapid deterioration, and under ordinary conditions the fiber becomes brittle and weak. Bleached fiber is especially unstable; its principal uses are in the manufacture of coarse-woven fabrics such as gunny sacks, bagging, for binding thread in carpets and rugs. As a substitute for hemp it has been extensively used in the manufacture of twine and small ropes, and, owing to its cheapness, is largely used to adulterate better fibers.

Ramie, and China Grass are obtained from the bast of the stingless nettle. They are two distinct fibers, but the names are generally used interchangeably. The fiber is the strongest and most durable of all vegetable fibers and the least affected by moisture. Ramie can be separated into fibers of great fineness and possesses three times the strength of hemp. It is white in color, resembling bleached cotton, and possesses a higher luster than linen. It lacks the elasticity of wool and silk and the flexibility of cotton, and consequently produces a harsher fabric in which the fine fibers do not adhere well to each other.

Hemp is a name applied to a number of bast fibers of similar appearance and properties, and is obtained from the plant by "retting." Its composition is a mixture of cellulose and lignocellulose. It contains more hygroscopic moisture than cotton or linen. It is principally used for the manufacture of twine and cordage on account of its great strength and durability. It is not readily affected by water as contrasted with jute. It is not much used for woven textiles on account of its harshness and stiffness and lack of pliability and elasticity. The fiber is of dark brown color and cannot be successfully bleached without injury.

Manila Hemp is obtained from the leaf-stalks of the *Musa textilis*. The fiber is white and lustrous, light and stiff, easily separated, very strong, and of great durability. The coarser fibers are used for the manufacture of cordage on account of their great strength. Manila hemp ropes are stronger than English hemp ropes. See p. 748.

Sisal Hemp is obtained from the leaves of a plant found in Central America, and to some extent from the West Indies and Florida. It is of light-yellowish color, straight and smooth. Its principal use is in cordage manufacture, its strength being second only to that of Manila hemp. It is also used for paper-making.

Waste. The best **wool waste** consists of all-wool carpet yarn in threads not less than 3 in. long and comparatively free from moisture or dirt. **Cotton waste** should consist of equal parts of white and colored new cotton threads properly mixed and free from water and dirt. White cotton waste should be made up entirely of new white cotton threads not less than 3 in. long and free from dirt or water. It is customary to purchase waste by sample. Inferior quality is indicated by the presence of fibers other than wool or cotton, by sweepings or dirt, or where the waste gives evidences of having been previously used.

FREEZING PREVENTIVES

Common Salt is sometimes used to prevent the freezing of water; it does not, however, lower the freezing point sufficiently to be of use in very cold weather, and in concentrated solution tends to "creep" and to crystallize all over the receptacle. It also tends to corrode metals. For freezing temperatures, see p. 299.

Calcium Chloride ($CaCl_2$) is a white, solid substance widely used for preventing freezing of solutions and (owing to its great hygroscopic power) for keeping sizing materials and other similar substances moist. It does not "creep" as in the case of salt. It does not rust metal but attacks solder. It can be purchased in solid form containing 75 per cent. calcium chloride at from 1 to 1½ cents per lb. For freezing temperatures see p. 299.

Glycerine is a colorless, viscid liquor without odor and miscible with water in all proportions. It should have a specific gravity of approximately 1.25. It has no effect on metals but disintegrates rubber. Costs from 17 to 20 cents per lb. (1 gal. = 10½ lb. approx.). A solution containing 3½ lb. of glycerine per gal. has a freezing temperature of + 10 deg. fahr. With 5½ lb. per gal. the freezing temperature is reduced to − 10 deg. fahr. See p. 298.

Denatured Alcohol is free from the disadvantages of calcium chloride, salt, and glycerine solutions. A solution containing 50 per cent. alcohol becomes inflammable, but it is rarely necessary to use more than 30 per cent. Cost, approximately 50 cents per gal. See p. 298.

Per cent. solution	20	30	40	50
Alcohol per gal. of water, qt.	1	1½	2½	4
Freezing point, deg. fahr.	10	−5	−20	−35

GLASS

References: Rosenhain, "Glass Manufacture." Hovestadt, "Jena Glass."

Glass is generally a mixture of several silicates, produced by melting together silica, an alkali and lime or lead. There are two general kinds of glass: **lime glass** and **lead glass.** The former is the more common, is cheaper, harder, more resistive and less fusible than lead glass. The latter has greater luster and brilliancy and is used chiefly for cut-ware and optical purposes. In general, the higher the percentage of silica the harder, less fusible, and more brittle the glass.

Fusibility is decreased and hardness increased by increasing the lime, but the glass does not become so brittle as in the case of high silica. The use of a mixture of soda and potash produces a very fusible glass. In colored glass a part of the lime and lead is replaced by oxides of iron, manganese, cobalt, etc. The addition of borates and phosphates improves glass for various optical and chemical purposes, as do also zinc and barium. German optical glass contains both zinc and barium. Practically all glass is decolorized in manufacture by the addition of manganese dioxide which oxidizes the iron present to a less troublesome form. The remedy is not permanent, as is shown by the development of a violet tint in old window glass and particularly in the glass globes of gas lamps.

Glass possesses the property on cooling from a molten condition of assuming first a pasty, tough condition, and finally a rigid state. This property of plasticity while hot permits its being blown. Blowing was originally entirely done by "hand blowers" blowing through a pipe into a ball of molten glass. Mechanical blowing has recently superseded this practice for all the common forms of glass.

The **compressive strength** of glass is considerably greater than its **tensile strength,** and this can be still more increased by cooling between metal plates, although the glass becomes very brittle. Rosenhain gives the following values:

Authority:	Strength, Tons per Sq. In: Tensile	Crushing
Trautwine	1 to 4	9 to 16
Winkelmann and Schott	2 to 5½	3 to 8
Kowalski	5 to 6	20 to 27
Henrivaux	½ to 1¼	....

The values given by Winkelmann and Schott are probably the most reliable, but they refer to a series of special Jena glasses, not resembling ordinary glass.

The **modulus of elasticity** of glass may be taken at from 10,000,000 to 11,000,000 lb. per sq. in. **Modulus of rupture,** 3000 to 4000 lb. per sq. in. **Coefficient of expansion** per deg. fahr., from 21×10^{-7} to 68×10^{-7} (Rosenhain). **Specific gravity,** 2.5 to 3.45. Average **weight per cu. ft.,** 186 lb.

Poor qualities of glass are injured by rain and air, and even good glass if stored in wet places or if soaked in seawater becomes dull or iridescent. The best qualities of glass are not attacked by bases or by acids with the exception of hydrofluoric. Superheated steam is very corrosive, resulting in the destruction of boiler gage glasses.

Window Glass is generally a soda-lime glass and is always blown. The sheets are cut to marketable size, and since the surface is fused and not polished, it is brilliant, hard and less easily scratched or etched than plate glass. It is graded by quality as A, AA and AAA, and appears on the market in two thicknesses known as single thickness (about $\frac{1}{16}$ in.) and double thickness (about ⅛ in.). Single-thick glass weighs about 82 lb. per square, and double, 164 lb., no allowance being made for lap. A box of ordinary window glass contains as nearly 50 sq. ft. as the size of panes admits. Any size of pane can be made to order, but standard sizes run from 6 × 8 in. to 36 × 50 in. for single-thick and 60 × 70 in. for double-thick.

Plate Glass is usually soda-lime glass cast on large iron plates and subsequently ground and polished. It varies in thickness and can be obtained in any size from 6 × 16 in. to 144 × 200 in. Ground plate glass is extensively used for flooring.

Skylight Glass. The weight of fluted or rough plate glass required for one square of roof (no allowance being made for lap) is approximately 350 lb. for ¼ in. glass and in proportion for other thicknesses. A square of roof is 10 ft. square or 100 sq. ft.

Pressed Glass is made by forming heat-softened glass to shape in dies or mold under pressure. It is fairly inexpensive.

Luxfer Prisms are white glass plates whose interior side is provided with parallel, prismatic, transverse ridges. They are mounted vertically in front of windows or as protecting roofs more or less obliquely on the outside, and serve to diffuse the light passing through them into the darker portion of the apartment. They possess great strength and considerable resistance to fire.

Quartz Glass is made by melting rock crystal and, lately, purest quartz sand in the electric furnace. It is unaffected by changes of temperature, is fireproof and acid-resistant, does not conduct electricity and has practically no expansion under heat. It is used considerably for high-temperature laboratory apparatus.

Wire Glass is a glass having an iron wire screen thoroughly embedded in it. It offers about 1½ times the resistance to bending that plain glass does, and very thin sheets may be walked on. If properly made, it does not fall apart when cracked by shocks or heat, and is consequently fireproof. It is used for flooring, skylights, fireproof doors, fire walls, etc. It must be ordered exactly to measure as it cannot be readily cut. Less light passes through it than through plain glass.

GRAPHITE

REFERENCES: "Graphite, Its Properties, Occurrence, Refining and Uses," Department of Mines, Canada. "Mineral Resources of the United States," 1909. E. G. cheson, "Seventeen Years of Experimental Research and Development," Am. cademy of Arts and Science, 1908. "Mineral Industry," 1893, 1898, 1900, 1902, 1904.

Graphite is an amorphous form of carbon, other forms being the diamond and lampblack. Three commercial varieties are obtainable—flake, amorphous and artificial. Flake and amorphous graphite exist in nature and are separated from their accompanying rock mechanically. The latter is much more abundant but of less value commercially. The best flake graphite comes from Ceylon, although certain valuable varieties occur in the United States, particularly those in New York State controlled by the Jos. Dixon Crucible Company. The **specific gravity** of commercial graphite ranges from 2.015 to 2.583; for refined graphite it is 1.802. Its **hardness** on Mohs's scale is between 1 and 2. The **specific heat** of natural graphite is 0.2019; of furnace graphite, 0.1970. The **heating value** of natural graphite is 14,033 B.t.u. (Favre and Silberman), and of artificial graphite, 14,222 B.t.u. (Berthelot and Petit) per lb. According to Fizeau, the **coefficient of linear expansion** per deg. fahr. is 0.00000437 at 104 deg. fahr., and the elongation of a unit length from 32 deg. to 212 deg. fahr. is 0.000796. Graphite conducts heat better than diamond and is also a good conductor of electricity.

Specific Electrical Resistance: Natural, 14.20 ohms (Streints), 12.20 ohms (Muraoka); graphitized electrode, 12 ohms; Ceylon, 2 to 8 ohms (Zellner); Acheson electrode, 12 ohms (Zellner).

Flake Graphite is extensively used in the manufacture of crucibles and other refractories, owing to its resistance to heat and its ability to form a stiff mix with clay. It is also used in stove polish, foundry facings, paint and pencil manufacture and as a lubricant.

Amorphous Graphite is extensively used in paints owing to its resistance to acids and alkalies and ability to form an elastic film with oil; also for packings, lubrication, electrodes and pencils. For lubrication it must be entirely free from grit; owing to its unctuous nature, it is an excellent lubricant either alone or with oil.

Artificial Graphite is made by the International Acheson Graphite Company, of Niagara Falls, by converting amorphous carbon to graphite by subjecting carbonaceous material to a temperature in the electric furnace above the volatilization point of impurities such as iron, silicon, etc. It is possible to produce absolutely pure graphite in this manner. Its principal use at present is in the manufacture of electrodes. Large amounts are sold as a lubricant after a special treatment called "deflocculation," which makes possible its colloidal suspension in water or oil. "Aquadag" and "oildag" are products of this kind containing deflocculated graphite in water and oil, respectively.

Graphite for foundry use is often called **plumbago**, as it was originally supposed that graphite was a form of black lead. The United States Navy specifies that plumbago shall be dry, free from coal dust or grit and shall contain not less than 55 per cent. of graphitic carbon.

Graphite refractory brick are used for furnace linings on account of their great heat-resisting qualities. The product known as **kryptol**—composed of graphite, carborundum, and clay—is used for electric resistance furnaces, as its resistance is sufficient to localize a high degree of heat without the material itself being destroyed.

HEAT INSULATORS

References: "Asbestos, Its Origin and Production," *Chemical World*, Jan., 1913. Printed matter issued by the H. W. Johns-Manville Co. and the Armstrong Cork Co.

Air is the most efficient insulator available, and the essential requirement of an insulating material is that it retain a large amount of air entrapped in minute spaces. The material should not absorb moisture and should be free from rot, mold, or offensive odors. The principal materials used for this purpose are cork, asbestos, and mixtures of asbestos and magnesia.

Cork is the outer bark of the cork oak. It is highly compressible, possesses great permanent elasticity, is an excellent non-conductor of heat, waterproof, is unaffected by moisture and very slow-burning. It possesses considerable strength and can be readily bonded to concrete. While comparatively expensive initially, its lasting qualities offset the increased price. Cork is obtainable in granulated form and in sheets or boards, the latter being generally made by building up granulated cork under pressure with a binding material such as glue, asphalt, pitch, or cement. One commercial variety is obtainable in which the natural resin of the cork is used as the binding material.

The United States Navy specifies compressed **cork in sheets** 36 × 12 in. and 1 to 3 in. in thickness, and requires that it stand boiling for 3 hr. without disintegration or natural linear expansion. **Granulated cork** is obtainable in the following sizes: Unscreened, screened, 3/32, 8/20, and 12/30. Unscreened cork is the standard grade for insulating purposes and will pass through a 1/2-in. mesh screen. 8/20 granulated will pass through an 8-to-the-inch mesh, but not through a 20-mesh screen.

Cork is used extensively aside from insulation for stoppers, artificial stone, and, notably, **linoleum.** This material is made of cork dust specially treated with linseed or other drying oils and is generally reinforced on one side by fabric and varnished; it is used for floor covering and for dressing walls. It can be obtained in various thicknesses. Excellent **substitutes** are obtainable, the best being compounds of stearin, pitch, and similar substances.

Asbestos is a fibrous mineral, the most important deposits of which are found in Canada. The amphibole or hornblende variety of asbestos does not possess the fineness of fiber, tensile strength, elasticity, or flexibility of the chrysotile variety, but both are equally heat-resisting. The former variety is of no value for spinning or weaving. The chrysotile fiber is white in color and is difficult to spin on account of its perfectly smooth surface, consequently cotton or linen is generally woven with it. Asbestos thread weighs about 1 oz. to the 100 yd.

The valuable **properties** of asbestos are its flexibility, fibrous structure, incombustibility, its low heat and electrical conductivity, and its resistance to the action of most chemical agents. **Uses.** It is spun and woven into thread, rope and cloth, made up into paste for insulation, and in finely divided wool in the form of felt or paper is used for building purposes and also for building board. Mixed with caustic lime it produces a fireproof wall plaster; mixed with Portland cement it is used to make fireproof shingles; with asphalt, it is used as a roofing; and with magnesia, as an insulation for steam and hot water pipes. It is also extensively used as packing in sheet form with and without metallic insertion, and for gaskets. It has an approximate **dielectric strength of** 4000 volts per mm. and a specific resistance of 16×10^4. Good asbestos should not burn or show any flame under the blowpipe nor should it be affected by concentrated hydrochloric acid. **Asbestos wood** is obtainable in standard sheets 36 × 48 in., and in thicknesses from 1/4 in. every 1/8 in. to 1 in., and then by 1/4-in. increases to 2 in.

The United States Navy specifications calls for **asbestos millboard** in standard heets 40 × 40 in., the various thicknesses to have the following weights: 1/2 in., 25 to 9 lb., 3/8 in. 21–24 lb.; 1/4 in., 14–16 lb.; 3/16 in., 11–12 lb.; 1/8 in., 7–8 lb.; 1/16 in., 3 1/2–4 1/2 b. Asbestos millboard is generally made hard, but, if desired, can be made medium r soft. The material should stand a dry heat of 400 deg. fahr. without injury and should not be affected by acids.

The United States Navy specifies for **asbestos plaster for pipe covering** a mixture of 5 per cent. of long asbestos fiber, 65 per cent. of infusorial earth (p. 617) and 30 per cent. of fireproof binding material. The material must mix with water to proper consistency, and, after drying, should not burn or show any flame. It should not bake hard like a brick but be capable of compression. One bag, 140 lb. net weight, should cover 40 sq. ft. of surface 1 in. thick.

Mineral Wool is a fiber made by sending a blast of steam through molten slag or rock. It should be of fine, fibrous structure and as free as possible from lumps. Rock wool should be used in contact with metal, as the sulphur in slag wool may corrode the metal.

LEATHER

Belts. See Belting, p. 621.

Rawhide is prepared by rubbing oil or fats into a strip of hide, twisting and stretching it until the moisture is removed and the skin thoroughly filled with oil. It is very strong, tough and waterproof, and is chiefly used for belt lacing and similar purposes.

Leather Substitutes generally consist of refuse leather reduced to a pulp, molded, pressed or wound into suitable shapes, and frequently waterproofed by a final treatment. The earlier of these preparations were composed of glue, starch, waxes and adhesives and also included water-repellent ingredients. Of the leather-free artificial leathers, of which there are many types, the best known are **leatherine,** made by coating calico with rubber and rubber substitute; **leather board,** prepared by pulping fibrous materials of various sorts rendered absorptive by the addition of powdered chalk or whiting and after being molded into form covered with a glazing solution composed of starch, gelatine and turpentine; and **leatheroid,** a combination of chemically treated paper with rubber and sandarac often used for trunks and suitcases.

NATURAL STONES

REFERENCE: Baker, "Masonry Construction."

The important **qualities** in stone for building construction are cheapness, durability, and strength. Stones are seriously affected by weather, chemicals, gases, and temperature. Resistance to weathering depends upon both the hardness and the absorbent properties of the stone. Porosity is an objectionable element. If the constituents differ greatly in characteristics, weathering is apt to be unequal, consequently starting disintegration.

In general, crystalline structure is more durable than amorphous. Examination of the condition of the stone in the quarry affords some idea as to its durability. Further information can be obtained by artificial tests of weight, crushing strength, absorption, and resistance to freezing, to acids and to heat.

The **structure** of the stone is of prime importance where heavy loads are to be carried. All stones are classified on the basis of the mineral forming the chief constituent, namely, **siliceous stones,** such as granite, syenite, gneiss, trap, quartz, etc.; **argillaceous** or clayey **stones,** in which alumina is the predominating mineral, such as slate; **calcareous stones** in which carbonate of lime predominates, such as limestone, marble, and dolomite. From a practical standpoint, stones are also divided into two classes—**stratified** and unstratified—the former being represented by such stones as quartz, marble, slate, etc., whereas the **unstratified** stones consist of an aggregate of crystalline grains such as granite, trap, and basalt-lava.

The following table gives the composition and some of the properties of the more common minerals.

Properties of Common Minerals*

	Composition	Hardness, Mohs's scale	Density
Amphibole	$Ca_5(ClF)(PO_4)_3$	5.0	3.2
Andalusite	Al_2SiO_5	7.5	3.1 to 3.2
Anhydride	$CaSO_4$	3.0 to 3.5	2.9 to 3.0
Apatite	$CO_5(ClF)(PO_4)_3$	5.0	3.2
Aragonite	$CaCo_3$	3.5 to 4.0	2.9
Barite	$BaSO_4$	2.5 to 3.5	4.3 to 4.6
Bauxite	$Al_2O(OH)_4$	1.0 to 3.0	2.4 to 2.5
Biotite	$(HK)_2(MgFe)_2Al_2(SiO_4)_3$	2.5 to 3.0	2.7 to 3.1
Borax	$Na_2B_4O_7.10H_2O$	2.0 to 2.5	1.7
Calcite	$CaCO_3$	3.0	2.7
Chrysolite	$(MgFe)_2SiO_4$	6.5 to 7.0	3.3 to 3.6
Corundum	Al_2O_3	8.5 to 9.0	3.95to 4.1
Cryolite	$AlNa_3Fe_6$	2.5	2.9 to 3.0
Cuprite	Cu_2O	3.5 to 4.0	5.8 to 6.1
Dolomite	$CaMg(CO_3)_2$	3.5 to 4.0	2.8 to 2.9
Epidote	$Ca_2(AlFe)_2(AlOH)(SiO_4)_3$	6.0 to 7.0	3.2 to 3.5
Garnet	$(SiO_4)_3$	6.5 to 7.5	3.1 to 4.3
Graphite	C	1.0 to 2.0	2.1 to 2.2
Gypsum	$CaSO_4.2H_2O$	1.5 to 2.0	2.3
Hematite	Fe_2O_3	5.5 to 6.5	4.9 to 5.3
Hypersthene	$(MgFe)SiO_3$	5.0 to 6.0	3.4 to 3.5
Kaolinite	$H_4Al_2Si_2O_9$	2.0 to 2.5	2.6
Lepidolite	$(KLi)_3Al(SiO_3)_3$	2.0 to 2.5	2.8 to 3.2
Leucite	$KAl(SiO_3)_2$	5.5 to 6.0	2.4 to 2.5
Magnesite	$MgCO_3$	3.5 to 4.5	3.0 to 3.12
Magnetite	Fe_3O_4	5.5 to 6.5	4.9 to 5.2
Malachite	$Cu_2(OH)_2CO_3$	3.5 to 4.0	3.9 to 4.0
Microcline	$KAlSi_3O_8$	6.0 to 6.5	2.5 to 2.6
Nephelite (Elaeolite)	$(NaK)_8Al_8Si_9O_{34}$	5.5 to 6.0	2.5 to 2.6
Orthoclase	$KAlSi_3O_8$	6.0 to 6.5	2.4 to 2.6
Plagioclase	$nNaAlSi_3O_8 + mCaAl_2Si_2O_8$	5.0 to 7.0	2.6 to 2.7
Pyrite	FeS_2	6.0 to 6.5	4.9 to 5.2
Pyrolusite	MnO_2	1.0 to 2.5	4.7 to 4.86
Pyroxene	$RSiO_3$	5.0 to 6.0	3.2 to 3.6
Pyrrhotite	FeS	3.5 to 4.5	4.5 to 4.6
Quartz	SiO_2	7.0	2.6
Serpentine	$H_4Mg_3Si_2O_9$	2.5 to 4.0	2.5 to 2.65
Siderite	$FeCO_3$	3.5 to 4.0	3.8 to 3.9
Talc	$H_2Mg_3(SiO_3)_4$	1.0 to 1.5	2.5 to 2.9

* From "A Guide to the Sight Recognition of 120 Common or Important Minerals," by A. J. Moses.

Granite, composed of feldspar, quartz and mica, is the strongest and most durable of stones in common use and is quarried into shape with facility. It is extremely hard and tough and can be wrought into elaborate shapes only with great difficulty. The feldspar content determines the coloring, while the quartz determines essentially the hardness.

Trap is a very strong and durable stone, but quarried and wrought with great difficulty. It is exceedingly tough and is widely used for roads and railroad ballast.

Syenite, composed of feldspar and hornblende, is crystalline, granular, and speckled black and white; it is hard, and takes a good polish. **Diorite** and **diabase** are similar stones and are frequently known as **greenstone.**

Serpentine is generally green in color and disintegrates in the open air. **Soapstones** and **asbestos** are related to it.

Trachytes are dense, frequently porous, feldspathic rocks with admixtures of crystals of hornblende, biotite and magnetite. They are gray in color. **Pumice stone** is a variety.

Augitites. Basalt, a solidified product of volcanic emission is a common variety, and the most durable and pressure-resisting structural stone; it is valuable for road-building and for bank and supporting walls. **Basalt-lava** is very porous rock varying in color and hardness, used for stairs, paving blocks and millstones.

Gneiss, a schistose structure of granite, is more subject to decomposition than granite, especially if rich in feldspar and mica.

Quartzite (pure or almost pure quartz) is characterized by its vitreous crystallization. When porous, it is used for millstones; it is also used in the manufacture of glass, and as broken stones or as gravel in road building, for preparing concrete, etc.

Mica-schist consists of gray quartz between layers of mica. It is used for roofing plates.

Clay-schist is composed of hardened clay and quartz, often with little lamellæ of mica. It cleaves readily and is therefore suitable for roofing. See also Slate, p. 640.

Limestone (carbonate of lime), if capable of taking high polish, is called **marble**. The color varies with amounts of iron oxide, copper oxide, etc. By ignition it produces **caustic lime**. **Calcite** is transparent and used as sculptor's marble. **Chalk**, another form of limestone, is white and earthy.

Marl is a dense, earthy or slaty rock, consisting of a mass of carbonate of lime mixed with clay and siliceous sand. Certain species are well suited for the manufacture of cement.

Dolomite, a magnesian carbonate of lime, is whitish-yellow or gray to brown in color, crystallized and dense. Certain deposits produce a hard, durable building stone, well suited for road building.

Gypsum, hydrated sulphate of lime, is generally white, but often yellowish to reddish, or gray to blackish; it is not durable when exposed to weather.

Sandstone consists of sand grains made up into a more or less compact rock by a binder consisting generally of silicon, lime, or clay. It often contains calcite, mica, iron ore, and admixtures of red and green clay. Iron pyrites has a disintegrating effect; an abundance of mica is also undesirable.

Conglomerates consist of rounded pebble stones formed by the aggregation of various rocks, held together by a binder such as clay or marl.

Gravel and Sand consist of small fragments of quartsy minerals, often mixed with lime, marl, and clay, from which they can be liberated by washing. Pit sand is ordinarily gritty but frequently more impure than river sand.

Clay is a hydrous oxide of aluminum; as it occurs in nature it is frequently a mixture of clay with sand, limestone and oxide of iron produced by the erosion of rocks containing feldspar minerals. The purest variety, **kaolin**, is used for the production of chinaware and as a paper-making material. Plastic varieties are used for pipe clays, fireproof clays and potter's clays. Clay shrinks in drying and subsequently in burning without losing its form as a whole, and becomes extremely hard. Certain varieties known as **fuller's earth** are very absorbent of oils or dyes. See also Brick, p. 622.

For strength and other physical properties of natural stones, see Table 4, p. 385.

PAINT OILS

China Wood Oil (tung oil), expressed from the tung nut, is being increasingly used as an adulterant and **substitute for linseed oil** in paints and varnishes. It has a peculiar rancid odor and yellow color, usually darker than that of linseed oil. It has the unique property of apparently drying throughout at a uniform rate when spread in a film instead of forming a skin by surface drying as does linseed oil. It dries "flat" instead of glossy, with an opaque, white film. When heated to about 400 deg. fahr. it is converted into a jelly-like mass insoluble in ordinary solvents. Specific gravity, from 0.936 to 0.944; its other constants are very similar to those of linseed oil. It can be mixed with lead and manganese driers. Its peculiar drying properties and resistance to water when dry have been successfully **utilized in varnish making.**

Linseed Oil is a brownish-yellow vegetable oil with a specific gravity between 0.931 and 0.937. It possesses the property of absorbing oxygen and consequently drying to a greater extent than most other oils; hence largely used for paints and varnishes. It is frequently adulterated with cottonseed, rosin, fish, China wood and soya bean oils. **Adulteration** can sometimes be detected by odor, color or gravity, but chemical analysis is usually necessary. Mixtures of China wood, soya bean and linseed oils can be made which are extremely difficult to detect. Adulteration with mineral or rosin oil can frequently be detected by a green or blue fluorescence which appears when the oil is viewed on a black background with the back to the light.

As raw oil dries very slowly, it is frequently used as "**boiled oil.**" The name was derived from the original practice of boiling the oil in open kettles at a temperature of 300 to 500 deg. fahr. and incorporating oxides of lead and manganese, this process greatly increasing the drying properties. Little if any boiled oil is now made in this way, as the original process was expensive and darkened the oil greatly. So-called "boiled oil" is now made by heating a small quantity of oil with lead and manganese oxides and subsequently adding this drier to the raw oil. A third class, known as "**bung hole" oil**, is made by adding driers dissolved in benzine or turpentine to the raw oil. If properly made the quicker processes produce satisfactory oil. Boiled oil should have a similar odor and taste to raw oil; specific gravity, between 0.931 and 0.950.

PAPER

REFERENCES: Griffin and Little, "The Chemistry of Paper-making." L. E. Andes, "The Treatment of Paper for Special Purposes."

Paper is made from cotton, linen and hemp rags and waste, from chemically prepared wood, from straws, and from wood not chemically prepared. The best papers are made from cotton, linen and hemp; rags and spinning wastes having longer and stronger fibers and consisting of purer cellulose are less affected by the chemical and mechanical operations of paper-making and do not wear and crack so easily as paper made from wood, straw, or mechanically prepared wood. Paper is weakened in manufacture by the addition of mineral fillers, by large amounts of sizing materials, or by rapid drying. **Fillers** are added to increase weight, improve printing quality and increase opacity. **Sizing** is added to prevent the spreading of ink.

The highest grades of **writing and book papers** are made from rags alone, cheaper grades from rags and wood pulp, or from wood pulp alone. The lower grades of paper, such as **newspaper**, are made largely from ground wood (*i.e.*, wood reduced to fiber by mechanical grinding) and readily disintegrate.

The highest-grade **wrapping and tag papers** are made from old manila rope, which produces a strong, tough paper. Extensive adulteration is practiced by the use of rope stock other than manila and by the substitution of wood pulp, principally sulphite, in whole or in part. **Cable paper** should be made from pure high-grade manila stock and should be free from all chemical residues, acids, etc. The use of "**Kraft" paper** is rapidly extending as a wrapper. This is made by cooking wood by the sulphate process and produces a strong, tough paper of a characteristic brownish color.

Box boards, container boards, etc., are made from ground wood alone, mixtures of ground wood and sulphite, and in the form of lined boards which have a layer of paper on the outside and are filled with a waste material such as old newspapers beaten to a pulp, ground wood, liquorice root, etc. **Blotting papers** are made from wood pulp with or without small additions of rag. Comparison is readily afforded by the speed with which the paper absorbs water.

In general, light, strong papers should be selected as additional weight and bulk beyond that necessary to secure sufficient strength, opacity, and resistance to wear, results in less durability and greater cost both of material and handling of transportation.

In **testing** papers, **tensile strength** (500 to 2500 lb. per sq. in.), stretch, and bursting are of importance; tests should be made on special machines. Comparison of different samples of the same grade of paper can be roughly made by tearing, crumpling and by visual examination for freedom of dirt and other indications of careless manufacture.

ROOFING MATERIALS

See Report of Committee on Buildings, *Bulletin Am. Ry. Eng. Assn.*, Feb., 1913; also p. 1280 and pp. 1327 to 1329.

Asphalt. Asphalts are bitumens occurring naturally in the solid state In crude form they are too hard and brittle for most purposes, and are therefore generally softened or fluxed with petroleum oil products. Tars do not mix well with asphalt. Mixtures of different asphalts give better results than single ones. Asphalts become hard and brittle with age, losing their elasticity and binding power. Properly refined, they are excellent for roofing purposes.

Trinidad Asphalt is widely used, due to its uniform quality. It is affected by sunlight and water, but is not volatile. It is not suitable for underground waterproofing or for places where it cannot dry out. Contains about one-third mineral matter.

Bermudez Asphalt is not so uniform as Trinidad, and is softer than the other commercial asphalts. It contains little mineral matter.

Gilsonite and Elaterite are nearly pure bitumens obtained from Colorado and Utah. Gilsonite is hard and brittle, requiring considerable fluxing. It is not always uniform in quality, nor a good saturant, although used in many roofings and in making varnish. Elaterite contains considerable sulphur, but is considered valuable for roofing.

Rock Asphalt or Mastic is sandstone naturally saturated with bitumen. It is little used for roofing or waterproofing, but is excellent for paving and floors.

Petroleum Residuals are obtained by the distillation of petroleum. Pennsylvania oils have a paraffin base, California oils an asphaltic base, while the Middle Continent oils are between the two. Most paraffin compounds are useless as binding materials; some of fluid paraffins are excellent fluxes for asphalt. The California oil residues are very similar to native asphalts, and are extensively used for roofing and paving. The Gulf, Middle Continent, and Texas residues are widely used, are cheaper than the California, but weaker and less ductile. These residual oils are treated by blowing air through them when hot and by vulcanizing with sulphur, which produces a material very stable and unaffected by the sun, but not a good saturant.

Tars. Coal Tar is produced by the distillation of coal either in manufacture of illuminating gas or in by-product coke ovens. It contains from 5 to 35 per cent. of carbon in a finely divided state due to cracking of hydrocarbons, which is claimed to be of value in roofing materials, as it makes tar less affected by temperature. Moderate amounts do not affect saturating power. The percentage of carbon content and the melting point are of importance. The U. S. Treasury Department specifications for **roofing pitch** require a "straight-run" pitch from coal tar, having the following properties: Melting point (m.p.), 135 to 155 deg. fahr.; insoluble in benzol 15 to 35 deg. Bé.; specific gravity, 1.25 to 1.35; evaporation loss (7 hours, at 325 deg. fahr.) not over 9 per cent. for pitch of 145 to 155 deg. m.p. and 11 per cent. for pitch 135 to 145 deg. m.p.; specific gravity of distillate to 670 deg. fahr., not less than 1.07 at 140 deg. fahr.

Water-gas Tar is a by-product of carbureted water gas obtained from the petroleum used, and is sometimes called **oil tar**. It contains generally less than 2 per cent. of free carbon, is affected by water and forms an emulsion with it, and is generally considered less stable than coal tar. As many gas plants do not separate their coal and oil tars, mixtures of the two are very common.

When properly compounded, asphalts and oil residuals produce a wide range of valuable roofing materials, whose durability can be foretold. This is even more true of tars. Laboratory tests are of negative value only, and specifications must include factory inspection and knowledge of materials used.

Felts for use with asphalts must have high absorbing capacity. With coal tar this is not so important, as it is more liquid when hot. Felts are generally made of cotton rags, woolen felts being expensive and too soft and tender. A small proportion of wool rags improves the absorbing capacity, but this rarely exceeds 25 per cent. Wood pulp and straw are often added to cheapen the price, but they reduce the value of the felt. Felts should be free from lumps. Dry felts are sold by weight, the standard being the amount required to lay 480 sq. ft. A felt weighing 28 lb. to 480 sq. ft. is known as No. 28. Mineral fillers are often added to make weight. Specifications should limit ash to 5 per cent.

Asbestos felts are much more expensive, are poor absorbents and act merely as protection to asphalt, as they neither burn nor decay. Tar has not been successfully used with **asbestos felts.** Jute burlap or canvas is of doubtful value, as jute is not absorbent and decays more readily than cotton. Average weight, 15 lb. per 100 sq. ft.; about 10 per cent. extra is required for laps.

Prepared Roofings. A large amount of roofing is made with a cheap, oily saturant composed of asphalt and a large percentage of oil. This material leaks out from the felt and continually distills under heat, the roofing rapidly crumbling and deteriorating. The best **saturant** is made from a mixture of asphalt and stearin pitch. Such a compound gives body to the felt and durability to the material and enables it to remain flexible. After the felt is properly saturated it should be coated to prevent the elements from attacking the felt and saturant. The **coating** used on the best qualities of roofing is a mixture of stearin and **Calabria pitch**, which is the most permanent and substantial waterproof coating developed, as it remains flexible, does not deteriorate readily and is very resistant to moisture. Many cheaper coatings are on the market composed of asphalt and gilsonite fluxed with petroleum oil, but these are not durable and allow roofing to rapidly become hard and brittle. Most prepared roofings are inferior to properly built-up roofing.

Tile. Hard-burned clay tiles with overlapping or interlocking edges cost about the same as slate. They should have a durable glaze and be well made. Unvitrified tiles with "slip" glaze are satisfactory in warm climates, but vitrified tiles only should be used in the North. Weight, from 750 to 1200 lb. per square (100 sq. ft.). Properly made tile does not deteriorate, is a poor conductor of heat and cold, and is not so brittle as slate.

Slate should be hard and tough and have a well-defined vein that is not too coarse. If too soft, they will absorb water; if too brittle, they are easily broken on cutting and installing. The surface when freshly split should have a bright metallic luster, free from loose flakes or dull surfaces and straight and true. Slate should give a clear metallic ring when struck. Color is not an indication of quality. Black ribbon slate is cheaper than all-black slate and equally good if appearance is unimportant.

Stock **sizes** range from 7 × 9 in. to 14 × 24 in.; thickness, from 1/8 to 3/8 in., 3/16 in. being the usual thickness. Approximate weight, 650 lb. per square. Slate roofs rank well in regard to fire hazard, but are not so good as tile on exposure to adjacent conflagrations.

Cement Roofings. Reinforced-concrete tiles are used with steel roof trusses, and are generally formed with projections enabling them to be placed directly on the purlins and held in place by their own weight. Wire glass can be inserted, avoiding expensive skylights. Cost, about the same as slate. **Small cement tiles** are less expensive than clay tile but more absorbent and brittle. **Asbestos shingles** made of Portland cement and asbestos are excellent. They cost more than slate but can be laid in the French or diagonal methods better than slate. They are sometimes strengthened by the insertion of wire mesh or perforated steel sheets.

Shingles. Clear **white pine** shingles are the best; **red cedar** shingles of good quality are obtainable from the Pacific Coast. In the South **red cypress** from the Gulf States is preferable. Redwood shingles come 5½ butts to 2 inches; lesser thicknesses are more liable to crack, and have shorter life. Shingles 8 in. wide or over should be split before laying. Dimension shingles of uniform width are obtainable. Dipping in oil or creosote adds to life. Creosote stains are both preservative and decorative. Shingles should be dipped before laying for best results. Wood shingles make a lasting roof, but materially increase the fire hazard. See also p. 583.

Metallic Roofings are laid in large sheets without sheathing (often strengthened by corrugating), sometimes cut into small sizes and laid as shingles, bent into interlocking shapes like tile, or soldered into a single structure as in tin roofing. The first cost is less than that for clay tile. Sheet steel covered with a coating of bitumen and asbestos is a recently developed roofing material. For data on corrugated sheets, see p. 1303.

RUBBER, GUTTA PERCHA AND BALATA

REFERENCES: C. O. Weber, "Chemistry of India Rubber." F. Clouth, "Rubber, Gutta Percha and Balata." H. L. Terry, "India Rubber and Its Manufacture." P. L. Schidrowitz, "Rubber."

These three substances which are frequently confused are all produced by the coagulation of the latex from certain shrubs and trees and are similar in many respects. The essential difference between gutta percha and rubber is that the former becomes soft and plastic on immersion in hot water, retaining any shape then given to it on cooling, whereupon it becomes hard but not brittle like other gums. Rubber or caoutchouc, on the other hand, does not soften in hot water and retains its original elasticity and strength almost unimpaired. Balata behaves on heating very much the same as gutta percha but possesses very little elasticity and can be vulcanized only with difficulty, whereas rubber and gutta percha are readily vulcanized, although the two latter substances possess different properties after vulcanization.

Rubber is obtained principally from South America, Africa and Ceylon, the the former country producing most of the better grades. **Para rubber** is the best rubber obtainable, but in recent years "plantation" rubber from the Malay Peninsula has become an important factor. Certain lower-grade rubbers, notably Guayule, Jelutong and Ceara, are rapidly coming into use for the cheaper materials.

Unvulcanized rubber is little used except for insulating tape, dental rubber, rubber cements and a few minor purposes. The bulk of the rubber used is **vulcanized** either by heating under pressure with sulphur or by exposing in the cold to the fumes of sulphur monochloride.

High-grade rubber will stretch to approximately ten times its length and at this point will bear a **load** of 10 tons per sq. in. It can be compressed to one-third its thickness thousands of times without injury. When vulcanized for elasticity it behaves like other engineering materials up to a load of 30 per cent. of the breaking load and at an extension of one-half the maximum. From this point on, however, the resistance increases in greater proportion than the extension, and finally assumes a comparatively high value. Even when stretched almost to the point of rupture it restores itself very nearly to its original dimensions on being released, and gradually recovers a part of the loss of form at that instant observable.

The **specific inductive capacity**, of rubber ranges from 2.22 to 3.70; its **dielectric strength** per cm. is 476 kilovolts. The **color** of vulcanized rubber containing only rubber and sulphur is light gray; mineral and other additions vary the color from a more-or-less dark gray to black.

Raw rubber possesses the power of **self-adhesion** which practically disappears in vulcanized rubber. Cold water indefinitely preserves rubber, but if exposed to the air, and particularly to the sun, all rubber goods tend to become hard and brittle. Dry heat up to 120 deg. fahr. should have little deteriorating effect, but at temperatures of 360 to 400 deg. rubber begins to melt, loses its elasticity and becomes sticky; at higher temperatures it becomes entirely carbonized. Unvulcanized rubber is soluble in carbon bisulphide, benzine, petroleum ether and turpentine. These **solvents** have little effect on vulcanized rubber except to cause it to swell. Vulcanized rubber is very resistant to alkalies and acid.

Rubber is seldom used alone industrially, but mixed with mineral matter, waxes, rubber substitutes or reclaimed rubber. The highest grades, such as insulation, fire hose, etc., seldom contain more than 40 per cent. of rubber. A small quantity of paraffin or ozokerite is beneficial in reducing the tendency to oxidize. Rubber substitutes are only suitable for very cheap material. While some excellent reclaimed rubber is now made, its use is undesirable where permanency is desired.

Specifications should state the percentage and kind of rubber desired, the specific gravity of compound and suitable physical tests. Tensile strength and stretch tests are of importance, but vary widely with different compounds. A good 30 per cent. Para compound should have a **tensile strength** of at least 1000 lb. per sq. in. and should stretch to at least five times its length before breaking. A piece stretched to three times its length should show a permanent elongation of not more than 20 per cent. Chemical analysis is of value in detecting rubber substitutes, reclaimed rubber and foreign substances, but, generally speaking, does not serve to identify the grade of rubber. Red lead is stated to be undesirable in high-grade compounds as it tends to increase oxidation, which is the primary cause of deterioration of rubber products. Zinc oxide, whiting, clay, barytes and similar substances are generally used and are harmless. Rubber for permanent use should be slightly under-vulcanised rather than over-vulcanised. Rubber compounds are extensively used for electrical insulation, hose, steam and water packing, buffers, tiling and numerous other purposes where electrical strength, resilience and waterproofing qualities are desired.

Hard Rubber, also known as **ebonite** and **vulcanite,** is made by vulcanising rubber with a large quantity of sulphur and for a greater length of time. It can be softened by heat and then be shaped or molded as desired. It is capable of being highly polished when free from mineral admixtures. It does not oxidise readily and is not affected by air and sunlight. It is very impervious to electricity but becomes charged with static electricity when rubbed. The substance is black, inodorous and resembles horn in appearance. The solvents which dissolve raw rubber and partly dissolve vulcanised rubber have no influence on hard rubber. It offers great resistance to all acids. If exposed for a long time to temperatures above 400 deg. fahr. it does not melt but carbonizes. It is extensively used for switch handles, for covering tools for electrical purposes, insulating tubes for electrical conduits, fountain-pen handles, linings for acid vats and numerous other purposes. Its use is being somewhat superseded by rubber substitutes.

The United States Navy **specifications** require that "hard rubber shall be tough and hard, show a shiny black fracture and shall be capable of being worked with machine tools and readily take a fine jet-black polish and must show high insulation and dielectric strength. The samples shall be exposed to live steam at a temperature of 212 deg. fahr. for two hours and must show no signs of disintegration or softening."

A **semi-hard rubber** is also made by varying the degree of vulcanization.

This is more flexible and elastic than hard rubber and more durable than ordinary vulcanized rubber.

Reclaimed Rubber. Large quantities of recovered or reclaimed rubber are used, generally mixed with new rubber. This is prepared either by merely cleansing and grinding up the waste rubber or by a chemical-mechanical process of reclaiming which removes as much as possible of the sulphur and foreign ingredients from the rubber and brings it as nearly as possible to its original crude condition. The quality of reclaimed rubber is widely variable, but a good quality can be obtained which is of considerable value in the production of cheap rubber articles.

Synthetic Rubber. Artificial rubber has been produced by chemical synthesis on a laboratory scale and it has been claimed recently (1912) that commercial synthetic rubber is being produced in both England and Germany, although the details of manufacture are as yet secret. Production on a large scale, however, is a possibility in the near future.

Rubber Substitutes. Although numerous so-called substitutes for rubber have been prepared, there is at the present time no real substitute, all of these compounds being merely cheapening ingredients and in no way the equivalent of real rubber. The great bulk of this material is used in admixture with new or reclaimed rubber. These substitutes are of two kinds: **Black substitutes**, which are made by oxidizing vegetable oils either by blowing or by treatment with nitric acid, producing a solid, elastic, brown substance which softens in water and is soluble in turpentine, carbon bisulphide and alkalies, and largely used in admixture with rubber and alone on cheap waterproof fabrics; and **white and brown substitutes**, the white substitute being made by cold vulcanization of vegetable oils with sulphur monochloride, producing a spongy, elastic substance soluble in alkalies and largely used as a filler in white rubber goods. The brown substitute is made by heating vegetable oils with flowers of sulphur and produces a substance of rubber-like appearance but possessing little elasticity or density. It is sometimes employed alone on waterproof cloth, but generally in combination with rubber.

Gutta Percha. Pure gutta percha is colorless, and, when finely cut, transparent. It is tasteless, inodorous, softens at 99 deg. fahr., and can be molded readily at 195 deg. fahr. If heated above 265 deg., it melts to a colorless oil; it is not affected by cold and is very resistant to water. When exposed to air and sunlight, it rapidly deteriorates. It possesses excellent heat resistance and the greatest electrical resistance of any plastic material.

Wunschendorff states that the **resistance** of gutta percha at a temperature of 75 deg. fahr., copper taken as a unit, is 6×10^{19}. Gutta percha is insoluble in most reagents, is slightly soluble in pure alcohol and partly dissolved by turpentine, olive oil and benzine. The best **solvents** are carbon bisulphide and chloroform. It is very little affected by acids or alkalies. On account of its great electrical resistance, waterproof qualities and permanency under water, it was largely used in the first transatlantic cables. Is little used to-day except for the manufacture of golf balls and minor uses.

Balata. Raw balata is gray, brown or whitish-red and possesses little elasticity. It is softer than gutta percha under ordinary temperatures, does not become so firm when cooled, is soluble in turpentine, benzine and carbon bisulphide, but resistant to acid and alkalies. It can be readily molded at 125 deg. fahr. On account of its great toughness and resistance to moisture and air, it is particularly well suited for the manufacture of rubber belts; also used to a small extent in rubber sheets, shoe soles, etc.

SHELLAC

The most commonly used shellac for pattern and varnish work is the T. N. grade, which usually contains about 5 per cent. of rosin. A grade called Garnet-lac, sells at about the same price as T. N., and is free from rosin or lac-wax.

Shellac is **soluble** in alcohol, hot aqueous solutions of sodium and potassium carbonates, caustic alkalies, borax and acetic acid. Its **specific resistance** is approximately 9×10^9 megohms per cu. cm.; **specific inductive capacity**, about 2.74. It is slightly hygroscopic but not sufficiently so to impair its value as an electrical insulator. Shellac softens at 181 deg. fahr., flows readily at 230 to 248 deg., hardens again at 356 to 384 deg. and begins to carbonize at 446 deg. fahr.

Shellac is **used** extensively as a sticker and insulator in the manufacture of electrical apparatus, for bonding abrasive wheels, and as a bond for a variety of molded goods. The most common **adulterant** is rosin, which makes the shellac brittle. A common test is to heat a piece of shellac with a lighted match until one corner is melted, then blow out the flame and attach match to the piece of shellac and let the latter drop to the floor. If the shellac is of good quality and ordinarily free from adulteration, it will string out in a thin flexible threaded form the height of a man's hand held as high as possible from the floor. It has been found that for certain purposes as a sticker the addition of 5 per cent. of rosin increases the adhesiveness. **Bleached shellac** is used very largely in lacquers and has less adhesive strength than **orange shellac**. It is not completely soluble in alcohol and nearly always contains some chlorine. The ordinary spirit **varnish** is made by dissolving from 4½ to 9 lb. of shellac to a gallon of alcohol. 4½ lb. per gal. makes 1½ gal. of varnish and 9 lb. per gal. makes 2 gal. of varnish.

LUBRICANTS

BY

AUGUSTUS H. GILL

REFERENCES: Archbutt and Deeley, "Lubrication and Lubricants;" Brannt, "Petroleum and Natural Gas;" Holde-Mueller, "The Examination of Hydrocarbon Oils, Fats and Waxes;" Lewkowitsch, "Analysis of Fats, Oils and Waxes;" Gill, "Short Handbook of Oil Analysis" and "Engine-room Chemistry."

Properties. A good lubricant should possess: 1. Minimum cohesion among its own particles. 2. Maximum adhesion to the surfaces to be lubricated. 3. Slight changeability as regards oxidation by the air or by changes in the temperature or pressure of the bearings. 4. Freedom from acid. 5. Purity.

A thin film of oil should interpose itself between the bearing metal and the shaft; as the rotation of the latter separates the particles of oil, low cohesion facilitates this. High adhesion prevents the oil from running off the shaft and out of the bearing. The oil should be sufficiently viscous to prevent it from being squeesed out of the bearing except by unusual pressures.

Exposure to the air may result in rancidity with the animal and vegetable oils or in resinification with the mineral oils; this is aided by heat and dust.

Heat produces an evaporation of hydrocarbon gases from petroleum oils—particularly the lighter or spindle oils—increasing the danger from fire.

Inability to withstand cold—high cold test—may freeze the oil in the bearings and stop lubrication.

Acid attacks and roughens the shaft and bearings. It can be formed by oxidation of the oil or come from the sulphuric acid used in refining.

Purity is freedom (*a*) from water which may emulsify the oil and diminish its lubricating power (water also gets into the lubricating wicks and diminishes their capillarity); (*b*) from solid matter which would stop up the oilers. This may be metal from the machinery, stearin, dirt, chips, etc., glue from the barrels, coke with mineral oils, cracklings with animal oils, and cellulose or gelatinous matter with vegetable oils.

Tests of Lubricants. Viscosity is the degree of fluidity of an oil—its internal friction or shearing modulus. The **viscosity test** consists in noting the time in seconds required for a certain quantity of oil to flow through an orifice at a standard temperature. In this country the Saybolt universal **viscosimeter** is the one commonly used, although the European Engler viscosimeter is increasingly employed. Another instrument for testing viscosity is the Doolittle torsion viscosimeter.

The **gumming test** is performed by treating the oil with acid, which brings about in a short time the changes that take place in an oil when used; it is also a measure of the extent to which an oil will "carbonize" in a gas-engine cylinder.

The **flash test** determines the lowest temperature at which the oil will give off vapors in quantity sufficient to produce an explosive mixture when mixed with air. The **fire test** is the lowest temperature at which the vapors given off will burn continuously when ignited.

The **evaporation test** shows the quantity of oily vapor an oil will give off at the average temperature of the bearing. It represents the amount of oil serving its purpose, and of oily vapor affecting the fire risk.

The **free-acid test** shows the amount of uncombined acid contained in the oil. This, in the case of mineral oils, is sulphuric acid coming from the refining process; with the organic oils it is an indication of age or rancidity and is usually oleic acid. The amount of sulphuric acid (calculated as SO_3) should not exceed 0.3 per cent. The permissible amount of oleic acid varies according to the purpose for which the oil is to be used. For tallow for cylinder oils, not more than 0.15 per cent.; for prime lard for signal oil, not more than 0.2; and for extra No. 1 lard, not more than 1.5 per cent. Free acid in oil attacks the metals of the bearings, journals, cylinders and containers, and in the case of signal oils chars the wick.

The "Oil Pulp" or **Soap Test.** To increase artificially and temporarily the viscosity of oils—in order to pass specifications—recourse is had to the addition of a small percentage of "dope," "oil thickener" or "white gelatin." This greatly increases the viscosity and causes the oil to chill more easily and to emulsify, thus increasing the friction. Furthermore, it is precipitated by contact with water or steam, causing clogging of the machinery.

The **saponification value** indicates the number of milligrams of potassium hydrate required to saponify 1 gram of oil. As this is about 193 for most of the oils, it is no criterion by which to distinguish one oil from another. Its chief value is to determine if an organic oil be adulterated or compounded with an unsaponifiable one, as mineral or rosin oil.

The **specific gravity** of organic oils is generally stated as a decimal indicating its relation to that of water. The specific gravity of the mineral oils is expressed in degrees of the Baumé hydrometer scale (see p. 85) for liquids lighter than water.

The **iodine number** or value represents the percentage of iodine absorbed by an organic oil under fixed conditions, and is used in detecting adulteration. Vegetable oils are subject to the influence of changing seasons and animal oils to that of changes in feed; as in the case of olive oil the iodine number varies from 77 to 88, it is impossible by this method to ascertain the adulteration of olive and some other oils more closely than about 5 per cent.

The **Maumené value** is the rise in temperature (deg. cent.) produced by mixing 10 cu. cm. of strong sulphuric acid with 50 grams of oil contained in a jacketed beaker. It is used for detecting adulteration.

The **cold test** gives the temperature at which the oil will just flow, and indicates the availability of the oil at this temperature.

The **friction test** measures the power consumed by the oil. This is carried out upon a bearing under ideal conditions—regularity of feed, temperature and pressure. The effects of the oil previously used upon the machine may persist for many hours, even though the shaft and bearing be apparently clean. Reliable readings cannot be obtained until after the machine has run at least 8 hours with the oil to be tested.

Choice of a Lubricant. In choosing a lubricant, the following points should be considered: (1) The pressure on the moving surfaces; (2) the velocity with which the surfaces are moving; and (3) their temperature. The cardinal principle underlying all lubrication is to **use the least viscous oil that will stay in place and do the work.** Besides this, the following will aid in the selection of a suitable lubricant:

1. The flash point should be above 300 deg. fahr.
2. The result of an evaporation test should be under 5 per cent.
3. For light pressures and high speeds, mineral oils (of sp. gr. 30.5 deg. Bé., flash point 360 deg. fahr.), sperm, olive and rape oils may be used.
4. For ordinary machinery, mineral oils (of sp. gr. 27–29 deg. Bé., flash point 400–450 deg. fahr.), lard, whale, neatsfoot, and tallow or heavy vegetable oils may be employed.
5. For cylinder oils, mineral oils (of sp. gr. 27 deg. Bé., flash point 550 deg. fahr.) alone or with small percentages of animal or vegetable oils (degras, tallow, linseed, cottonseed and blown rape) may be used.

6. For watches and fine machinery, clarified sperm, jaw and "melon" oils may be employed.

7. For very heavy pressure and slow speed, lard, tallow and other greases, either by themselves or mixed with graphite and soapstone.

Properties of Various Lubricating Fats and Oils

Animal and vegetable fats and oils are distinguished from mineral oils by being saponifiable with caustic alkalies, making hard or soft soaps according as soda or potash lye is used. Organic oils oxidize, becoming rancid and setting free fatty acids; they also gum or "dry" to a certain extent, this being most noticeable with cottonseed and corn oil. Subjected to high temperatures they are somewhat decomposed, evolving acid products. They are refined to remove albuminous and mucilaginous substances by treatment with a small amount of caustic soda, and bleached with fuller's earth and air or by sunning.

Animal Oils are commonly obtained by rendering the fatty parts of the different animals, usually with high-pressure steam. Extraction with solvents is seldom practiced. As a result of the rendering operation a more-or-less solid fat is obtained, as beef tallow, mutton tallow or lard. When this is chilled and pressed, the corresponding oil and stearin result. **Tallow** should be "acidless," that is, free from sulphuric acid and contain only the smallest possible quantity of free fatty acid. It is hard, does not turn rancid easily, and should melt at 113 deg. fahr. It forms a constituent of belt dressings, cylinder oils and lubricating greases. **Tallow** (or ox) **oil** is obtained by chilling and pressing tallow; it is a light-yellow bland **oil** used for mixing with other oils and as a lubricant. **Lard oil** is prepared similarly to tallow oil and appears in the market in five or six different varieties including Prime, Pure, No. 1 and No. 2, which are graded according to color, the first being very light straw-yellow and the last dark brown and ill-smelling. It is used to increase the viscosity of lubricants, as a burning oil, and for oiling textile stock. **Neatsfoot oil** is obtained by boiling the bones of the feet of horned cattle with water and running off the oil. It is often adulterated with sheep and horse foot and hide oil, as well as rape, cottonseed and mineral oils. It is light yellow and bland, with little tendency to turn rancid. It is used similarly to lard oil, and particularly for softening leather. **Whale oil** (train oil) is made by rendering the blubber of various species of whales, and consequently is of very variable composition. It is used as a leather dressing, as a burning oil, and to mix with other oils as a lubricant. **Sperm oil** comes from the great cavity in the head of the sperm whale and also from its blubber. It is a limpid, pale yellow oil particularly well adapted for fine machinery. **Degras** is the grease obtained in scouring wool. It usually contains sulphuric acid, except when made by the naphtha extraction process. It possesses the property of emulsifying with water to a marked degree and finds use in increasing the viscosity of lubricants, as a leather dressing, and in cylinder oils.

Vegetable Oils are usually prepared by pressing the crushed cooked seed or by extraction with benzine or carbon bisulphide. In America, the chief vegetable lubricating oils are castor (and to a lesser extent), corn and cottonseed; in Europe, rape, olive and almond oils are used. **Castor oil**—obtained from the castor bean—is a very viscous oil which gums on standing and does not naturally mix well with mineral oils. To render this possible it is heated to 212 deg. fahr. and a current of air forced through, whereby it becomes more viscous and is known as "blown oil." **Cottonseed oil**

is a pale or deep yellow oil of slight drying properties, chiefly used as an adulterant for other oils and, as well as rapeseed and castor, for the manufacture of blown oils. **Corn** (or maize) **oil** is a somewhat viscous oil with some drying properties. It is used as a lubricant, but more particularly with cottonseed oil for the preparation of soft soaps for lubricating greases. **Rapeseed oil** should be clear, *i.e.*, free from gelatinous matter. It was formerly one of the most commonly used and highly prized lubricants, particularly in Germany. **Olive oil** resembles rapeseed oil, except that it turns rancid more easily and is more fluid.

Mineral Oils are obtained by the distillation of crude petroleum. They are refined by agitation with sulphuric acid, and washed with water and caustic soda, or are filtered through fuller's earth or bone black. They do not change on exposure to the air (except upon very prolonged standing), neither thickening nor turning rancid. Their colors range from straw yellow in the filtered oils through reddish-brown to dark brown, and they all have a bluish or greenish fluorescence or "bloom" except when specially refined or treated. Some at 50 deg. fahr. even separate out paraffin or become pasty, but the Russian oils remain fluid at much lower temperatures.

Table 2. Properties of Some of the Mineral Oils

Oil	Specific gravity, deg. Baumé at 60 deg. fahr.	Flash point, deg. fahr.	Viscosity (Saybolt), at 70 deg. fahr.	Cold test, deg. fahr.

Miscellaneous Oils and Lubricants

Belt Dressings are (1) mixtures of fats, waxes, degras or tallow with castor or fatty oils; (2) vulcanized corn or cottonseed oil thinned with naptha; (3) preparations containing wood tar; or (4) preparations containing rosin which is undesirable (see also p. 622). **Black oils, car oils, well oil or reduced oils** are crude oils from which the napthas and burning oils have been separated by distillation. **Crank-case oils** are pure mineral oils which emulsify but little with water. **Graphite, plumbago or black lead** (see p. 632), when mixed with grease or by itself, is an excellent lubricant for very heavy service where a more fluid lubricant would be squeezed out by the pressure. It should be finely ground and carefully freed from the rock with which it occurs. Artificial graphite may replace it. **"Oildag"** and **"aquadag"** are colloidal suspensions of artificial deflocculated graphite in oil and water, respectively (see p. 633). **Milling-machine or soluble oils** are lard, sulphonated oils or mineral oils held in suspension in water by soaps or alkalies, as borax or soda; the soaps used are either ammonium, sodium or potassium with resin, oleic or sulphofatty acids. **Rosin oils** are obtained by distilling or "running" rosin, each distillate being called a "run" and numbered according to the times it has been distilled. They oxidise quite rapidly and should not be used as lubricants except as soaps in lubricating greases. **Screw-cutting oils** are often mixtures of 27 deg. Bé. paraffin and 25 per cent. fatty oil, preferably cottonseed, although lard oil was formerly used. **Stainless oils** are spindle or loom oils mixed with fatty oils—lard or neatsfoot. **Soapstone, talc or steatite** is a hydrated magnesium silicate. Like graphite, it must be freed from the harder minerals with which it occurs. It is sometimes used by itself in valve packing, but is usually compounded with oil and grease. **Transformer oils** should be either pure mineral or rosin oils and as free as possible from water, acid, alkali and sulphur. **Turbine oils** should be of excellent quality, free from acid and tendency to resinify, and low in sulphur. **Watch oil** is obtained from the porpoise, dolphin, or blackfish, where it exists in cavities in the jaw and in the brain or "melon" of the fish. **Lubricating greases** are mixtures of soaps of palm oil, tallow or rosin oil (with lime or soda as bases) with various oils or fats such as rosin, tallow or mineral oil. The best are those made from tallow by saponification with caustic soda. They may also contain finely powdered talc or graphite. **Non-fluid oils** are oils or their greases stiffened with "oil pulp" or "dope," *i.e.*, aluminum oleate or palmitate.

Spontaneous Combustion of Oils. Certain conditions are necessary to produce spontaneous combustion, namely, 1. A substance capable of absorbing oxygen with avidity, as a drying oil; 2. An open or porous organic substance upon which the oil can be spread out in thin layers; 3. Sufficient air to furnish oxygen, but not enough to cool the mass off appreciably; 4. Effective heat insulators.

The oils likely to produce spontaneous combustion are, in their order of danger: The drying—linseed, menhaden and "cod;" the semi-drying—corn, cottonseed, fish, lard, and neatsfoot; finally, red oil and oleic acid. Mineral oils are not susceptible of spontaneous combustion. When mixed with other oils—for example, neatsfoot or lard to the extent of 40 per cent. and cottonseed to 75 per cent.—the resulting compounds will not spontaneously ignite. The same holds true of emulsions of oils with water and soap or alkali, so long as water is present. With the animal oils the greater the percentage of free acid (oleic acid) the greater the liability to heating. Textile fibers and sawdust serve as media upon which the oils oxidise. As a rule, the larger the iodine number the more liable the oil to spontaneous combustion.

Definition. A mechanism is that part of a machine which contains two or more pieces so arranged that the motion of one compels the motion of the others according to a definite law depending upon the nature of the combination.

Linkages

Links may be of any form so long as they do not interfere with the desired motion. The simplest form is that of four bars, *A*, *B*, *C*, *D*, fastened together at their ends by cylindrical pins, and which are all movable in parallel planes. If the links are of different lengths and each is fixed in turn, there will be four possible combinations; but as two of these are similar there will be produced three mechanisms having distinctly different motions. Thus, in Fig. 1, if *D* is fixed *A* can rotate and *C* oscillate, giving the **beam-and-crank** mechanism, as used on side-wheel steamers. If *B* is fixed the same motion will result; but if *A* is fixed (Fig. 2) links *B* and *D* can rotate, giving the **drag-link** mechanism used to feather the floats on paddle wheels. Fixing link *C*

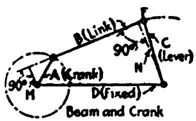

FIG. 1.

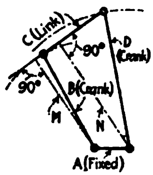

FIG. 2.

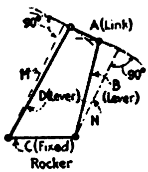

FIG. 3.

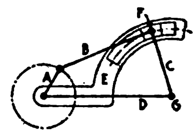

FIG. 4.

(Fig. 3), *D* and *B* can only oscillate, and a **rocker** mechanism sometimes used in straight-line motions is produced. It is customary to call a rotating link a **crank**; an oscillating link a **lever**, or beam; and the connecting link a **connecting rod.** The fixed link is often enlarged and used as the supporting frame.

If in the linkage (Fig. 1) the pin joint *F* is replaced by a slotted piece *E* (Fig. 4) no change will be produced in the resulting motion, and if the length of links *C* and *D* is made infinite the slotted piece *E* will become straight and the motion of the slide will be that of pure translation, thus obtaining the engine, or **sliding-block, linkage** (Fig. 5).

If in the sliding-block linkage (Fig. 5) the long link *B* is fixed (Fig. 6), *A* will rotate and *E* will oscillate and the infinite links *C* and *D* may be indicated as shown. This gives the **swinging-block linkage**. When used as a quick-return motion the slotted piece and slide are usually interchanged (Fig. 7) which in no way changes the resulting motion. If the short link *A* is fixed (Fig. 8) *B* and *E* can both rotate, and the mechanism known as the **turning-block linkage** is obtained. This is better known under the name of the

Whitworth quick-return motion, and is generally constructed as in Fig. 9. The **ratio of time of advance to time of return** H/K of the two quick-return motions (Figs. 7 and 9) may be found by locating, in the case of the swinging-block (Fig. 7), the two tangent points (t) and measuring the angles H and K made by the two positions of the crank A. If H and K are

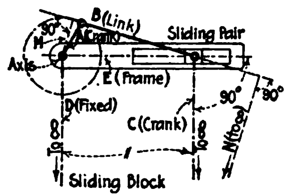

Fig. 5.

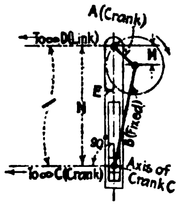

Fig. 6.

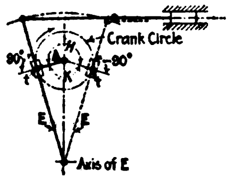

Fig. 7.

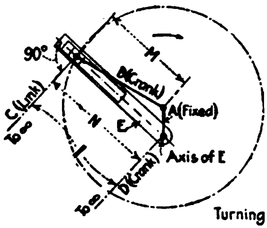
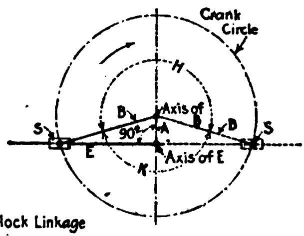
known the axis of E may be located by laying off the angles H and K on the crank circle and drawing the tangents E, their intersection giving the desired point. For the turning-block linkage (Fig. 9), determine the angles H and K made by the crank B when E is in the horizontal position; or, if the angles are known, the axis of E may be determined by drawing a





Turning Block Linkage

Fig. 8. Fig. 9.

horizontal line through the two crank-pin positions (S) for the given angle, and the point where a line through the axis of B cuts E perpendicularly will be the axis of E.

Velocities of any two or more points on a link must fulfill the following conditions (see p. 193): (1) Components along the link must be equal and

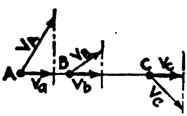


Fig. 10.

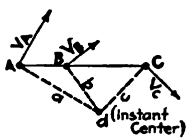

Fig. 11.

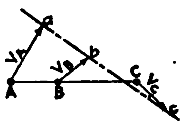

Fig. 12.

in the same direction (Fig. 10): $V_a = V_b = V_c$. (2) Perpendiculars to V_A, V_B, V_C from the points A, B, C, must intersect at a common point d, the **instant center** (or instantaneous axis). (3) The velocities of points A, B, and C are directly proportional to their distances from this center (Fig. 11): $V_A/a = V_B/b = V_C/c$. For a straight link the tips of the vectors representing the velocities of any number of points on the link will be on a straight line (Fig. 12): abc = a straight line. To find the velocity of any point when the velocity and direction of any two other points are known, condition (2) may be used, or a combination of (1) and (3). The **linear velocity ratio** of any two points on a linkage may be found by determining the distances e and f to the instant center (Fig. 13); then $V_e/V_b = e/f$. This may often be simplified by noting that a line drawn parallel to e and cutting B produced forms two similar triangles efB and sAy, which gives $V_e/V_b = e/f = s/A$. The **angular velocity ratio** for any position of two oscillating or rotating links A and C (Fig. 1), connected by a movable link B, may be determined by scaling the length of the perpendiculars M and N from the axes of rotation to the center line of the movable link. The angular velocity ratio is inversely proportional to these perpendiculars, or $O_C/O_A = M/N$. This method may be applied directly to a linkage having a sliding pair if the two infinite links are redrawn perpendicular to the sliding pair, as indicated in Fig. 14. M and N are also shown in Figs. 1, 2, 3, 5, 6, 8. In Fig. 5 one of the axes is at infinity, therefore N is infinite, or the slide has pure translation.

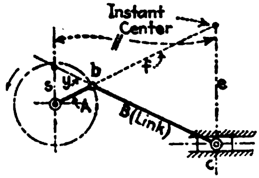

FIG. 13.

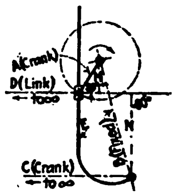

FIG. 14.

Forces. A mechanism must deliver as much work as it receives, neglecting friction, therefore the force at any point F multiplied by the velocity V_F in the direction of the force at that point must equal the force at some other point P multiplied by the velocity V_P at that point; or the forces are inversely as their velocities and $F/P = V_P/V_F$. It is at times more convenient to equate the moments of the forces acting around each axis of rotation (sometimes using the instant center) to determine the force acting at some other point. Applying this to Fig. 15, $(F \times a \times c)/(b \times d) = P$.

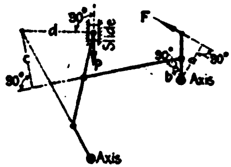

FIG. 15.

Cams

Cam Diagrams. A cam is usually a plate or cylinder which communicates motion to a follower by means of its edge or a groove cut in its surface. In the practical design of cams the angular velocity ratio is not directly involved, but the follower must assume a definite series of positions while the driver occupies a corresponding series of positions. The relationship of driver to follower may be represented by a diagram in which the ordinates represent the rise or fall of the follower and the abscissæ the angular motion of the cam.

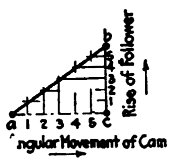

FIG. 16.

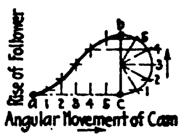

FIG. 17.

The three most common forms of motion used are uniform motion (Fig. 16), harmonic motion (Fig. 17), and uniformly accelerated and retarded motion

(Fig. 18). In plotting the diagrams (Fig. 18) for this last motion, divide *ac* into an even number of equal parts and *bc* into the same number of parts with lengths increasing by a constant increment to a maximum and then decreasing by the same decrement, as, for example, 1, 3, 5, 5, 3, 1, or 1, 3, 5, 7, 9, 9, 7, 5, 3, 1. In order to prevent shock when the direction of motion changes, as at *a* and *b* in the uniform motion, the harmonic motion may be used; if the cam is to be operated at high speed, the uniformly accelerated and retarded motion should preferably be employed; in either case there is a very gradual change of velocity.

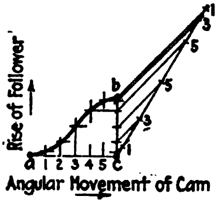

FIG. 18.

Pitch Line. The actual pitch line of a cam varies with the type of motion and with the position of the follower relative to the cam's axis. Most cams as ordinarily constructed are covered by the following four cases.

FOLLOWER ON LINE OF AXIS (Fig. 19). To draw the pitch line, subdivide the motion *bc* of the follower in the manner indicated in Figs. 16, 17, 18. Draw a circle with a radius equal to the smallest radius of the cam *a*0 and subdivide it into angles 0*a*1′, 0*a*2′, 0*a*3′, etc., corresponding with angular displacements of the cam for positions 1, 2, 3, etc., of the follower. With *a* as a center and radii *a*1, *a*2, *a*3, etc., strike arcs cutting radial lines at *d*, *e*, *f*, etc. Draw smooth curve through points *d*, *e*, *f*, etc.

OFFSET FOLLOWER (Fig. 20). Divide *bc* as indicated in Figs. 16, 17 and 18. Draw a circle of radius *ac* (highest point of rise of follower) and one tangent to *cb* produced. Divide the outer circle into parts 1′, 2′, 3′, etc., corresponding with

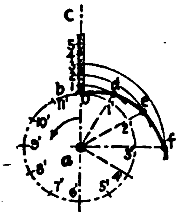

FIG. 19.

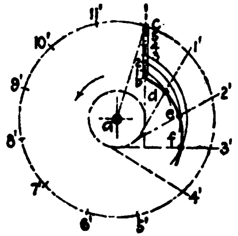

FIG. 20.

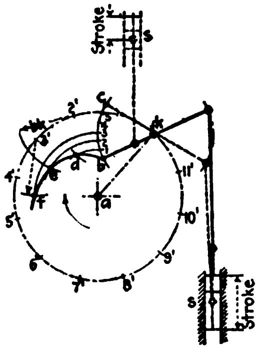

FIG. 21.

the angular displacement of the cam for positions 1, 2, 3, etc., of the follower, and draw tangents from points 1′, 2′, 3′, etc., to the small circle. With *a* as a center and radii *a*1, *a*2, *a*3, etc., strike arcs cutting tangents at *d*, *e*, *f*, etc. Draw a smooth curve through *d*, *e*, *f*, etc.

ROCKER FOLLOWER (Fig. 21). Divide the stroke of the slide *S* in the manner indicated in Figs. 16, 17, and 18, and transfer these points to the arc *bc* as points 1, 2, 3, etc. Draw a circle of radius *ak* and divide it into parts 1′, 2′, 3′, etc., corresponding with angular displacements of the cam for positions 1, 2, 3, etc., of the follower. With *k*, 1′, 2′, 3′ etc., as centers and radius *bk*, strike arcs *kb*, 1′*d*, 2′*e*, 3′*f*, etc., cutting at *bdef* arcs struck with *a* as a center and radii *ab*, *a*1, *a*2, *a*3, etc. Draw a smooth curve through *b*, *d*, *e*, *f*, etc.

CYLINDRICAL CAM (Fig. 22). In this type of cam more than one complete turn may be obtained, provided that in all cases the follower returns to its starting point. Draw rectangle *wxyz* (Fig. 22) representing the development of cylindrical surface of the cam. Subdivide the desired motion of the follower *bc* horizontally in the manner indicated in Figs. 16, 17 and 18, and plot the corresponding angular displacements 1′, 2′, 3′, etc., of the cam vertically; then through the intersection of lines from these points draw a smooth curve *bdef*, etc. This may best be shown by an example, assuming the following data for the diagram in Fig. 22: Total motion of follower = *bc*; circumference of cam = $2\pi r$. Follower to move with harmonic motion 4 units to the right in 0.6 turn, then rest (or "dwell") 0.4 turn, and finish with uniform motion 6 units to the right and 10 units to the left in two turns.

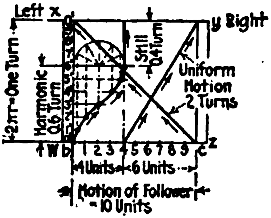

FIG. 22.

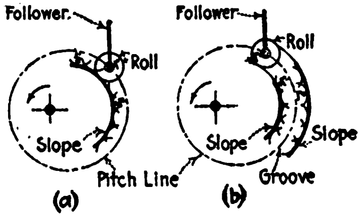

FIG. 23.

Cam Design. In the practical design of cams the following points must be noted. If only a small force is to be transmitted, sliding contact may be used, otherwise **rolling contact.** For the latter the pitch line must be corrected in order to get the true slope of the cam. An approximate construction (Fig. 23) may be employed by using the pitch line as the center of a series of arcs the radii of which are equal to that of the follower roll to be used; then a smooth curve drawn tangent to the arcs will give the slope

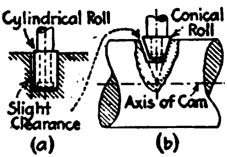

FIG. 24.

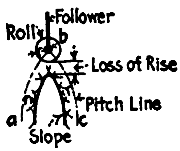

FIG. 25.

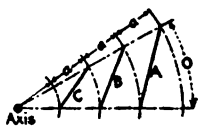

FIG. 26.

desired for a roll working on the periphery of the cam (Fig. 23*a*) or in a groove (Fig. 23*b*). For plate cams the roll should be a small cylinder, as in Fig. 24*a*. In cylindrical cams it is usually sufficiently accurate to make the roll conical, as in Fig. 24*b*, in which case the taper of the roll produced should intersect the axis of the cam. If the pitch line *abc* is made too sharp (Fig. 25) the follower will not rise the full amount. In order to prevent this **loss of rise** the pitch line should have a radius of curvature at all parts of not less than the roll's diameter plus ⅛ in. For the same rise of follower, *a*, and angular motion of the cam, *O*, the slope of the cam changes considerably, as indicated by the heavy lines *A*, *B*, and *C* (Fig. 26). Care should be taken to keep a moderate slope and thereby keep down the side thrust on the follower, but this should not be carried too far, as the cam would become too large and the friction increase.

Rolling Surfaces

In order to connect two shafts so that they shall have a definite angular velocity ratio, rolling surfaces are often used; and in order to have no slipping between the surfaces they must fulfill the following two conditions: the line of centers must pass through the point of contact, and the arcs of contact must be of equal length. The angular velocities, expressed usually in r.p.m., will be inversely proportional to the radii: $N/n = r/R$. The two surfaces most commonly used in practice, and the only ones having a constant angular velocity ratio, are cylinders where the shafts are parallel, and cones where the shafts (produced) intersect at an angle. In either case there are two possible directions of rotation, depending upon whether the surfaces roll in opposite directions (external contact) or in the same direction (internal contact). In Fig. 27, $R = nc/(N + n)$ and $r = Nc/(N + n)$; in Fig. 28, $R = nc/(N - n)$, and $r = Nc/(N - n)$. In Fig. 29, $\tan B = \sin A/[(n/N) + \cos A]$, and $\tan C = \sin A/[(N/n) + \cos A]$; in Fig. 30, $\tan B = \sin A/[(N/n) - \cos A]$, and $\tan C = \sin A/[(n/N) - \cos A]$. With the above values for the angles B and C, and the length d or e of one of the cones, R and r may be calculated.

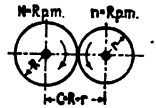

FIG. 27.

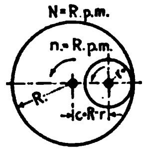

FIG. 28.

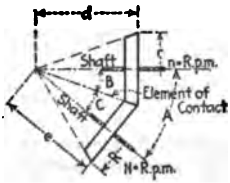

FIG. 29.

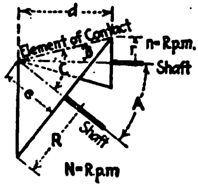

FIG. 30.

Epicyclic Trains

Epicyclic trains are combinations of gears in which some or all of the gears have a motion compounded of rotation about an axis and a translation or revolution of that axis. The gears are usually connected by a link called an arm, which often rotates about the axis of the first gear. Such trains may be calculated by first considering all gears locked and the arm turned; then the arm locked and the gears rotated. The algebraic sum of the separate motions will give the desired result. The following examples and method of tabulation will illustrate this. The figures on each gear refer to the number of teeth for that gear.

	A	*B*	*C*	*D*
Gear locked, Fig. 31..	+1	+1	+1	+1
Arm locked, Fig. 31..	0	−1	+1×59/20	−1×59/20×29/40
Value, Fig. 31........	+1	0	+3 1/5	−1/4
Gears locked, Fig. 32.	+1	+1	+1	+1
Arm locked, Fig. 32...	0	−1	+1×39/20	+1×39/20×29/40
Value, Fig. 32........	+1	0	+2 1/4	+1 3/4

For common epicyclic trains, see also p. 725.

In Figs. 31 and 32 lock the gears and turn the arm *A* right-handed through 1 revolution (+1), then lock the arm and turn the gear *B* back to where it started (−1); gears *C* and D will have rotated the amount indicated in the tabulation. Then the algebraic sum will give the relative turns of each gear. That is, in Fig. 31, for one turn of the arm, B does not move and C turns in the same direction $3\frac{1}{2}$ rev., and D in the opposite direction $\frac{1}{4}$ rev.; whereas in Fig. 32, for one turn of the arm, B does not turn, but C and D turn in the same direction as the arm respectively $2\frac{1}{2}$ and $1\frac{3}{70}$ rev. (Note: The arm in the above case was turned $+1$ for convenience, but any other value might be used.)

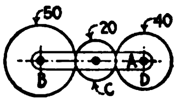

FIG. 31.

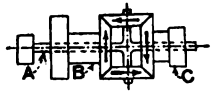

FIG. 33.

FIG. 35.

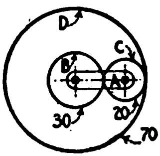

FIG. 32.

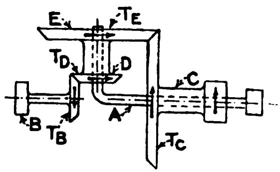

FIG. 34.

Bevel Epicyclic Trains are epicyclic trains containing bevel gears and may be calculated by the preceding method, but it is usually simpler to use the general formula which applies to all cases of epicyclic trains:

$$\frac{\text{Turns of } C \text{ relative to arm}}{\text{Turns of } B \text{ relative to arm}} = \frac{\text{Absolute turns of } C - \text{turns of arm}}{\text{Absolute turns of } B - \text{turns of arm}}$$

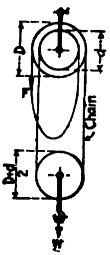

FIG. 36.

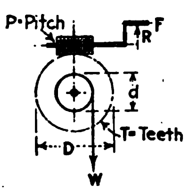

FIG. 37.

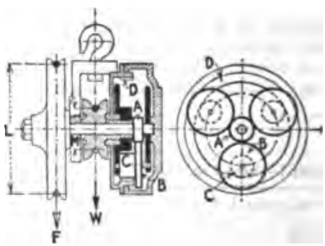

FIG. 38.

The left-hand term gives the value of the train and can always be expressed in terms of the number of teeth (T) on the gears; care must be used, however, to express it as either plus (+) or minus (−), depending upon whether the gears turn in the same or opposite directions.

$$\frac{\text{Relative turns of } C}{\text{Relative turns of } B} = \frac{C - A}{B - A} = -1, \text{in Fig. 33}; = +\frac{T_E}{T_C} \times \frac{T_B}{T_D} \text{ in Fig. 34.}$$

Hoisting Mechanisms

Pulley Block (Fig. 35). Given the weight W to be raised, the force F necessary is $F = V_W \times W/V_F = W/n$ = load/number of ropes; V_W and V_F being the respective velocities of W and F.

Differential Chain Block (Fig. 36). $F = V_W \times W/V_F = W(D - d)/2D$.

Worm and Wheel (Fig. 37). $F = \pi d(n/T)W/2\pi R = WP(d/D)/2\pi R$, where n = number of threads, single, double, triple, etc.

The **triplex chain block** (Fig. 38) is a geared hoist making use of the epicyclic train. $F = W \times M/L\{1 + [(T_D/T_C) \times (T_B/T_A)]\}$, where T = number of teeth on gears.

Toggle Joint (Fig. 39). $P = F \times s \cos A/t$.

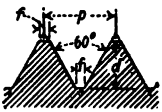
SCREW FASTENINGS

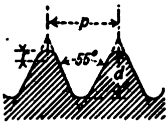
Machine Screw Threads: Forms and Proportions

The Sellers or U. S. Standard Thread for machine screws, shown in Fig. 1, is proportioned by the formulæ p = pitch = 1/No. of threads per inch, d = depth = $0.6495p$, f = flat = $p/8$. See Table 1.

The A.S.M.E. Standard Thread is of the same form as the Sellers thread, but has the following proportions:

$$d = 0.7037p;\ \text{flat (top)} = p/8;\ \text{flat (bottom)} = p/16$$





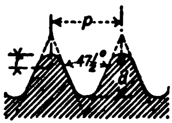


FIG. 1.—Sellers or U. S. FIG. 2.—Whitworth. FIG. 3.—British Association. Standard Screw Threads.

The Whitworth Standard Thread (Fig. 2) is used in Great Britain and is based on the formulæ $d = 0.6403p$, r = radius = $0.1373p$. See Table 2.

The British Association Screw Thread is shown in Fig. 3, and dimensions of bolts with such threads are given in Table 3.

The French (Metric) Screw Thread (Fig. 4) is based on the formulæ p = pitch in mm., $d = 0.6495p$, $f = p/8$. See Table 4.

Power Transmission Screw Threads: Forms and Proportions

The Acme 29-deg. Screw Thread is shown in Fig. 6. The proportions of screws with Acme threads, given in Table 6, are obtained from the formulæ $d = 0.5p + 0.01$ in.; flat (top) $= 0.3707p$; flat (bottom) $= 0.3707p - 0.0052$ in.

The Buttress Thread (Fig. 8) is a strong form, adapted for taking load in one direction only.

Screw Threads for Pipes

The Briggs Pipe Thread is the standard in use in America. Its form is shown in Fig. 9, and it is made to the following specifications: Taper of pipe end = 3/4 in. per ft. = 1/16 in. per in. Depth of thread (E) = 0.8/No. of threads per in. (n). See Table 8.

7/8	1 13/16	3/4	1	1 7/8	13/16	1 3/16

Eyebolts used by the Union Iron Works are made to the proportions given in Fig. 18 and Table 17.

Table 17. Proportions of Eyebolts
(See Fig. 18)

Diam. of bolt, in.	Diam. of stock in eye, in.	*A*, in.	*B*, in.	*C*, in.	*D*, in.	*E*, in.	*F*, in.	Capacity, lb.
3/8	3/8	1 1/2	2 1/4	1 3/8	5/8	1	2	767
1/2	3/8	1 1/2	2 1/4	1 3/8	5/8	1	2	1,104
5/8	1/2	2	3	1 3/4	1	1 1/4	2 3/4	1,963
3/4	1/2	2	3	1 3/4	1	1 1/4	2 3/4	2,485
7/8	5/8	2 1/4	3 1/2	2 1/8	1 1/4	1 3/4	3 3/8	3,712
1	5/8	2 1/4	3 1/2	2 1/8	1 1/4	1 3/4	3 3/8	5,185
1 1/8	3/4	2 1/2	4	2 1/2	1 1/2	2 1/4	4	6,903
1 1/4	3/4	2 1/2	4	2 1/2	1 1/2	2 1/4	4	7,854
1 3/8	7/8	2 3/4	4 1/2	2 3/4	2	2 1/2	4 3/4	9,940
1 1/2	7/8	2 3/4	4 1/2	2 3/4	2	2 1/2	4 3/4	12,270
1 5/8	1 1/8	3 1/2	5 3/4	3 1/2	2 1/2	3	6	13,520
1 3/4	1 1/8	3 1/2	5 3/4	3 1/2	2 1/2	3	6	16,210
1 7/8	1 1/4	4	6 1/2	4	3	3 1/2	7	19,150
2	1 1/4	4	6 1/2	4	3	3 1/2	7	22,340

Strength of Eyebolts. The following formula by O. M. Sames (*Ind. Engg.*, Sept., 1911) closely represents the practice of the General Electric Co.: Load in lb. at which deformation begins = 33,000 $d^3/(D_1 - 1.2D_2)$, in which d = diam. of stock in eye, D_1 = mean diam. of eye (= internal diam. + d), and D_2 = diam. of bolt shank at root of thread—all in inches. In designing, for eyebolts forged from double refined iron, take safe load equal to ⅓ that given by formula.

Set Screws for fastening collars and the like to shafting may have forms of heads and points as shown in Figs. 15, 16 and 17.

The round point will be found to give better service, since it will not work loose under repeated load application.

The **safe holding power** (P) of cup or flat-point set screws (B. H. D. Pinckney, *Am. Mach.*, Oct. 15, 1914) may be calculated from P (lb.) = $63{,}025N/nr$, where N = h.p. transmitted, n = r.p.m., and r = radius of shaft, in. Values of P for various diameters (d) of set screws are as follows:

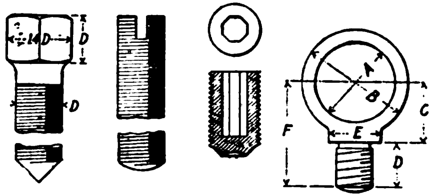

FIG. 15. FIG. 16. FIG. 17. Set Screws. FIG. 18. Eyebolt.

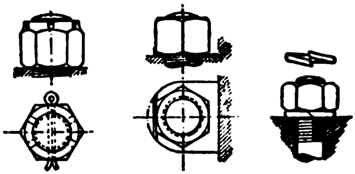
d (in.) =	¼	5/16	⅜	7/16	½	9/16	⅝	¾	⅞	1	1⅛	1¼
P (lb.) =	100	168	256	366	500	658	840	1280	1830	2500	3288	4198

Thus, for a pulley transmitting 6 h.p. at 300 r.p.m. on a 2-in. shaft, $P = 63{,}025 \times 6/(300 \times 1) = 1260$ lb., indicating the use of either one ¾-in. screw or two 9/16-in. screws.

Lock Nuts and special devices to prevent bolts and nuts from coming loose, as may result when vibrations are encountered, may be made to the forms shown in Fig. 19.



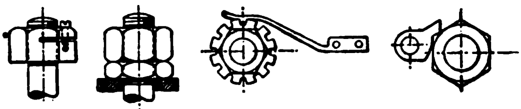


FIG. 19.—Lock Nuts.

Foundation Bolts may be made to the forms shown in Figs. 20 and 21. The difficulty in replacing such bolts as may become broken or injured in service, causes the form shown in Fig. 20 to be favored whenever it can be used. $l \geq 5d$.

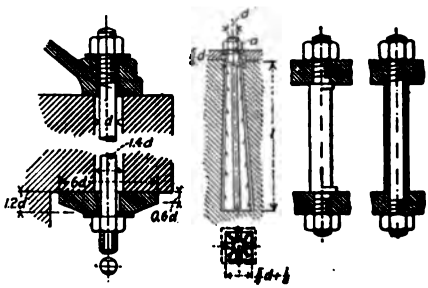

FIG. 20. FIG. 21. Foundation Bolts.

The Society of Automobile Engineers' (S.A.E.) Standard for Bolts and Nuts is shown in Fig. 22, proportions of bolts made to this standard being given in Table 18.

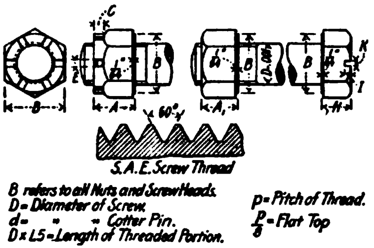

Fig. 22.—S.A.E. Standard for Bolts and Nuts.

Materials, Strength and Service Adaptability of Machine Bolts and Screws

The Materials to be used for bolts, screws and nuts depend on service conditions and relative costs. The stresses to be allowed in determining the proportions in any case depend on the nature of the loading and the material.

As a guide to the selection of **bolts and nuts for fastenings** in stationary machinery, the specifications of the Bureau of Steam Engineering of the U. S. Navy are given in Table 24.

Table 24. Materials for Bolts and Nuts

Class	Material	Minimum tensile strength, lb. per sq. in.	Minimum elastic limit, lb. per sq. in.	Minimum elongation in 8 in., per cent.	Maximum percentage of	
					Phosphorus	Sulphur
A	Open-hearth nickel or carbon steel.	75,000	40,000	23	0.04	0.03
B	Open-hearth carbon steel	58,000	30,000	28	0.04	0.03

Bending Tests. Class A material must bend cold after quenching about an inner diameter equal to the thickness of the test piece in each case without cracking; quenching temperature, 80 to 90 deg. fahr. For Class B the same test applies, except that inner diameter = 1/2 thickness of test piece.

Hammer Test. Class A material must flatten out cold to 1/2 the original diameter without showing cracks. Class B must flatten out while heated to a cherry red in daylight to a thickness equal to 1/4 the original diameter without showing cracks.

Bolts requiring unusual strength are made from material specified under forgings in Table 25. Connecting-rod bolts, for example, are made from "high-grade forgings." For the S.A.E. specifications, see p. 464.

Set Screws may be made from the following material recommended by the Carnegie Steel Co.: Carbon, 0.15 to 0.20 per cent.; manganese, 0.6 to 0.8 per cent.; phosphorus, not over 0.06 per cent.; sulphur, 0.06 per cent.

Safe Loads in Tension for U. S. Standard Bolts, as determined by Harvey D. Williams, of the Bureau of Steam Engineering, U. S. N., are given in Table 26. Colvin and Stanley ("Am. Mach. Handbook") compute the tensile and shearing strengths as given in Table 27.

Table 25. Steel Forgings for Bolts

Class	Material	Treatment	Minimum tensile strength, lb. per sq. in.	Minimum elastic limit, lb. per sq. in	Minimum elongation in 2 in., per cent.	Maximum percentage of phosphorus	Maximum percentage of sulphur	Cold bend about an inner diam. of
High grade..	Open-hearth nickel steel	Anneal and oil-temper	95,000	65,000	21	0.06	0.04	1 in. through 180 deg.
A......	Open-hearth nickel or carbon steel	Anneal; oil tempering optional	80,000	50,000	25	0.06	0.04	1 in. through 180 deg.
B......	Open-hearth carbon steel	Anneal	60,000	30,000	30	0.06	0.04	½ in. through 180 deg.

Table 26. Safe Loads for U.S. Standard Bolts

Nominal diam., in.	No. of threads per in.	Ultimate strength, lb. per sq. in. 20,000	40,000	50,000	60,000	65,000	80,000	95,000

General Notes on the Design of Bolts

Bolts subjected to shock and sudden change in load are found to be more serviceable when the body of the bolt is turned down or drilled to the area of the root of the thread. The drilled bolt is stronger in torsion.

When a **number of bolts** are **employed in fastening** together two parts of a machine, such as a cylinder and cylinder head, the load carried by each bolt depends on its relative tightness, the tighter bolts carrying the greater loads. When the conditions of attendance are such as to occasion a great difference in tightness, lower working stresses must be used in designing the bolts than otherwise are necessary. On the other hand, it may be desirable to have the bolts the weakest part of the machine, since their breakage from overload in the machine will result in a minimum cost of replacement. In such cases the breaking load of the bolts may well be equal to the load which causes the weakest member of the machine connected to be stressed up to the elastic limit.

Bolts screwed up tight have an initial stress due to the tightening before any external load is applied to the machine member. According to Professor Barr, the initial tensile load due to screwing up for a tight joint varies about as the diam. of the bolt, and may be estimated at 16,000 lb. per in. of diam. There is consequently danger of excessive stresses for bolts of less than 1 in. diam. If the bolt is manifestly more yielding than the connected members, it should be designed simply to resist the initial tension or the external load, whichever is the greater. If the probable yielding of the bolt is from 50 to 100 per cent. of that of the connected members, take the resultant stress as the initial tension plus one-half the external load. If the yielding of the connected members is probably from four to five times that of the bolt (as when certain packings are used), take the resultant stress as the initial tension plus three-fourths the external load.

In any given machine the bolts and screws used should be of **as few sizes as possible** in order to reduce the number of spanners required to tighten them and the number of drill and tap sizes needed in manufacture.

In **drilling and tapping cast iron for studs,** it is necessary to tap to a depth equal to one and one-half times the stud diameter in order that the strength of the cast-iron threads in shear may equal the tensile strength of the bolt. Drill sizes and depths of hole and thread are given in Table 28.

Table 28. Depths to Drill and Tap Cast Iron for Studs

Diam. of stud, in	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4	7/8	1
Diam. of drill, in	13/64	17/64	5/16	3/8	27/64	31/64	17/32	41/64	3/4	55/64
Depth of thread, in ...	3/8	15/32	9/16	21/32	3/4	27/32	15/16	1 1/8	1 5/16	1 1/2
Depth to drill, in	7/16	17/32	5/8	23/32	27/32	15/16	1 1/32	1 1/4	1 7/16	1 5/8

It is not good practice to drill holes to be tapped through the metal into pressure spaces, as the leakage resulting, even though the bolt fits tightly, will occasion much trouble.

Drill Sizes for Sellers or A. S. M. E. Standard Thread Taps. Diam. of drill = outside diam. of stud *minus* pitch of thread. Table 29 gives tap drill sizes for taps with U. S. (Sellers) Standard, "V" and Whitworth threads.

The form of the **joint at the junction of three or four plates** may be as shown in Figs. 32 to 35, inclusive.

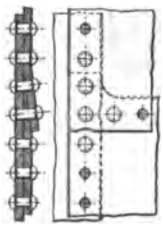

FIG. 32.

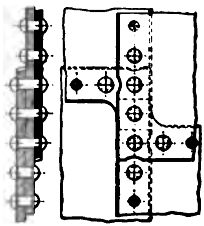

FIG. 33.

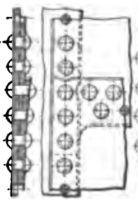

FIG. 34.

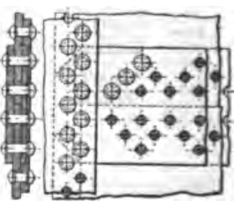

FIG. 35.

Forms of Riveted Joint at Junction of Three or Four Plates.

When **plates** are to be **joined at right angles** and riveted, the joint may have the form shown in Fig. 36. With such joints the outer radius of curvature of the plate should be at least four times the plate thickness. The overlap should be three times the rivet diameter. Frequently angle connections such as shown in Fig. 37 are used. In such construction it is good practice to have the rivet diameter $d = 2 \times$ plate thickness t, and the dimension $a = \frac{1}{2}(w - t_1)$, in which w = width of angle leg and t_1 = thickness of leg $= t + \frac{1}{16}$ in. The other dimensions in the figure are in terms of t.

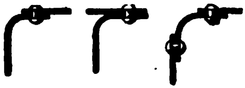

FIG. 36.

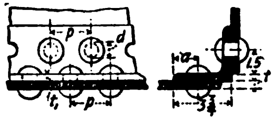

FIG. 37.

Joining Plates at Right Angles.

Table 31. Dimensions of Double-riveted Butt Joints (Steel Rivets in Steel Plates)

(All dimensions in inches. Letters refer to Fig. 29. Dimensions based on a tensile strength of 55,000 lb. per sq. in. for plates and straps, and a shearing strength of 42,000 lb. per sq. in. for rivets in single shear and 78,000 lb. for rivets in double shear.)

Straining Actions in Riveted Joints. The straining actions to which the several elements of a riveted joint are subjected are easily determined as to kind, but are most difficult to evaluate. More particularly is this true when the joint is one of several in a structure such as a boiler and receives its load according to the elasticity of the parts through which these loads are transmitted. Without regard to the friction between the plate and assuming all rivets in the joint to be equally well fitted and consequently sharing equally in taking up load, the accepted method of analyzing the stresses in the joint is as follows:

Let t = thickness of plate, in. d = diameter of rivet, in. p = pitch of rivets, in. n = number of rivets per pitch width of plate, in single shear. m = same, in double shear. f_t = intensity of stress in tension, lb. per sq. in. f_c = intensity of stress in crushing, lb. per sq. in., single shear. f_s = intensity of stress in shearing, lb. per sq. in., single shear (f'_c and f'_s for double shear). P = pressure existing in the tank or boiler, lb. per sq. in. D = internal diam. of tank, in. S = capacity of joint per pitch width to resist shearing with a given intensity of shearing stress, measured in lb. C = capacity of joint per pitch width to resist crushing with a given intensity of crushing stress, measured in lb. T = capacity of joint per pitch width to resist tearing of plate between the last or outside row of rivets with a given intensity of tensile stress, measured in lb. U = capacity of unpunched plate per pitch width to resist tearing with a given intensity of tensile stress, measured in lb.

$$\text{Then: } S = \pi d^2(nf_s + 2mf'_s)/4; \quad C = dt(nf_c + mf'_c); \quad T = (p - d)tf_t;$$
$$U = p \times t \times f_t;$$
$$\text{and } E_s = \text{efficiency in shearing} = S/U = \pi d^2(nf_s + 2mf'_s)/4ptf_t$$
$$E_c = \text{efficiency in crushing} = C/U = d(nf_c + mf'_c)/pf_t$$
$$E_t = \text{efficiency in tearing} = T/U = (p - d)/p$$

The above equations may be used to determine the **efficiency** of any form of riveted joint of known dimensions. When designing, the most economic relations between the pitch and diameter of rivet and the thickness of plate obtain when the three efficiencies are equal. If then these be equated and solved for p, d and t, it will be found that, for the **longitudinal seams** of boilers and tanks,

$$t = PD(nf_c + mf'_c + f_t)/2(nf_c + mf'_c)f_t$$
$$d = 4(nf_c + mf'_c)t/\pi(nf_s + 2mf'_s)$$
$$p = [\pi d^2(nf_s + 2mf'_s)/4tf_t] + d$$

For iron plates and rivets, $f_s = 38{,}000$, $f_c = 65{,}000$, $f'_s = 35{,}500$, $f'_c = 80{,}000$; for steel plates and rivets, $f_s = 44{,}000$, $f_c = 90{,}000$, $f'_s = 45{,}000$, $f'_c = 110{,}000$; $f_t = 40{,}000$ for iron and 55,000 for steel.

For the **girth seam** of single- or double-riveted lap joints, since the thickness of plate and diameter of rivets are established (all holes being of the same diameter for economy in fabrication), the pitch is determined such that a sufficient number of rivets may be placed to take up the total load on the joint with the proper limits of stress in shear and compression. The total load on the rivets in a girth seam is equal to $\pi D^2P/4$. The equations for t, d and p will be found to give proportions insuring steam-tightness up to pressures of 200 lb. per sq. in. when joints are properly calked.

The following **general practice rules** will also be found to be serviceable:

1. Butt joints are to be preferred to lap joints, since the latter occasion severe bending stresses in the rivet, which is a most frequent cause for failure.

2. The distance from the center line of the row of rivet holes nearest the edge of plate to edge of plate should be from 1½ to 2 times rivet diam.

3. The rivet diameter should be $d = 1.2\sqrt{t}$ to $1.4\sqrt{t}$.

4. In multiple-riveted joints the minimum distance between rows of rivets is 1.7d or 0.6 to 0.8 pitch for staggered riveting. For chain riveting this should be at least 2d and preferably 2½d.

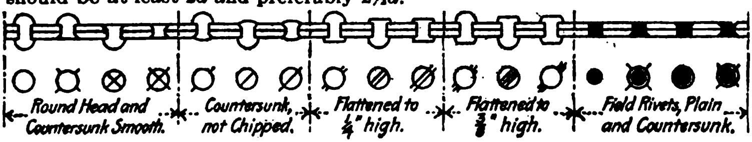

FIG. 38.—Conventional Signs for Rivets.

Materials Specifications for Rivets and Plates. See pp. 459–461, 866, 868. **A factor of safety** of from 4½ to 5 is usually employed for boiler joints.

Conventional Signs to indicate the form of the head to be used and whether the rivet is to be driven in the shop or the field at the time of erection, are given in Fig. 38. The **lengths of rivets for various grips** are given in Table 34 (see also Fig. 39).

For **structural riveting,** see p. 1286.

Punched vs. Drilled Plates. Holes in plates forming parts of riveted structures are either punched, punched and reamed, or drilled. Punching, while cheaper, is objectionable. Further, the holes in different plates cannot be spaced with sufficient accuracy to register perfectly on being assembled. If the hole is punched out say 1/16 in. smaller than is required and then reamed to size, the metal injured by cold flow during punching will be removed. Annealing after punching also largely obviates the injury. Drilling, while more expensive, permits of greater accuracy and does not injure the metal. The Mass. Boiler Inspection Law states: "Rivet holes, excepting for attaching stays or angle bars to heads, shall be drilled full size with plates, butt straps, and heads bolted up in position; or they may be punched not to exceed ¼ in. less than full size for plates over 5/16 in. in thickness, and ⅛ in. less than full size for plates not exceeding 5/16 in. in thickness, and then drilled or reamed to full size with plates, butt straps and heads bolted up in position." The U. S. Navy Department specifies that all holes in boiler plates must be drilled with the plates in place. In structural work the holes are generally punched for shop riveting, while for field riveting it is usual to drill them to a template, or, if punched, to ream them with the parts to be connected bolted in place.

The **tensile strength** of the metal between holes drilled in a plate has been found to be greater than that of an undrilled plate. For the spacings usual in riveted work the increase in strength as shown by experiment is from 10 to 12 per cent. Punching, on the other hand, results in a loss of tensile strength, experiments showing the strength of the metal between the holes to be from 5 to 20 per cent. under that of unpunched plates in the case of iron, and from 8 to 35 per cent. in the case of steel plates. With the latter the loss increases with the thickness of the plate.

Hand-riveted joints are of practically the same strength as those machine-riveted, but the load at which visible slip occurs is much greater in the case of the latter. In hot riveting, pressures up to 150,000 lb. per sq. in. and even higher are used, and in cold riveting the pressure required is about 300,000 lb. per sq. in. of rivet section. Where the pressure exceeds 225,000 to 270,000 lb., however, there is danger that the lateral pressure of the rivet may crack the plate.

Frictional Resistance of Riveted Joints. Rivets in cooling contract longitudinally and draw the plates together with considerable force. They also contract laterally and therefore do not completely fill their holes when cold. Before shearing can take place it is consequently necessary that the plates shall slip on each other, such slipping, however, being resisted by the friction of the surfaces in contact. According to C. Bach, this frictional resistance when slipping begins ranges from 14,000 to 30,000 lb. per sq. in. of rivet section at each pair of surfaces in contact. As any appreciable slip of a boiler joint will result in leakage, it is the practice of European engineers to design such joints according to rules based by Bach on the resistance to slipping. The proportions specified in these rules, however, do not differ greatly from those based on a consideration of shearing strength.

KEYS, COTTERS AND PINS

Keys for fastening gears, pulleys, cranks and other pieces to round shafting may be made to the following forms and dimensions depending on the service conditions under which they are used.

Woodruff Keys (Fig. 40) are made by the Whitney Mfg. Co., of Hartford, Conn., in the sizes given in Table 35, and for use with shafts not larger than 2¼ in. in diameter. Cutters for milling out the key seats, as well as special machines for using the cutters, are to be had from the manufacturer. Where the hub of the gear or pulley is relatively long, two keys should be used. Slightly rounding the corners or ends of these keys will obviate any difficulty met with in removing pulleys from shafts. They are not to be used as sliding keys or feathers.

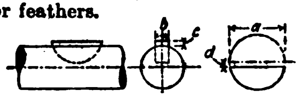

FIG. 40.—Woodruff Key.

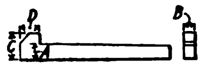

FIG. 41.—Gib-head Key.

Gib-head Keys (Fig. 41). This form of taper key is necessary when the smaller end is inaccessible for drifting out, and the larger end is accessible. It is successfully used with all sizes of shafts. Proportions are given in Table 36.

Sunk Keys are made by the Pratt & Whitney Co., of Hartford, Conn., to the form and dimensions given in Fig. 42 and Table 37. These keys are particularly adapted to the case of hubs fitting adjacent parts such that neither end of the key is accessible. The difficulties attending the sinking of keyways for these keys have militated against their frequent use. The Pratt & Whitney Co., however, has devised a successful spline miller which greatly facilitates this ordinarily troublesome operation.

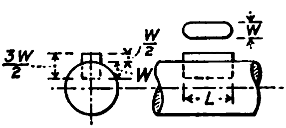

FIG. 42.—Sunk Key.

Feather Keys are used to prevent parts from turning on a shaft while allowing them to move in a lengthwise direction. They may be of the forms shown in Fig. 43, with dimensions as given in Table 37.

Saddle Keys and Flat Keys are used only for the transmission of small torques or turning efforts that are never liable to sudden changes in magnitude. Under excessive stresses they turn around the shaft and damage it. They may be made to the forms shown in Fig. 44.

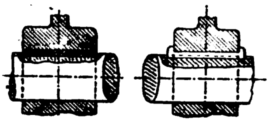

FIG. 43.—Feather Keys.

Saddle Key. Flat Key.

FIG. 44.

In **transmitting large torques** it is customary to use two or more keys as shown in Fig. 45. The arrangement shown at (*a*) permits more ready cutting of the keyway. If but one key is used with the arrangement shown at (*b*), torque can only be taken in one direction.

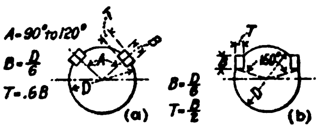

FIG. 45.—Double-keying of Shafts.

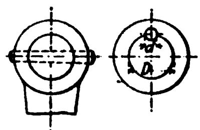

FIG. 46.—Taper Pins.

Taper Pins are sometimes used in transmitting very small torques, and may be placed in either of the ways shown in Fig. 46. They should be fitted so that the parts are drawn together when the pin is driven home to prevent their working loose. The Morse Twist Drill and Machine Co. furnishes taper pins in the sizes given in Table 38.

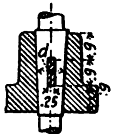
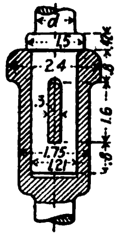
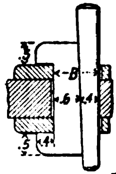
Cottered Joints may be employed for fastening rods to other rods, rods to pistons and cross heads, yokes to rods (as in the case of connecting rods) and for services of similar kinds. Some forms of such joints and proportions recommended are shown in Figs. 47–50, inclusive.

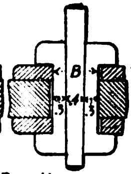


d = unit
FIG. 47.



d = unit
FIG. 48.





B = unit
FIG. 49. FIG. 50.

Cottered Joints.

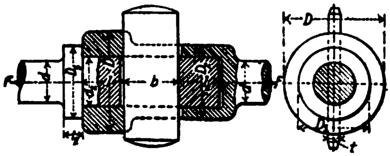


FIG. 51.—Cottered Joint.

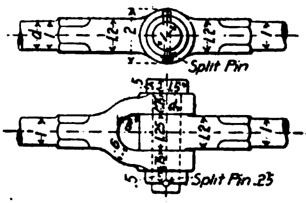

FIG. 52.—Knuckle Joint.

An analysis of the straining action in cotter joints which will serve as a guide in the determination of proportions for such joints in general, may be made with reference to the type of joint shown in Fig. 51. The joint may fail in any one of the following ways and the relation between load and stress is as specified. Let F = load on rod, lb.; d = diam. of rod, in.; f_t, f_s and f_c the tensile, shearing and crushing stresses in lb. per sq. in. Then (for wrought-iron rods),

1. Failure of rod by tension: $F = (\pi d^2/4)f_t$ (1)
2. Tearing of rod end across the cotter hole: $F = [(\pi d_2^2/4) - d_2t]f_t$ (2)
   Equating (1) and (2) and letting $t = d_2/4$, then $d_2 = 1.21d$ and $t = 0.3d$.
3. Tearing of socket across the hole: $F = [\pi/4(D_2^2 - d_2^2) - (D_2 - d_2)t]f_t$, whence (allowing for clearance), $D_2 = 1.75d$.
4. Double shearing of cotter: $F = 2btf_s$, whence
   $b = d_2(f_t/f_s) = 1.6d$ (approx.) for iron and steel.
5. Crushing the cotter bearing surface in rod end: $F = d_2tf_c$.
6. Crushing the cotter bearing surface in socket: $F = t(D - d_2)f_c$.
7. Shearing socket end: $F = 2[l(D - d_2)f_s]$. $(D = 2d_2.)$
8. Shearing rod end: $F = 2l_2d_2f_s$. (Let $f'_s = \frac{1}{2}f_s$ because of grain.)
   Letting $l = l_2$, then $l = 0.65d$, say, $l = 0.75d$.
9. Crushing collar on rod: $F = (\pi/4)(D_3^2 - d_2^2)f_c$, whence $D_3 = 1.4d$, say, $1.5d$.
10. Shearing collar off rod: $F = \pi d_2t_2f_s$, whence $t_2 = 0.42d$, say, $0.5d$.

When two rods are to be joined so as to permit movement at the joint, a round pin is used in place of a cotter. In such cases the proportions may be as shown in Fig. 52.

PRESS AND SHRINK FITS

Cranks, wheels, armature spiders and other parts are frequently secured to shafts and axles by pressing or shrinking them on. When shrink fits are employed the shaft and hole are usually cylindrical; with press fits the best results are obtained by slightly tapering one or both (from 1/16 to 3/16 in. per ft.), which permits the effective use of a lubricant. Experiments have shown that shrink fits resist torsion and axial load better than press fits.

Allowances for Shrink Fits. Practice differs widely in the allowances prescribed for both press and shrink fits. For shrink fits in iron or steel, the New York Shipbuilding Co. (Cathcart, "Machine Design," p. 24) allows 0.001 in. per inch of shaft diameter plus 0.001 in., and in large fits employs a taper of 1/16 in. per ft. for both shaft and hole. If the conditions are such that it is more convenient to ream the hole with a standard parallel reamer, the hole is tapered 0.0005 in. per inch of length unless the fit is so long that this taper will reduce the allowance at the small end of the hole to less than one-half that at the large end.

The Russell Engine Co. uses the following allowances in shrinking cast-iron cranks on to steel shafts:

Diam. of shaft, in.	4–5	5–7½	7½–9	10–12	12–16	16–18
Allowance, in.	0.0045	0.0030	0.0027	0.0025	0.0020	0.0015

A large railway company employs the following allowances in shrinking steel tires on to locomotive wheels:

Diam. of wheel center, in.	38	44	50	56	62	66
Allowance, in.	1/32	3/64	1/16	1/16	5/64	5/64

S. H. Moore (*Trans. A. S. M. E.*, vol. 24) gives the following formula for the allowance to be made for shrink fits:

Allowance in in. = $[(17D/16) + 0.5]/1000$, where D = shaft diam., in.

The Brown & Sharpe Mfg. Co. (Viall. *Trans. A. S. M. E.*, vol. 32, p. 1328) have the following grinding limits for shrink fits:

	Fits for shells, etc., having a thickness of more than 3/8 in.	Fits for hardened shells 3/8 in. thick and less
	Large	Large
To ½ in. diam., inc.	0.0005–0.001	0.00025–0.0005
To 1 in. diam., inc.	0.001 –0.0025	0.0005 –0.001
To 2 in. diam., inc.	0.0025–0.0035	0.001 –0.0015
To 3½ in. diam., inc.	0.0035–0.005	0.0015 –0.002
To 6 in. diam., inc.	0.005 –0.007	0.002 –0.003

The practice of the General Electric Co. for shrink fits (John Riddell, *Trans. A. S. M. E.*, vol. 24) is given in Table 38.

Table 38. Allowances for Shrink Fits
(General Electric Co.)

Diam., in.	Allowance, in.	Diam., in.	Allowance, in.	Diam., in.	Allowance, in.	Diam., in.	Allowance, in.
2	0.0015	18	0.0075	34	0.012	60	0.020
4	0.00275	20	0.008	36	0.01275	72	0.024
6	0.0035	22	0.00875	38	0.01325	84	0.027
8	0.0045	24	0.00925	40	0.01375	96	0.030
10	0.00525	26	0.00975	42	0.01425	108	0.033
12	0.00575	28	0.0125	44	0.015	120	0.0355
14	0.0065	30	0.011	46	0.0155	132	0.038
16	0.0070	32	0.0115	48	0.016	144	0.040

Allowances for Press Fits (Forced Fits). The New York Shipbuilding Co. uses the same allowances for press fits as for shrink fits (*q.v.*). For cast-iron cranks on steel shafts, the Russell Engine Co. employs the following allowances:

Diam. of shaft, in.	4–5	5–7½	7½–9	10–12	12–16	16–18
Allowance, in.	0.003	0.004	0.005	0.0055	0.006	0.009

S. H. Moore (*Trans. A. S. M. E.*, vol. 24) states that the allowance for press fits may be obtained from the formula $d = (2D + 0.5)/1000$ where d = allowance and D = shaft diam., both in inches.

For parallel shafts and holes the C. W. Hunt Co. finishes the shafts to from $0.001d$ to $0.001d + 0.001$ in. over size, and reams the holes with reamers kept between the following limits:

Diam. of shaft (D), exact size, in.	1 to 3	4 to 6	7 to 10
Reamers to be under size from	0.000 in. to 0.002 in.	0.003 in.	0.004 in.

For taper fits the shafts are kept to standard size (+ or −0.001 in.) and the holes are tapered 1/16 in. to the foot, the large end of the hole after reaming being small by from $(D + 4) \times 0.001$ in. to $(D + 5) \times 0.001$ in. That is, for a 3-in. fit the hole should be from 0.007 to 0.008 in. smaller than the nominal shaft diameter.

The Brown & Sharpe Mfg. Co. (Viall. *Trans. A. S. M. E.*, vol. 32, p. 1328) have the following grinding limits for press fits:

	Large
To ½ in. diam., inc.	0.00075–0.0015
To 1 in. diam., inc.	0.0015 –0.0025
To 2 in. diam., inc.	0.0025 –0.004
To 3½ in. diam., inc.	0.004 –0.006
To 6 in. diam., inc.	0.006 –0.009

The practice of the General Electric Co. for press fits is given in Table 39. The allowances for armature spiders are smaller than usual in work of this nature, as the limited facilities for assembling in the field are taken into consideration. For heavy parts, such as couplings, the values given in Table 39 are used.

Table 39. Allowances for Press Fits
(General Electric Co.)

A—Tight fits for parts with light hubs, as commutator shells. *B*—Press fits for solid steel armature spiders. *C*—Press fits for solid cast-iron armature spiders.

Shaft diam., in.	Allowances, in.			Shaft diam., in.	Allowances, in.			Shaft diam., in.	Allowances, in.		
	A	*B*	*C*		*A*	*B*	*C*		*A*	*B*	*C*
2	0.0005	0.0005	0.0005	18	0.0012	0.00225	0.00375	34	0.0017	0.003	0.006
4	0.00075	0.00075	0.00075	20	0.0012	0.00225	0.004	36	0.0017	0.00325	0.00625
6	0.001	0.00125	0.00125	22	0.0012	0.0025	0.00425	38	0.0017	0.00325	0.0065
8	0.001	0.0015	0.00175	24	0.0015	0.0025	0.0045	40	0.002	0.0035	0.00675
10	0.001	0.0015	0.002	26	0.0015	0.00275	0.00475	42	0.002	0.0035	0.007
12	0.001	0.00175	0.0025	28	0.0015	0.00275	0.005	44	0.002	0.00375	0.00725
14	0.001	0.002	0.003	30	0.0015	0.00275	0.0055	46	0.002	0.004	0.00775
16	0.0012	0.002	0.00325	32	0.0017	0.003	0.00575	48	0.00225	0.004	0.008

C. F. MacGill (*Jour. A. S. M. E.*, Nov., 1913) states as a result of 20 years experience that in making press fits it is not necessary to increase the allowance with the diameter of the shaft, as the increased surface area of the fit adds sufficient friction to bring the pressure up to the required tonnage; that an allowance of from 0.002 in. to 0.004 in. on steel shafts pressed into steel hubs, and an allowance of from 0.003 in. to 005 in. on steel shafts pressed into cast-iron hubs of ordinary hardness will give good results; and that allowances greater than 0.006 in. on steel shafts pressed into cast-iron hubs serve no useful purpose, but, on the contrary, tend to set up strains injurious to the castings.

Allowances for Drive Fits. Allowance in in. = $(\frac{1}{2}d + 0.5)/1000$ (S. H. Moore, *Trans. A. S. M. E.*, vol. 24), where d = shaft diam., in. For parallel shafts and holes the C. W. Hunt Co. finishes the shafts from $0.0005d$ to $0.0005d + 0.001$ in. over size, and the holes as for press fits (see above). For taper fits the holes are tapered as for press fits, the large end of the hole after reaming being smaller than the shaft diameter by from $0.5d \times 0.001$ in. to $(0.5d + 1) \times 0.001$ in.

The Brown & Sharpe Mfg. Co. (Viall. *Trans. A. S. M. E.*, vol. 32, p. 1328) have the following grinding limits for driving fits:

	For such pieces as are required to be readily taken apart	For other driving fits
	Large	Large
To ½ in. diam., inc.....	Standard-0.00025	0.0005-0.001
To 1 in. diam., inc.....	0.00025-0.0005	0.001 -0.002
To 2 in. diam., inc.....	0.0005 -0.00075	0.002 -0.003
To 3½ in. diam., inc.....	0.00075-0.001	0.003 -0.004
To 6 in. diam., inc.....	0.001 -0.0015	0.004 -0.005

Stresses in Hubs Due to Press and Shrink Fits on Steel Shafts. Maximum fiber stress in the hub (lb. per sq. in.) = 10,000 Kd, where d = allowance in in. per in. of diam. of hole, and K = constant having the following values derived by S. H. Weaver from a formula given by Professor Morley in *Engg.*, Aug. 11, 1911 (m = thickness of hub ÷ diam. of bore, usually from 0.3 to 0.5):

For m =	0.0	0.1	0.2	0.3	0.4	0.5	1.0	1.5	2	∞
K(steel hub) =	2790	2400	2110	1900	1820	1750	1550	1480	1440	1390
K(cast-iron hub) =	1400	1250	1150	1070	1030	1000	917	889	867	846

From a consideration of Lamé's formula for hoop stresses, A. L. Jenkins (*Eng. News*, Mar. 17, 1910) deduces the following expressions for radial unit pressure between surfaces (S) and unit tensile or hoop stress in the hub (S_1), both in lb. per sq. in.:

$S = 15{,}000{,}000d/(K + 0.6)$ for cast-iron hub on steel shaft
$S_1 = 15{,}000{,}000d/[1 + (0.6/K)]$ for cast-iron hub on steel shaft
$S = 30{,}000{,}000d/(1 + K)$ for steel hub on steel shaft
$S_1 = 30{,}000{,}000d/[1 + (1/K)]$ for steel hub on steel shaft

d = allowance in in. per in. of shaft diam., and K = constant depending on the ratio of hub thickness (t) to radius of shaft (r), as follows:

for t/r =	0.4	0.5	0.6	0.7	0.8	1.0	1.25	1.5	2.0	3.0
K =	3.08	2.60	2.28	2.06	1.89	1.67	1.49	1.38	1.25	1.13

Pressures Required in Making Press Fits. The pressure required for crank and crank-pin press fits may be computed by the following formulæ (*Am. Mach.*, Mar. 7, 1907): For crank fits with diam. D = 2 to 10 in., pressure in tons = $P = 9.9D - 14$; for D = 12 to 24 in., $P = 5D + 40$. For straight crank pins, $P = 13D$, and for tapered crank pins, $P = 14D - 7$.

According to Sanford A. Moss (*Jour. A. S. M. E.*, Sept., 1912), the average force in lb. required to press a hub on a shaft, the press fit being 0.001 in. per in. of bore diam., is $0.12dlS$, in which l and d are respectively the length and diam. of bore in in. and S is the radial stress at the bore in lb. per sq. in.

S has the following approximate values depending on the ratio d/D, in which D is the outer diam. of the hub, and on the ratio d_1/d, in which d_1 is the diam. of the hole (if any) in the shaft:

	Values of d/D					
	0.1	0.2	0.4	0.6	0.8	1.0
d_1/d	Values of S					
0.0	14,400	13,900	12,200	9,300	5,200	0
0.2	13,800	13,300	11,700	9,000	5,000	0
0.3	13,000	12,700	11,200	8,800	4,900	0
0.5	10,800	10,500	9,400	7,700	4,700	0
0.7	7,300	7,100	6,700	5,800	4,400	0
0.9	2,800	2,700	2,600	2,400	2,000	0
1.0	0	0	0	0	0	0

SHAFTS, AXLES, CRANKS

(For critical speeds of shafts see p. 783)

Strength and Stiffness of Shafting. (See Table 18, p. 424, for torsion of shafts of various cross-sections.) Shafts may be subjected to torsion, to torsion and bending in varying proportions, or to bending alone. To establish the relations between these actions and the resulting stresses and deflections, let T = torque on shaft, in.-lb. d = diam. of solid circular shaft, in. d_1 = inside diam. of hollow circular shaft, in. d_2 = outside diam. of hollow circular shaft, in. f_t = maximum intensity of tensile stress at outer surface of shaft, lb. per sq. in. f_s = maximum intensity of shearing stress at outer surface of shaft, lb. per sq. in. h.p. = horse power transmitted by shaft. N = rev. per min. of shaft. I_p = polar moment of inertia of shaft cross-section in inches to the fourth power (in.^{4}). I = rectangular moment of inertia of shaft cross-section, in.^{4}. M = bending moment on shaft at any section, in.-lb. r = radius of shaft to outer surface, in. a = angle passed through by any radius of shaft section under the influence of any torque and length of shaft, deg. E_s = modulus of elasticity in shear, lb. per sq. in. l = length of shaft, in.

Then for the **strength of a solid circular shaft** subjected to torque,

$$T = f_s I_p/r = 63{,}024 \text{ h.p.}/N;\ d = 68.5\sqrt[3]{\text{h.p.}/Nf_s} = \sqrt[3]{5.1T/f_s}$$

For the **torsional stiffness of a solid circular shaft,**

$$d = 4.9\sqrt[4]{Tl/aE_s} = 77.66\sqrt[4]{\text{h.p.}l/NaE_s}$$

The angle a is usually limited to 0.1 deg. per ft. of length.

The **strength of hollow circular shafting** subjected to torque may be determined from

$$d_2 = \sqrt[3]{5.1T/(1 - n^4)f_s} = 68.5\sqrt[3]{\text{h.p.}/(1 - n^4)Nf_s},\ \text{where } n = d_1/d_2.$$

For **non-circular shafts,** see Table 18, p. 424.

Strength of Solid Circular Shafts Subjected to Torque and Bending

Let M_e = that bending moment which when acting alone on the shaft will produce the same maximum intensity of tensile stress (f_t) as that produced by the combined action of a bending moment (M) and torque (T). = equivalent bending moment.

T_e = that twisting moment which when acting alone on the shaft will produce the same maximum intensity of shearing stress (f_s) as that produced by the combined action of a bending moment (M) and torque (T). = equivalent twisting moment.

Then $$M_e = \tfrac{1}{2}(M + \sqrt{M^2 + T^2}).$$

If $$M = kT,\ M_e = \tfrac{1}{2}(k + \sqrt{k^2 + 1})T$$

and $$T_e = \sqrt{M^2 + T^2} = T\sqrt{k^2 + 1}$$

Hancock's tests of metals under combined stresses (*Proc. Am. Soc. T. M.*, 1908, p. 376) show that shafts should be designed for their strength in shear. He recommends the following expression for the equivalent twisting moment (T_e), in which a = elastic limit in tension and b = elastic limit in shear: $T_e = \sqrt{M^2 + (4a^2T^2/b^2)}$.

Then for **solid circular shafts**

$$d = \sqrt[3]{5.1(M + \sqrt{M^2 + T^2})/f_t} = \sqrt[3]{5.1(k + \sqrt{k^2 + 1})T/f_t} \qquad (1)$$

or

$$d = \sqrt[3]{5.1\sqrt{M^2 + T^2}/f_s} = \sqrt[3]{5.1\,T\sqrt{k^2 + 1}/f_s} \qquad (2)$$

Example. A 2½-in. round shaft carries a 30-in. pulley weighing 500 lb. The total pull of the belt is 2000 lb. and the unbalanced pull is 1500 lb. horizontally. Pulley is 6 in. from hanger.

Resultant force acting on shaft $= \sqrt{500^2 + 2000^2} = 2060$ lb. $M = 2060 \times 6 =$ 12,360 in.-lb. at hanger, $T = 1500 \times 15 = 22{,}500$ in.-lb. From (1), $f_t = (5.1/d^3)(M + \sqrt{M^2 + T^2}) = (5.1/15.625)(12{,}360 + \sqrt{12{,}360^2 + 22{,}500^2}) = 12{,}400$ lb. per sq. in. Similarly, from (2) $f_s = (5.1/15.625)\sqrt{12.360^2 + 22{,}500^2} = 8{,}400$ lb. per sq. in.

For ductile materials the ratio of the allowable maximum intensity of shearing stress (f_s) to the allowable maximum intensity of tensile stress (f_t) is such as to result in the correct proportioning of shafts being accomplished by the use of equation (2).

See paper by James J. Guest in *Phil. Mag.*, July, 1900.

For **hollow circular shafts,**

$$d = \sqrt[3]{5.1\ (k + \sqrt{k^2 + 1})T/(1 - n^4)f_t} \text{ for tension,}$$

or

$$d = \sqrt[3]{5.1\ (\sqrt{k^2 + 1})T/(1 - n^4)f_s} \text{ for shear.}$$

The **relative torsional strength of solid and hollow shafts** may be determined by means of Table 40.

Examples. What is the diameter of a solid shaft equal in strength to a 10-in. shaft having a 4-in. hole? $d_1/d_2 = 4/10 = 0.40$; for this ratio $D/d_2 = D/10 = 0.991$, from which $D = 9.91$ in.

Required the outside diameter of a hollow shaft with hole = 0.6 × outside diameter equal in strength to an 8-in. solid shaft. d_2/D(for $d_1/d_2 = 0.60$) $= 1.047 = d_2/8$, whence $d_2 = 8.38$ in.

Required the dimensions of a hollow shaft but ⅔ the weight of a 12-in. solid shaft of the same strength. Here w = ⅔ = 66.7 per cent., for which (from table) $d_1/d_2 = 0.64$ and $d_2/D = 1.063$; hence $d_2 = 12 \times 1.063 = 12.76$ in., and d_1(from $d_1/12.76 = 0.64$) = 8.16 in.

Table 40. Relative Strengths of Solid and Hollow Shafts

D = diam. of solid shaft, d_2 = outside diam. of hollow shaft of equal torsional strength, d_1 = inside diam. of hollow shaft of equal torsional strength, w = weight of hollow shaft in percentage of the weight of a solid shaft of equal torsional strength, $D = \sqrt[3]{(d_2^4 - d_1^4)/d_2}$.

Forces in Different Planes Acting on Shaft. Frequently the forces acting on shafts causing bending do not act in the same plane. The following procedure may be followed in determining the resultant bending moment at any section.

In Fig. 53 (*a*), let *OQ* represent a shaft on which are acting forces normal to the axis at the points *A*, *B*, and *C*, and in the directions shown. In (*b*) draw *OQ* at *any* angle (conveniently 45 deg.) and to scale as in orthographic projection. Compute respectively the bending moments at *A*, *B*, and *C* occasioned by the force acting at each point. Lay off *AP*, *BN* and *CM* representing to scale the bending moments at *A*, *B*, *C* and in the direction of the force producing each. To determine the resultant bending moment at *B*, for example, there is required the combination by the parallelogram of forces of the bending moment *BN* due to the force acting at *B*, the bending moment *BT* due to the force acting at *C*, and the bending moment *BR* due to the force acting at *A*. Thus, the resultant of *BN* and *BR* is *BS* and the resultant of *BS* and *BT* is *BU*. The resultant bending moment at *B* due to all forces acting on the shaft is therefore *BU*, and it acts in the direction in which *BU* is shown. A similar procedure at *C* and at *A* will result in finding the resultant moments at these points. The following example will illustrate the application of the above methods to a particular case.

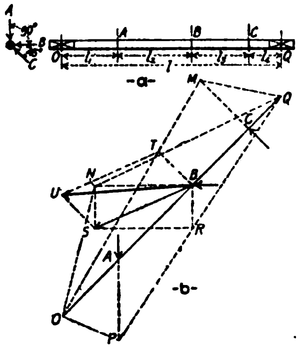

FIG. 53.

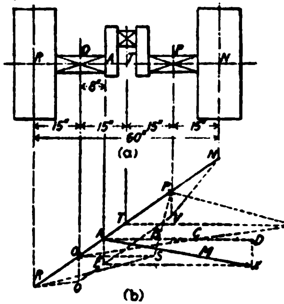

FIG. 54.

Let Fig. 54(*a*) represent the crank shaft of a 16 × 18-in. center-crank engine as made by the Atlas Engine Co., and carrying 100 lb. steam pressure. The flywheels *R* and *N* each weigh ¾ ton and *R* is assumed to carry the belt. The sum of the belt tensions for 50 per cent. overload is 2¼ tons. The worst straining action occurs when the belt leads off horizontally. Accordingly, the bending moments at *O* and *P* due to the flywheel weights will be *OQ* and *PV* (Fig. 54*b*), each equal to 11¼ in.-tons. The bending moment at *O* due to the belt pull will be *OS* and equal to 33¾ in.-tons. The bending moment due to the thrust of the connecting rod will be *TU* and equal to 75 in.-tons. Lay off these moments as shown in Fig. 54(*b*).

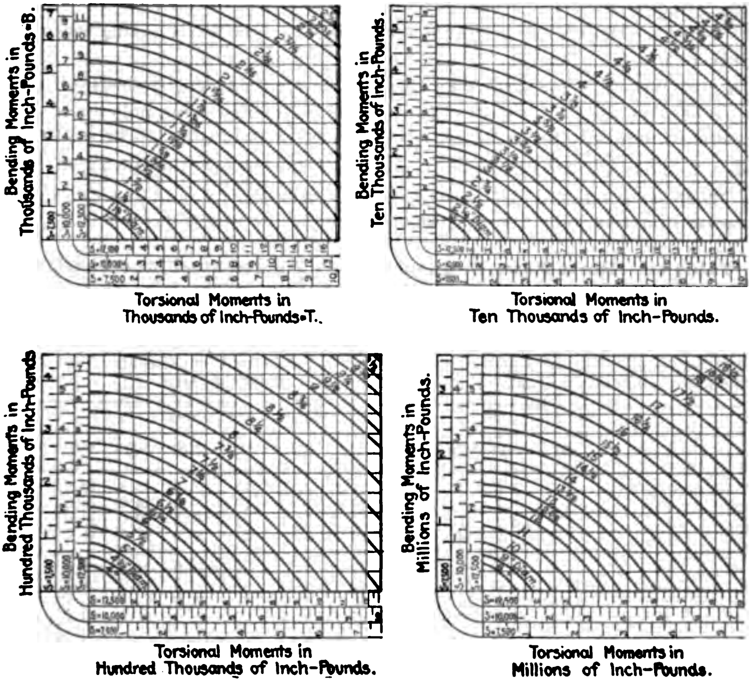
The torque in the shaft will exist in the length *RA*, and consequently it is necessary to determine the section in the length *RA* in which the greatest bending moment exists. This by inspection is seen to be at *A*. Therefore the resultant bending moment at *A* will be due to the bending moment *AB* caused by the belt pull, *AC* caused by the connecting-rod thrust and *AE* caused by the flywheel weight. Let *AD* equal *AB* plus *AC* and combine with *AE*, obtaining the resultant *AX* = *M*. It will be found that *M* scales 65 in.-tons. The torque on the shaft is 90 in.-tons, whence, for $f_t = 8000$,

$$d = \sqrt[3]{5.1\left(M + \sqrt{M^2 + T^2}\right)/8000} = 6\tfrac{1}{4}\text{ in.}$$

The diameter of the shaft is given in the catalog of the Atlas Engine Co. as 6½ in.

The crank pin is subjected to bending alone. The combined bending moments at *T* will give a resultant of 95 inch-tons, whence, $d = \sqrt[3]{10.2M/f_t} = 6\tfrac{1}{4}$ in.

Diameters of Shafts Subjected to Combined Torsional and Bending Stresses. Figs. 55–58 (*Machinery*, July, 1908) afford a convenient means of determining the diameters of shafts subjected both to bending and twisting. The diagrams are based on the formula $d = \sqrt[3]{(5.1/s)\,(M + \sqrt{M^2 + T^2})}$. For ductile materials it is well to check the value of d by means of the formula based on maximum intensity of shearing stress, namely, $d = \sqrt[3]{(5.1/s)\,\sqrt{M^2 + T^2}}$.; s = fiber stress in lb. per sq. in.



FIGS. 55–58.—Diagrams for Determining the Diameters of Shafts Subjected to Combined Torsional and Bending Stresses.

Practical Rules for Proportioning Mill Shafting. The impossibility of determining exactly the amount and position of the loads causing bending and twisting in shafting used for power transmission in mills and factories, as well as the probability that additional pulleys will be used at some time and changes required in the positions of pulleys due to the shifting of machines, make it necessary to depend upon empirical formulæ in determining sizes. Not only is **strength** to be considered but **stiffness** also, since through lack of proper stiffness much trouble may arise in the upkeep of bearings.

The **speed** of shafting in machine shops is about 150 r.p.m., with tendencies to higher values. In wood-working shops, speeds of 250 r.p.m. are usual. In textile mills speeds from 300 to 400 r.p.m. are common. The following rules are suggested by the Jones & Laughlin Steel Co. for determining suitable diameters of mill shafting.

For **shafts** subjected to torque alone, that is, **for power transmission over considerable distances between pulleys,** and for short countershafts having bearings not more than 8 ft. apart and pulleys close to bearings,

$d = \sqrt[3]{50 \text{ h.p.}/N}$ for turned shafting $= \sqrt[3]{40 \text{ h.p.}/N}$ for cold-rolled shafting, where h.p. = horse power to be transmitted, N = r.p.m., and d = shaft diam., in.

When the shaft is a first receiving shaft, that is, a line shaft having bearings, 8 ft. apart,

$d = \sqrt[3]{90 \text{ h.p.}/N}$ for turned shafting $= \sqrt[3]{70 \text{ h.p.}/N}$ for cold-rolled shafting.

When the shaft is a head shaft carrying the main driving pulley and distributing power to receiving or line shafts and is well supported by bearings,

$d = \sqrt[3]{125 \text{ h.p.}/N}$ for turned shafting $= \sqrt[3]{100 \text{ h.p.}/N}$ for cold-rolled shafting.

Table 41 is based on the formula $d = \sqrt[3]{90 \times \text{h.p.}/N}$, and affords a rapid means of determining the shaft diameter for any desired transmission.

Table 41. Horse Power Transmitted by Turned Steel Line Shafting

(Shafting well supported and with pulleys near to the bearings)

For cold-rolled line shafting (up to 5 in.) add 30 per cent. For head shafts of turned steel, subtract 30 per cent. For head shafts of cold-rolled steel, subtract 10 per cent. For transmission shafts (without pulleys) of turned steel, add 80 per cent. For transmission shafts (without pulleys) of cold-rolled steel, add 125 per cent.

Difficulty may be encountered in the use of **cold-rolled shafting** from the fact that its processes of manufacture being such that a state of stress exists in the shaft, any disturbance of this state by the cutting of keyways or wear in journals will tend to disalign the shafting and cause trouble in the operation of the bearings. The cost of upkeep to maintain satisfactory service may therefore more than offset the difference in installation cost.

Line shafting may be purchased from stock in lengths up to 24 ft., generally varying by 2 ft.

Shaft hangers should so be spaced that the deflection of the shaft will not exceed 0.01 in. per ft. of length to insure proper load distribution in the bearings. Accordingly, the Pencoyd Iron Works recommends the following rule for **spacing hangers:**

Let L = maximum distance in ft. between bearings for continuous shafting. Then $L = \sqrt[3]{873d^2}$ for bare shafting, $= \sqrt[3]{175d^2}$ for shafts carrying a fair proportion of pulleys placed near bearings.

In the use of any of the foregoing formulæ, the designer must have in mind the probability that more pulleys will be added and therefore more power transmitted as extensions are made to the mill.

Engine Shafts may be designed by the method given on p. 690. It is generally satisfactory, however, to employ certain empirical formulæ derived from data representing good practice. **Stationary steam-engine shafts** were investigated by Trooien, who found the average proportions to be as follows:

For slow-speed and Corliss engines, $d = 7.2\sqrt[3]{\text{h.p.}/N} - 0.3$ in.

For high-speed center-crank engines, $d = 6.6\sqrt[3]{\text{h.p.}/N}$.

For **marine-engine shafts,** see p. 1242. For **automobile crank shafts,** see p. 1194. **Gas-engine crank shafts** (see p. 1046) may be computed by the graphical method of p. 690, or by the methods given in Haeder and Hoskisson's "Handbook on the Gas Engine." In the latter, no account is taken of the belt pull, and hence for belted engines the results will be inaccurate.

Cranks of the Overhung Type may have the proportions given in Fig. 59, when made of wrought iron or steel, the stressing actions being as follows:

Bending at the section a-b: $Fl = tw^2f/6$; $t = 6Fl/w^2f$; $w = \sqrt{6Fl/tf}$;

Bending at the section c-e: $Fx = w_1t^2f/6$; $t = \sqrt{6Fx/w_1f}$; $w_1 = 6Fx/t^2f$;

where F = load on crank pin, lb.; l and x = lever arms, in. (see Fig. 59); w =

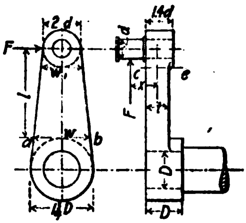

Fig. 59.—Overhung Crank.

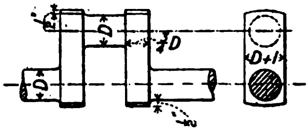

Fig. 60.—Center Crank.

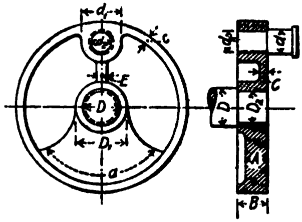

Fig. 61.—Crank Disk.

width of crank web near the shaft boss, in.; w_1 = width of crank web near pin boss, in.; t = web thickness, in.; f = allowable stress, lb. per sq. in. = 4500 to 6000 for wrought iron and steel. Both pin and shaft should be secured to the crank by press or shrink fits.

Center Cranks slotted from the solid may have the proportions shown in Fig. 60.

Crank Disks of cast iron (Fig. 61) may be designed with the following proportions:

$D_2 = 0.8D$	$B = \frac{3}{4}D$	$A = \frac{5}{8}D$	$C = \frac{1}{4}D$
$E = \frac{1}{2}D$	$d_1 = 2d$	$D_1 = 1\frac{3}{4}D$	$d_2 = 0.8d$

The arc dimension a varies with the amount of counterweight to be provided.

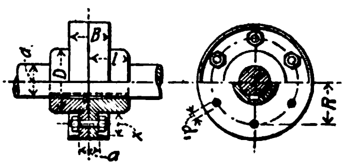

Fig. 62.—Flange Coupling.

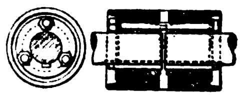

Fig. 63.—Sellers Coupling.

COUPLINGS AND CLUTCHES

Flange Couplings may be made as shown in Fig. 62. The proportions are in terms of $k = d + \frac{1}{2}$ in., where d = shaft diam. in in.

$D = d + 0.8k$ $\quad$ $B = 0.55k + 3d_1$
$a = 0.55k$ $\quad$ $l = 1.4k$
d_1 = bolt diam. $= 0.6d/\sqrt{N}$ $\quad$ $R = 1.5d$
N = number of bolts $\quad$ $X = 2.5d_1$

Flange couplings may be purchased in the market for shafts from 1 in. to 12 in. in diameter.

Sellers Coupling. This device (Fig. 63) is made by Wm. Sellers & Co., Inc., for shafts from 1 7/16 in. to 5 15/16 in. in diam. The principal dimensions are given in Table 42.

Friction Clip Couplings are frequently employed for shafts not over 1½ in. in diameter. The dimensions are as shown in Fig. 65. They are not easily removed and therefore should be used only when the shafting is permanent.

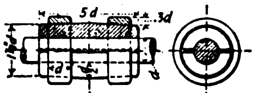

FIG. 65.—Friction Clip Coupling.

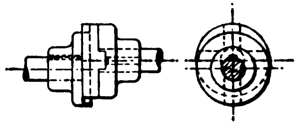

FIG. 66.—Oldham's Coupling.

Oldham's Coupling (Fig. 66) is frequently used aboard ship for connecting the engine and tail shafts. It permits a permanent displacement of the shaft center lines and maintains practically constant angular velocity of the connected shafts.

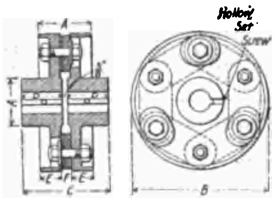

FIG. 67.

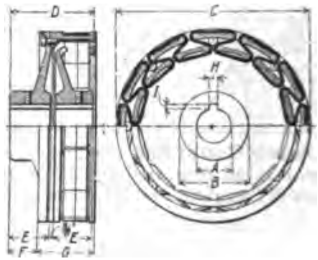

FIG. 68.

General Electric Co. Flexible Couplings.

Flexible Couplings are used for connecting two shafts not in exact alignment. Two types employed by the General Electric Co. for connecting engine and generator shafts are shown in Figs. 67 and 68, dimensions and power ratings being given in Tables 44 and 45. In one, the connection is through leather links; in the other, two endless belts are laced alternately over prongs on the spiders of each half of the coupling. The leather links and belts used serve also as insulation to prevent grounding of the generator through the engine frame. The De Laval coupling, shown in Fig. 69, consists of two forged steel disks, the driving half having a number of rigid studs which project into corresponding holes in the driven half. The torque is transmitted through steel-lined rubber bushings which allow for any defect in alignment and supply the flexibility necessary to prevent injurious stresses on the shafts and bearings.

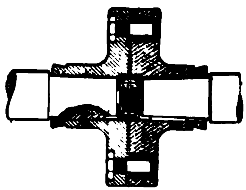

FIG. 69.—De Laval Flexible Coupling.

Hooke's Joint as shown in Fig. 70 is a form of coupling which is adapted to connecting shafts fixed at an angle which is either constant or variable. Suitable proportions are as follows:

$$d = \tfrac{1}{2}D;\quad L = 1\tfrac{1}{2}D;\quad t = \tfrac{1}{2}D;\quad x = d + \tfrac{1}{16}\text{ in.};\quad y = 0.05d;\quad T = 1.2D.$$

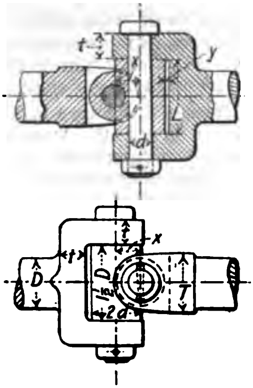

FIG. 70.—Hooke's Joint.

With this coupling a variable angular velocity ratio exists between the shafts during each quarter revolution.

The Jaw Coupling (or claw clutch) shown in Fig. 71 is used in cases where the shafts need frequently to be disengaged, as in punches and presses. Suitable proportions are as follows: Let d = shaft diam. in in. and $k = d + 1$ in. Then $L = 2.65k$; $D = 2.1k$; $D_1 = 1.6k$; $D_2 = 1.5k$; $l = 1.25k$; $l_2 = 0.6k$; $x = y = 0.3k$.

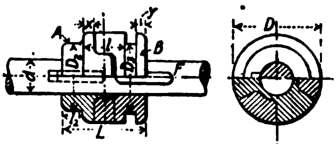

FIG. 71.—Jaw Coupling.

* With tensile stress of 400 lb. per sq. in. in the leather belts.

The teeth are frequently made in the shape of saw teeth, with one side normal to the direction of driving. This form of tooth permits more ready engagement of the coupling and limits the driving to one direction. This is frequently a decided advantage, as in the case of cranks for cranking gas engines.

Cone Friction Clutches (see also automobile clutches, p. 1197) are adaptable to connecting shafts whose loads are frequently thrown on and off. An automobile clutch is shown in Fig. 72. The force relations obtaining in the operation of this clutch are shown diagrammatically in Fig. 73 and may be formulated as follows:

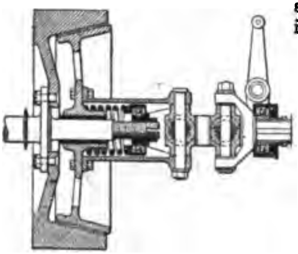

FIG. 72.—Cone Friction Clutch.

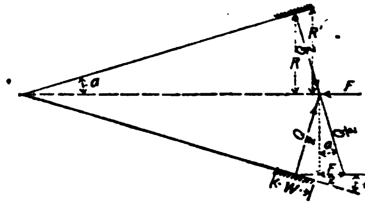

FIG. 73.

Let R = mean radius of clutch cone surface, in. T = torque transmitted through the clutch, in.-lb. Q = total force normal to conical surface, lb. P = tangential force at cone surface acting with leverage R, lb. F = axial force required to engage clutch (lb.) = force of the spring. a = angle between shaft axis and element of cone surface. f = coefficient of friction between the conical surfaces. N = r.p.m. of shaft. W = width of cone surface, in. p = pressure normal to cone surface, lb. per sq. in.

Then $T = QfR$; $F = Q(f \cos a + \sin a) = T(f \cos a + \sin a)/fR$.
Also $63{,}024 \times$ h.p.$/N = T = FfR/(f \cos a + \sin a)$
$\therefore F = 63{,}024 \times$ h.p. $(f \cos a + \sin a)/NfR$
and $Q = 63{,}024 \times$ h.p.$/NfR$. Also $Q = W \times 2\pi R \times p$.

Values of p are from 7 to 8 lb. per sq. in. for leather faces and from 40 to 50 lb. for metal faces. Values of f are given in Table 46. In order that the clutch may not disengage of its own accord, tan a must be less than the coefficient of friction f. Accordingly, for leather or greasy metal, a would be 12 deg. or less; or tan 12 deg. = 0.213, which is less than $f = 0.23$. For free disengagement, wood or metal surfaces, $a \overline{>} 20$ deg.; leather-faced cone clutches with a = 18 to 20 deg. need an operating device for disengagement (C. W. Hunt, *Trans. A. S. M. E.*, vol. 30).

Table 46. Friction Coefficients for Cone Clutches

Cast iron on cast iron (dry)	0.15 to 0.20	Cork on metal	0.35
Cast iron on wood (dry)	0.20 to 0.25	Leather on metal (greasy)	0.23
Cast iron on brass (dry)	0.21	Cork on metal (greasy)	0.32
Leather on metal (dry)	0.56	Leather on metal (oily)	0.15

C. F. Blake (*Machy.*, Jan., 1907, p. 238) recommends the following proportions as suitable for cone clutches on hoisting devices (See Fig. 74):

$A = 4d$ to $8d$	$a = 0.3d + 0.3$ in.	$g = 0.8d$ to $2d$
$f = 0.2d + 0.1$ in.	$b = 0.4d + 0.4$ in.	$D = 1.8d + 0.5$ in.
$B = A - (2f + 0.257$ in.$)$	$e = 0.3d + 0.1$ in.	$m = 2d$
$h = 2d + 1$ in.	$k = 0.2d + 0.3$ in.	$n = d$ to $1.5d$
$c = 0.5d$		

Ring Friction Clutches of a great variety of designs may be purchased on the market. The type manufactured by The Hill Clutch Co. is illustrated in Fig. 75, dimensions (in.) and ratings being given in Table 47.

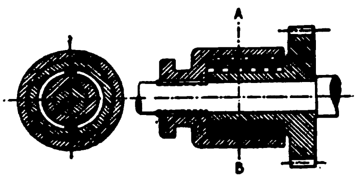
Plate Friction Clutches (see also automobile clutches, p. 1198) of the form known as the **Weston clutch** are as shown in Fig. 76. Alternate rings of wood and metal may be used, or thin metal disks only. The force relations are as follows: Let R = mean radius of rubbing surface of rings, in. T = twisting moment transmitted, in.-lb. F = axial force, lb. f = coefficient of friction. n = number of rubbing surfaces. N = r.p.m. of the shaft. Q = tangential force acting on ring surfaces at mean radius R, lb. h.p. = horse



Section A-B. Sectional Elevation.

Cutler-Hammer Magnetic Clutches.

power transmitted at N r.p.m. Then $Q = fFn$. $T = QR = fFnR = 63{,}024 \times \text{h.p.}/N$. H.p. = $NfFnR/63{,}024$. The values of f given in Table 46 may be used for the materials proposed for any design.

Magnetic Clutches are being successfully applied to the connecting of shafts even of large size. Clutches of this type manufactured by the Cutler-Hammer Mfg. Co. are shown in Figs. 77 and 78 and the principal dimensions of the standard sizes made are given in Tables 48 and 49.

BRAKES

(See also pp. 1108 and 1201)

Block Brakes are shown diagrammatically in Figs. 79, 80 and 81. The force relations obtaining in the operation of these brakes may be formulated as follows:

In Fig. 79 let F = load applied at end of lever arm, lb.; A = distance from point of application of P to block center, in.; B = distance from block center to center of fulcrum pin, in.; R = reaction between wheel and block, lb.; f = coefficient of friction; P = tangential frictional resistance, lb. Then, for rotation in either direction,

$$F(A + B) = RB, \quad R = P/f, \text{ and } F = PB/f(A + B)$$

In Fig. 80 let C = leverage distance from fulcrum pin to line of action of P, in. Then, for clockwise rotation, $F = PB[(1/f) - (C/B)]/(A + B)$. For counterclockwise rotation, $F = PB[(1/f) + (C/B)]/(A + B)$.

In the case of clockwise rotation it will be noted that C/B must be less than $1/f$, or the brake will be self-acting, that is, will bind.

In the arrangement shown in Fig. 81, for clockwise rotation, $F = PB[(1/f) + (C/B)]/(A+B)$, and for counterclockwise rotation, $F = PB[(1/f) - (C/B)]/(A+B)$.

In the latter case (for counterclockwise rotation) C/B must be less than $1/f$ or the brake will be self-acting, that is, will bind.

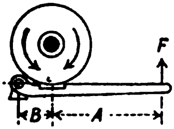

FIG. 79.

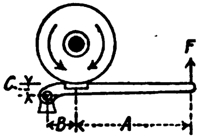

FIG. 80.

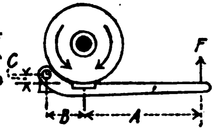

FIG. 81.

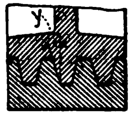

FIG. 82.

FIGS. 79–81.—Block Brakes.

Should the **face** of the brake wheel and blocks be **grooved,** as shown in Fig. 82, $f/(\sin y + f\cos y)$ must be substituted for f in the foregoing equations, y being equal to half the angle included by the faces of the grooves and not less than 23 deg., to prevent binding; y may have any value up to 30 deg.

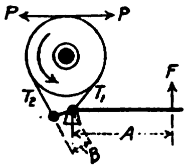

FIG. 83.

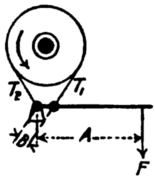

FIG. 84.

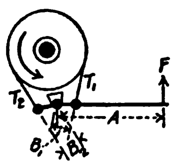

FIG. 85.

FIGS. 83–85.—Band Brakes.

Band Brakes are shown diagrammatically in Figs. 83, 84 and 85. The force relations obtaining in their operations are as follows:

In Fig. 83, let F = force at end of brake handle, lb.; P = tangential force at rim of wheel, lb.; f = coefficient of friction of materials in contact; a = angle of wrap of band, in deg.; T_1 = total tension in band on tight side, lb.; T_2 = total tension in band on slack side, lb. Then $T_1 - T_2 = P$ and $T_1/T_2 = 10^{0.0076fa} = 10^b$ where $b = 0.0076fa$. Also, $T_2 = P/(10^b - 1)$ and $T_1 = P \times 10^b/(10^b - 1)$.

For the arrangement shown in Fig. 83,

$$FA = T_2B = PB/(10^b - 1)$$

and

$$F = PB/A(10^b - 1).$$

For the construction illustrated in Fig. 84,

$$F = (PB/A)[10^b/(10^b - 1)].$$

For the differential brake shown in Fig. 85,

$$F = (P/A)[(B_2 - 10^bB_1)/(10^b - 1)].$$

In this arrangement the quantity $10^b \times B_1$ must always be less than B_2, or the band will grip the wheel and the brake, or part of the mechanism to which it is attached, will be ruptured.

It is usual in practice to have the leverage ratio A/B for block brakes about 5 : 1, and for band brakes about 10 : 1. The bands are faced with maple blocks.

If f for wood on iron be taken at 0.3 and the angle of wrap for the band be 270 deg., that is, subtends ¾ of the circumference, then, $10^b = 4$ approx. (see Table 11, p. 248, for values of $10^b = e^{fa}$), and C/B be taken equal to $1/0.5 = 2$, the loads required for a given torque will be as follows for the cases just considered:

Block brake, Fig. 79 .... $F = 0.55P$
Block brake, Fig. 80 (clockwise rotation) .... $F = 0.22P$

Block brake, Fig. 80 (counterclockwise rotation) .... $F = 0.90P$
Block brake, Fig. 81 (clockwise rotation).. $F = 0.90P$
Block brake, Fig. 81 (counterclockwise rotation) .... $F = 0.22P$
Band brake, Fig. 83 .... $F = 0.033P$
Band brake, Fig. 84 .... $F = 0.133P$
Band brake, Fig. 85 .... $F = 0.016P$

Clam-shell Brakes are block brakes adapted to absorbing great amounts of energy. Fig. 86 illustrates one way in which such brakes may be rigged. The force relations are as follows:

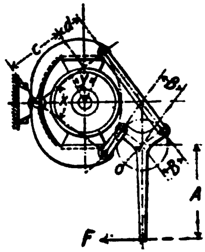

FIG. 86.

Let F = load applied at end of lever, lb.; R = reaction between wheel and *each* block, lb.; P = tangential frictional resistance on each block surface, lb.; f = coefficient of friction of materials in contact for a given condition of surface; r = drum radius, in., T = torque on drum shaft, in.-lb.; other notations as in the figure. Then,

$R = FA(c + d)/\cos(x/2)2Bc$; $P = Rf$; $T = 2Rfr$.

The point o should be a floating pivot to permit adjustment as the blocks wear. Values of f are given in Table 46.

In the case of Fig. 85 the dimension B_2 must be greater than $B_1 \times 10^b$. Accordingly, B_1 is taken at ¼, A at 10, and, since $10^b = 4$, B_2 is taken at 1¼.

The principal function of a brake is to absorb energy. This energy appears at the surface of the brake as heat, which must be carried away at a sufficiently rapid rate to prevent burning of the wooden blocks. Suitable proportions may be arrived at as follows:

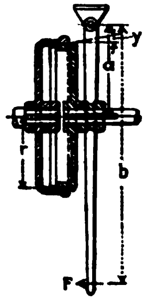

FIG. 87. Cone Brake.

Let p = unit pressure on brake surface, lb. per sq. in. = R (reaction against block)/area of block; v = velocity of brake rim surface, ft. per sec. = $2\pi rn/60$, where n = r.p.m. of brake wheel. Then pvf = work absorbed per sq. in. of brake surface per sec., and $pv \leqq 20$ for intermittent applications of load with comparatively long periods of rest and poor means for carrying away heat (wooden blocks); $pv \leqq 10$ for continuous application of load and poor means for carrying away heat (wooden blocks); $pv \leq 30$ for continuous application of load with effective means for carrying away heat (oil bath).

Cone Brakes may be made to the form shown in Fig. 87. The force relations are as follows:

Let F = load applied at end of lever, lb.; Q = normal pressure on cone surface, lb.; P = tangential force on the rim of the brake, lb.; r = mean radius of cone surface, in., and y = half angle of cone. Then $Q = F(b/a)/2(\sin y + f \cos y)$ and $P = fF(b/a)/(\sin y + f \cos y)$; $F = P(a/b)(\sin y + f \cos y)/f$. For $a = 1$, $b = 10$, $y = 15$ deg., and $f = 0.2$ for cast iron on cast iron, $F = 0.23P$, approx.

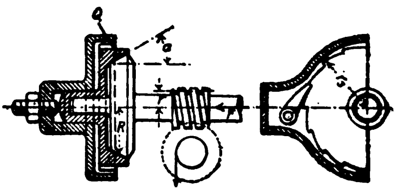

FIG. 88.—Cone Brake for Lowering Loads.

Such brakes are frequently used for lowering loads by the means shown in Fig. 88. The drum shaft is driven through the worm shaft by means of worm and wheel. In raising the load the ratchet runs free. As the load tends to lower the ratchet engages and the worm thrusts the cone surfaces together. Lowering of the load must be accomplished by the application of torque to the worm shaft. In the case of worms of small pitch no brake is required, for the wheel cannot turn the worm. This brake is therefore adapted to worms of large pitch, and the reason for employing a large pitch is that a more efficient drive is obtained (see p. 733). The force relations are approximately as follows:

Let R = mean radius of cone surface, in. Q = force normal to cone surface, lb. P = tangential force at cone surface, acting with the leverage R. F = axial force, lb. f = coefficient of friction between cone surfaces. a = angle between shaft axis and element of cone surface, deg. b = angle of pitch of worm on worm wheel, deg. f_1 = coefficient of friction of worm and wheel teeth. r = pitch radius of worm, in. r_3 = pitch radius of ratchet wheel, in. L = load on ratchet teeth, lb. Let $x = f \cos a + \sin a$, and $y = (\tan b - f_1)$; then Lr_3 = torque on worm shaft (in.-lb.) due to F, where F is the axial force due to load on drum = Fry approximately.

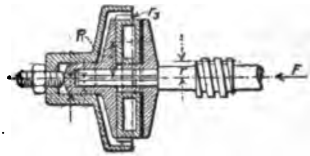

FIG. 89.—Disk Brake.

The resisting moment of the clutch is $PR = QfR = RFf/x$. To hold the load and prevent its lowering, the actuating torque, Fry, must be less than the reacting torque, RFf/x. Accordingly, $Rf/x \geqq ry$, or $R \geqq ryx/f$. The angles a and b may be assumed 22 deg., f at 0.08 and f_1 at 0.10, depending on the lubrication, whence x = 0.45 and y = 0.30. Then for the above assumptions $R \geqq 1.7r$. If a = 30 deg., b = 35 deg., then, for f and f_1 as before, x = 0.57, y = 0.60 and $R \geqq 4.3r$.

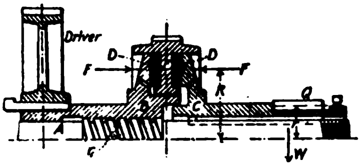

FIG. 90.—Disk Brake.

Disk Brakes of the same general type of construction but using a flat face instead of a cone, are as shown in Fig. 89. There are two faces to be moved against friction.

The force relations are $Lr_3 \leqq 2fFR = 2PR$, where $fF = P$. Also $R \geqq ry/2f$.

Frequently disk brakes are made as shown in Fig. 90. The motor pinion engages the gear in the drum (not shown). When the load is to be raised, power is applied through the gear and the connection between B and C is accomplished by the advancing of B along A and the clamping of the friction disks D and D and the ratchet wheel E. The reversal of the motor disconnects B and C. In lowering the load, only enough reversal of rotation of the gear is given as is needed to reduce the force in the friction disks so that the load may be lowered under control.

The force relations are as follows:

Let R = mean radius of friction plates, in.; f = coefficient of friction between plates; F = axial force along the screw = force in friction plates, lb.; P = tangential force on friction plates at mean radius R, lb., = fF; W = load on pinion teeth, lb.; r = radius of pinion pitch circle, in.; r_1 = radius of pitch circle of screw, in.; a = angle of screw thread, deg.; f_1 = coefficient of friction in thread.; $z = (\tan a + f_1)$.

Then the load in lowering causes a moment $Wr = fFR + Fr_1z$, approx. To sustain the load, $Wr \leqq 2fFR$ and $fR \geqq r_1z$.

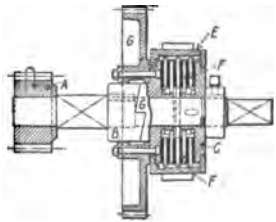

FIG. 91.—Multi-disk Brake.

Acceptable values of the several factors are: a = 10 deg.; f = 0.08; f_1 = 0.10; R = 9 in. Substituting these in the last equation, $r_1 \leqq 2.5$ in.+. Any radius of screw less than 2½ in. consistent with strength will be satisfactory for the above conditions.

A multi-disk brake is shown in Fig. 91. This type of construction results in an increase in the number of friction faces. The drum shaft is geared to the pinion A, while the motive power for driving comes through the gear G.

In raising the load, direct connection is had between G, B and A. In lowering, B moves relatively to G and forces the friction plates together, those plates fast to E being held stationary by the pawl on E. In the figure there are three plates fast to E, one fast to G and one fast to C.

In addition to the notation given in the previous case, let n = number of *faces* in sliding contact when the part C is moved relatively to part E which carries the ratchet. This condition obtains upon the load beginning to lower; and n_1 = number of *faces* in sliding contact when the parts G and C both move relatively to E. This obtains when full gripping of the plates takes place. The load in beginning to lower occasions the following force relation: $Wr = nfFR + Fr_1z$. To sustain the load it is necessary that $Wr \leq n_1fFR$. Hence, to prevent the load from dropping, $r_1z \leq fR(n_1 - n)$.

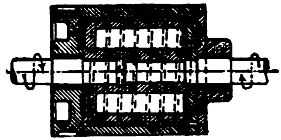

FIG. 92.—Coil Brake.

The Coil Brake shown in Fig. 92 is occasionally used for lowering loads under control. The coil is made by winding a Tobin bronze bar in a helix, or is cut from a solid steel cylinder. Wear occurs first and most severely at one end of the coil, which is an objectionable feature of this style of brake. The way to compensate for this is to bore the spring on a taper so that several turns of the coil will grip simultaneously.

BEARINGS

Plain Cylindrical Bearings

Dimensions of Plain Cylindrical Journal Bearings. The operation of a bearing depends upon the maintenance of an oil film between the sliding surfaces. The factors controlling the lubrication of the bearing are: 1. The intensity of pressure on the oil film. 2. The methods of introducing, distributing, carrying away and cooling the lubricant. 3. The characteristics of the lubricant under the operating conditions. 4. The characteristics of the sliding surface—oil grooves, etc. 5. The clearance between the journal and the bearing.

The intensity of pressure at any place on the oil film is dependent on the total load on the bearing, the projected area of the journal, the point or points of application of the load on the shaft with reference to the bearing, the stiffness of the bearing support and the journal, and the velocity of rubbing. According to the experiments of Prof. Herbert F. Moore (*Am. Mach.*, Sept. 10, 1903), the **pressure** on the projected area of a bearing **at which the oil film breaks down** is p(lb. per sq. in.) $= 7.47\sqrt{v}$, where v = velocity of rubbing, ft. per min. The **diameter of a bearing** in which a perfect oil film will be maintained at the final permissible temperature of the bearing, may be determined by the following formula derived by Axel K. Pedersen (*Am. Mach.*, Oct. 10, 1912) from a wide range of experimental data: $d^5 = 0.068453 \times (sW/x)^2(l/n)$ in which d = diam. of bearing, in.; s = factor of safety = p(in Moore's formula) divided by the *actual* pressure on projected area, lb. per sq. in.; W = total load on bearing, lb.; l = length of bearing, in.; x = l/d; and n = r.p.m. Values of l/d are given in Table 52. For ordinary light machinery, s may be taken as low as 2, and for heavy (especially high-speed) machinery, up to 8 or even 10. A fair average for preliminary design is 4 to 5.

The **allowable pressure** p (lb. per sq. in. of projected area) **with respect to the final temperature** (deg. fahr.) attained by the bearing may be determined from the following formulæ, in which v is the rubbing speed of journal, ft. per sec., and f the coefficient of friction:

For $v < 8.5$ ft. per sec., according to Pedersen, $p = 2.3\sqrt{60v}/f(t - 32)$.
For $v > 8.5$ ft. per sec., according to Lasche, $p = 51.2/f(t - 32)$.

The total load and the projected area (= length × diam.) of the bearing determine the bearing pressure. **Allowable bearing pressures,** according to Alford ("Bearings and Their Lubrication," p. 65), are given in Table 50. Representative German practice, according to "Hütte," is set forth in Table 51. For marine engines, see p. 1243; for gas engines, see also p. 1046.

Table 50. Allowable Bearing Pressures—Common Practice
(Pressures in lb. per sq. in. of projected area)

Gas engines		
Main bearings (total load)		500- 700
Crank-pin bearings		1500-1800
Cross-head-pin bearings		1500-2000
Air compressors (side-crank)		
Main bearings (total load)		160- 237
Crank-pin bearings		462- 850
Cross-head-pin bearings		628-1370
Air compressors (center-crank)		
Main bearings (total load)		122- 220
Crank-pin bearings		244- 402
Cross-head-pin bearings		400- 785
U. S. Navy		
Main engine bearings		275- 400
Main engine crank pins		400- 500
Steam turbine bearings		up to 85
Thrust bearings for torpedo boats		" " 50
Rolling mills	Rubbing vel., ft. per min.	
Pinion housing	350-600	30- 50
Roll housing	350-600	100-2000
Table roller	150	30- 50
Table line shafting	150	30- 50
Main bearing of shears	50-65	1800-2500
Railroads		
Cross-head-pin bearings		3000-4000
Crank-pin bearings		1500-1700
Driving wheel journal bearings		up to 556
Car-axle bearings		300- 325
Tender axle bearings		up to 425
Stationary engines (high-speed)		
Main bearings (dead load)		60- 120
Main bearings (total load)		150- 250
Crank-pin bearings		900-1500
Cross-head-pin bearings		1000-1800
Stationary engines (low-speed)		
Main bearings (dead load)		80- 140
Main bearings (total load)		200- 400
Crank-pin bearings		800-1300
Cross-head-pin bearings		1000-1500
Merchant marine		
Main bearings (total load)		400- 500
Crank-pin bearings		400- 500
Electrical machinery		
Horizontal steam turbine bearings		40- 60
Vertical steam turbine steps		200-1000
Generator and motor bearings		30- 80
Main bearings of engines driving generators		40- 80
Miscellaneous		
Bearings for slow speed and intermittent load, as for punch presses, shears, etc		3000-4000
Light line-shaft bearings, cast iron		15- 25
Heavy line shaft bearings, bronze or babbitt-lined		100- 150
Main bearings of slow-speed pumping engines		up to 600
Bearings for very low speeds and intermittent service, as for turn tables and bridges		7000-9000
Heavy slow-speed step bearings		up to 2000
Drill press thrust collars		" " 325
Angular thrust bearings for boring-mill tables		" " 75

Table 51. Allowable Bearing Pressures—German Practice

Materials in contact:	Pressure, lb. per sq. in. of projected area
Hardened crucible steel on hardened crucible steel	2130
Hardened crucible steel on bronze	1280
Unhardened crucible steel on bronze	850
Mild steel with smooth surface on bronze	570
Mild steel with slightly imperfect surface (or cast iron) on bronze	425
Mild steel with slightly imperfect surface on cast iron	355
Mild steel on lignum vitæ with water lubrication	355

If the total pressure maintains approximately the same magnitude and direction even when the journal is at rest (for example, in heavily loaded shafts, heavy gears, etc.), the unit pressures of Table 51 should be taken smaller than the tabular values. For journals (or bearings) which oscillate only, the unit pressure may be slightly higher. For the bearings of rope and chain sheaves, etc., which turn intermittently and on which the wear is either small or unimportant, the unit values—850 to 355 lb.—may be doubled or trebled. For crucible-steel crank and cross-head pins running on bronze in ordinary steam engines the unit pressure may be taken from 710 to 995 lb. and 1070 to 1130 lb., respectively; for similar purposes on locomotives, 1420 and 2130 lb., respectively; on high-speed steam engines, 570 to 710 lb., respectively. For flywheel bearings of steam engines use 213 to 217 lb. For crank-pin bearings of punches and shears the unit pressure may be as high as 2845 lb. per sq. in. of projected area.

A rule devised by Dr. Thurston to determine the allowable pressure in bearings having a steady load in one direction, is $pV < 50{,}000$, where p = load per sq. in. of projected area of journal, lb., and V = velocity of rubbing in ft. per min. This rule is followed quite closely in the practice of the General Electric Co. (H. G. Reist, *Trans. A. S. M. E.*, vol. 27, p. 476.)

The customary ratios of bearing length to bearing diameter for various classes of service are given in Table 52. These values, if observed in design, will insure journals of requisite stiffness.

Table 52. Length-Diameter Ratios for Journal Bearings

Type of Bearing	l/d	Type of Bearing	l/d
Marine Engines:		Stationary Engines:	
Main bearings	1 to 1.5	Main bearings	1.5 to 2.5
Crank-pin bearings	1 to 1.5	Crank-pin bearings	1
Ordinary Shafting:		Wrist-pin bearings	1 to 1.5
Heavy—fixed bearings	2 to 3	Generator and motor bearings	2 to 3
Light—self-adjusting bearings	3 to 4	Machine-tool bearings	2 to 4

Standard practice in regard to the **clearance between journal and bearing**, as followed by the General Electric Co., is given in Table 53. The practice of the Brown & Sharpe Mfg. Co. for running fits is given in Table 54.

Types of Plain Cylindrical Bearings and Details of Construction

Pillow Blocks for **small shafts and light service** may have the proportions shown in Fig. 93. Taking $d_1 = D + ½$ in. as a unit dimension (D = diam. of shaft, in.), the following dimensions are to be used:

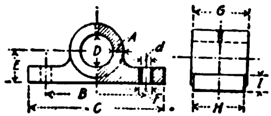

FIG. 93.—Light Pillow Block.

$A = 0.3d_1$		$G = 1.5d_1$	
$B = 2.5d_1$		$H = 1.25d_1$	
$C = 3.5d_1$		$I = 0.5d_1$	
$E = 0.8d_1$		d = bolt diam., in. $= 0.25d_1$	
$F = 0.3d_1$			

Pillow blocks for **heavy shafts** and greater loads may be made as shown in Fig. 94. The dimensions may be as follows, d_3 being the unit dimension $= D + ½$ in., where D = shaft diam., in.; $d_1(d_2)$ = diam. of bolts in base (cap), in.

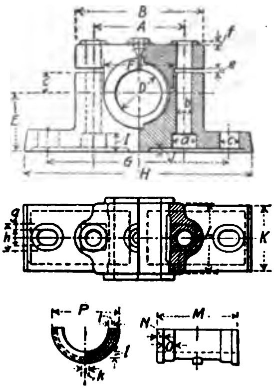

FIG. 94.—Pillow Block for Heavy Shafts.

$A = 1.75d_3$	$L = 1.25d_3$
$B = A + 2.75d_1$	$a = 1.5d_1 + ⅜$ in.
$C = 0.375d_3$	$b = 0.28d_3$
$E = d_3$	$c = 1.5d_2$
$F = 1.5d_3$	$d_1 = d_2 = 0.25d_3$
$G = 3.3d_3$	$e = D/16$
$H = G + 3.5d_2$	$f = 0.125d_1$
$I = 1.25d_2$	$g = 0.28d_2$
$J = {}^{11}/_{16}d_3$	$h = 1.5d_2$
$K = 1.125d_3$	

For the **brasses** the unit dimension is $D_1 = 0.09D + 0.15$ in., and

$i = 0.75D_1 \qquad N = l = D_1$

$k = 1.25D_1 \qquad O = 1.75D_1$

$M = L + 2N \qquad P = D + .36d_3$

Outboard Bearings or **pedestal bearings** with ring oiling may have the proportions shown in Fig. 95. Following are the principal dimensions in terms of the bearing diameter D:

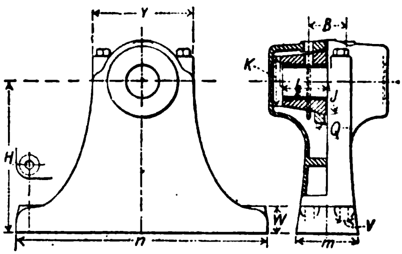

FIG. 95.—Pedestal Bearing.

L = length of bearing = $3D$ or $4D$	$K = 1.5D + \frac{1}{2}$ in.
$J = 2D + \frac{1}{2}$ in. for $L = 3D$ or $4D$	$m = 1.5D + (H - 2D)/5.55$ for $L = 3D$
$B = 1.25D$ for $L = 3D$	$= 1.8D + (H - 2D)/5.55$ for $L = 4D$
$B = 1.5D$ for $L = 4D$	$V = 0.25D$
$Q = 0.8D$ for $L = 3D$ } take nearest	$W = 0.625D + \frac{1}{4}$ in. } for $L = 3D$ or $4D$
$Q = 0.95D$ for $L = 4D$ } $\frac{1}{8}$ in. less	$n = 5D + 2H/3$ } for $L = 3D$ or $4D$
	$Y = 3D + 1$ in.

Grooving of Bearings for Oil Circulation.

Line-shaft Bearings are purchasable in standard sizes ranging from $1\frac{7}{16}$ in. to $3\frac{15}{16}$ in. in diam. by steps of $\frac{1}{4}$ in., and from $3\frac{15}{16}$ in. to $6\frac{15}{16}$ in. by steps of $\frac{1}{2}$ in. The lengths in all cases are either 3 or 4 diameters.

Hangers for line-shaft bearings may be purchased in types permitting of ceiling, floor or wall suspension. For ceiling and floor suspension the drop varies from 8 in. to 36 in., and for wall suspension from 6 in. to 9 in.

Main Shaft Machine Bearings. Average practice in proportioning the diameters and lengths of **headstock bearings in lathes** is as follows:

Front bearings: $d = s/5$; $l = s/4$. Back bearings: $d = s/8$; $l = s/6$. where d(diam.), l(length) and s(swing) are all in inches. Fig. 96 shows the usual type of design for small lathes—a construction which is also utilized in a large variety of other machine tools.

Engine Bearings for steam-, gas- and oil-engine crank shafts are constructed with regard to adjusting for wear and lubrication as shown in Figs. 97 to 100. The form shown in Fig. 97 is adapted to small engines. For larger engines, requiring more complete adjustment, the form shown in Fig. 98 is used. These bearings may be chain-oiled or ring-oiled, as shown in Figs. 99 and 100. Forced lubrication is used for important engines.

Bearing Metals. For the composition of bearing metals for use in different classes of machinery, see p. 542. The **anchoring and grooving** of bearings according to the practice of the Westinghouse Machine Co. is shown in Figs. 101 to 104 and Table 55. Fig. 101 relates to horizontal solid bearings, Fig. 102 to vertical bearings, and Fig. 103 to horizontal split bearings. Fig. 104 shows the standard method employed in anchoring babbitt metal in bearings.

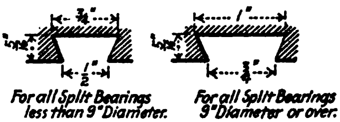

FIG. 104.—Method of Anchoring Babbitt Metal in Bearings.

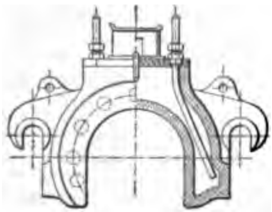
Thrust and Step Bearings

Thrust and Step Bearings for Marine Service are sometimes made with adjustable horseshoe bearing rings as shown in Figs. 105 and 106, and with provision for water-cooling. The thrust collars are formed by grooving the shaft and have an outside diam. $D = 1.6d$ to $1.9d$, where d is the normal shaft diameter. The thickness of each collar $= w = 0.13d$ to $0.16d$, and the distance between collars $= s = 2w$ to $3w$. The number of collars required $= n = P/\pi d_1 bp$, where P = total thrust on bearing, lb.; d_1 = mean diam. of collar, in.; b = radial width of collar, in., and p = allowable bearing pressure, lb. per sq. in., as follows: For cargo steamers, $p = 40$ to 55; for passenger steamers, $p = 55$ to 80; for heavy warships, $p = 70$ to 85; for light warships, $p = 100$ to 130.



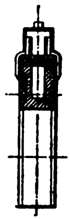


FIG. 105. FIG. 106.
Horseshoe Bearing Ring for Marine Thrust Bearing.

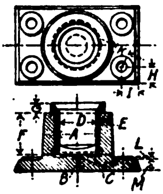

FIG. 107.—Step Bearing.

A simple **step bearing** may be made as shown in Fig. 107, acceptable proportions for which are as follows:

Shaft diam., in. $= D$	$C = 0.35D$	$H = I = K = 1.75d$
Bolt diam. $= d = 0.25D$	$E = 0.3D$	$L = 0.35d$
$A = 1.2D$	$F = D$	$M = 0.3D$
$B = 0.4D$	$G = 0.25D$	

The bearing pressures p depend on the mean velocity v of the rubbing surface and should be limited to the following values:

For v (ft. per min.) =	Slow and intermittent	50	50–100	100–150	150–200	Over 200
p (lb. per sq. in.) =	1500	200	100	75	60	50

Sliding Bearings

All sliding bearings, Fig. 108, to wear true must have the sliding parts of nearly equal lengths. Bearings made in this way will be found not to wear out of true. Oiling is accomplished in several ways, an acceptable method being that shown in Fig. 109. Short slides in many machine tools are lubricated by oil pads or direct oil application. The weight of the table and work and thrust of the tool cause wear on the bottom and sides of the guides. To compensate for the wear in both directions, bearings are sometimes made V-shaped, as shown in Fig. 110.

Simpler sliding bearings in machine tools are made with provision for adjustment, as shown in Figs. 111–113, of which there are many modifications.

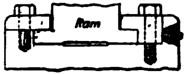

FIG. 111.

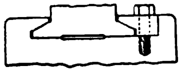

FIG. 112.

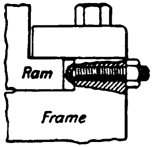

FIG. 113.

Ball Bearings

Ball bearings are used with great advantage in machinery, automobiles, line-shaft hangers, etc., under both thrust and radial loadings. **Typical mountings** for a variety of services are shown in Figs. 114, 115 and 116. Fig. 114 shows a typical mounting for a **pillow block.** The outer race should be made with a "sucking" or slip fit at *aa*, so that it may be easily inserted by hand. The inner race should be made with a light drive or force fit at *ee* and held securely against the shoulder *g* by firmly tightening the nut *f*, the nut being then pinned, as shown. The groove *c* has been found most effective in excluding dust and grit, which, if allowed to enter, will soon cause destruction of the ball and race surfaces. These general features of construction should be observed in mounting annular ball bearings of any sort.

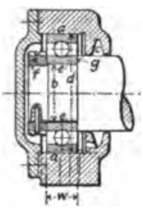

FIG. 114.—Hess-Bright Annular Ball Bearing.

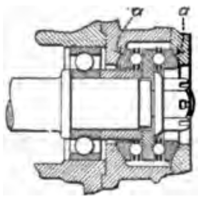

FIG. 115.—Combined Annular and Thrust Ball Bearing.

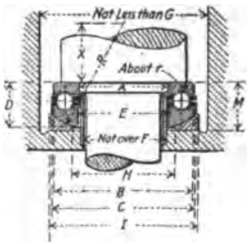

FIG. 116.—Hess-Bright Thrust Ball Bearing.

Fig. 115 shows a mounting of both **annular and thrust bearings.** In this case the thrust may occur in either direction. In thrust-bearing mountings the surfaces *aa* should be spherical in order to insure an even distribution of the load on the balls.

Annular and thrust ball bearings may be purchased in **standard sizes,** and are of different types according to the manufacturer. Knowing the speeds at which bearings are to operate and the nature of the service to which they are to be put, the manufacturers are able to specify the types best suited to the work and of the proper carrying capacities. Tables 56 and 57 give data on dimensions, loads and speeds of annular and thrust ball bearings made by the Hess-Bright Mfg. Co. It should be noted that the dimensions are given in millimeters, a practice due to the fact that German manufacturers were the first to take up their production on a large scale.

The S.K.F. self-aligning ball bearings have a double row of balls in a staggered arrangement. The outer ball race (Fig. 117) is ground spherical to a radius struck from the center of the bearing, thereby giving freedom for perfect adjustment to shaft flexure. The two grooves of the inner race are ground to a radius slightly larger than that of the balls. The inner cage, retainer and balls rotate as a unit within the spherical surface of the outer race. Tables 58 and 59 give data on bearings of this type. Fig. 117 relates to Table 58; Fig. 118 to Table 59.

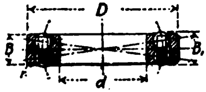

FIG. 117.—SKF Self-aligning Ball Bearing.

New Departure ball bearings for combined radial and axial loads are shown in Figs. 119 and 120. Tables 60 and 61 give the principal dimensions of these bearings and their capacities at various speeds.

Characteristics of Ball Bearings—Load Capacity. It is very necessary that the surfaces of the ball and of the race be not only accurate to dimensions but that the material of each should have a high elastic limit so that the loads encountered will not cause scaling and flaking. The ultimate or breaking load of the ball is in no way a measure of the capacity of the ball to take load safely.

When a hardened steel ball is placed between two other like balls and subjected to pressure, the **crushing load** is between $40{,}000d^2$ and $80{,}000d^2$ lb., where d is the ball diameter in inches. If placed between two plane surfaces the crushing load is greater. The **working load** must be much lower and may be determined from the formula $P = cd^2$, where P is the load on a single ball, lb., and c a coefficient having the following values determined by Stribeck and Bach:

Hard cast-iron balls between flat surfaces, 36; hard steel balls on flat, conical or cylindrical surfaces: intermittent running, 1400; continuous running, 700 to 1000; hard steel balls in races whose ball tracks have a radius of curvature = $\frac{2}{3}d$: intermittent running, 2800; continuous running, 1400 to 2000.

For three-point or four-point contact but one-third of these latter values should be used. The above values are limits possible with good workmanship and materials. Lower values must be employed when the quality of either the materials or workmanship is uncertain and also when high speeds are called for. For a single ring of balls, from 10 to 20 in number, the greatest load on any one ball, according to Stribeck, is $P = 5Q/n$, where Q is the total load on the ring. Equating $P = cd^2$ with $P = 5Q/n$, it is found that $d = \sqrt{5Q/cn}$.

The **starting friction** of ball bearings is very low. For **running friction,** see p. 244.

The Hess-Bright Mfg. Co. use the following formulæ for determining the **load-carrying capacities of ball bearings:**

For radial or annular bearings, $P = knd^2$, where n is the number of balls required to fill the race, k is a coefficient depending on the type of bearing, the material and the speed, and d is the ball diameter in eighths of an inch (*i.e.*, for a 1-in. ball $d = 8$). For uninterrupted ball tracks, the inner race being grooved to a radius $= 0.52 \times$ ball diam. and the outer race to a radius $= 0.625 \times$ ball diam., separated balls, uniform load and steady speed up to 3000 r.p.m., $k = 9$; for full-type bearings, the filling opening being in one race at the unloaded side, otherwise as above, $k = 5$; for both ball tracks interrupted by filling openings, in elastic cage separators for the balls, or for the full ball type, speeds not above 2500 r.p.m., uniform load, $k = 2.5$; for thrust on a radial bearing of the first type, as above, $k = 0.9$. In general, the larger the balls the smaller the value of k. The type with filling openings in each race is not suitable for withstanding end thrust.

For thrust bearings consisting of one flat plate and one flat seat plate with grooved ball races, $P = k_1nd^2/\sqrt[3]{R}$, where R = r.p.m. (up to 3000) and $k_1 = 25$ to 40 for materials used by the Hess-Bright Co., with ball race grooved to a radius of $0.82d$; $k_1 = 0.5$ for unhardened steel occasionally used for very large races where there is no hammering or sharp blows. When both races are flat, $k_1 = 6$ to 10 and 0.125 respectively for hardened and unhardened races.

For ball thrust bearings with two-point contact having a groove in each washer, the Standard Roller Bearing Co. uses the formula $P = knd^2/a\sqrt{R}$, where d is the ball diam. in in., a the pitch diam. of the ball grooves and $k = 32{,}000$ for light-type bearings with 17 balls and 19,200 for medium and heavy bearings with 11 and 9 balls, respectively.

Professor John Goodman (*Engr*. Dec. 19, 1913) gives the following formula for determining the maximum working load P on a ball bearing:

$P(\text{lb.}) = knd^2/(RD + Cd)$, in which d = the ball diam., in.; D = inside diam. of outer ball race, being taken from point of contact of ball with race, or for a thrust bearing, D = diam. taken from the center of balls, both in in.; n and R as in previous paragraphs. C and K are coefficients having the following values:

	C	K
Thrust bearings, flat races	200	500,000
Thrust bearings, grooved races	200	1,000,000 to 1,250,000
Radial bearings, flat races	2000	1,000,000
Radial bearings, grooved races	2000	2,000,000 to 2,500,000

Roller Bearings

Roller bearings are used on automobiles, trucks, line shafts and in a variety of machines where heavy loads have to be carried. **Typical bearings** are shown in Figs. 121 and 122. Fig. 121 illustrates a step bearing with conical rollers. The end thrust in such construction is liable to be excessive, in which case a ball at the larger end of each roller is employed. Fig. 122 shows a step bearing with short cylindrical rollers which has been found to be very successful. To equalize the load on the rollers, the bottom plate is made to fit in a lubricated spherical seat.

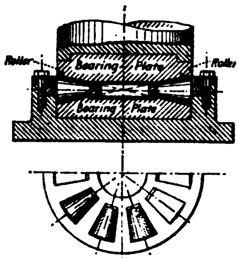

FIG. 121.—Roller Step Bearing.

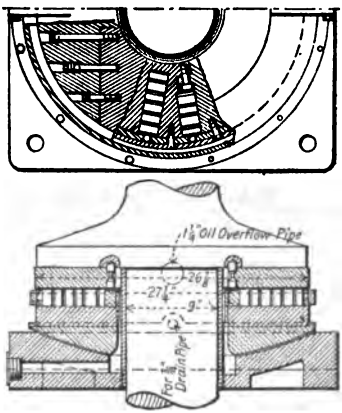

FIG. 122.—Roller Step Bearing.

In the **Hyatt roller bearing,** Fig. 123, the rollers are cylindrical and hollow, being wound helically from flat strip chrome-nickel steel and ground off on the ends to the proper length. The windings are alternately right- and left-hand. They are flexible and adjust themselves easily under ordinary pressures to small inaccuracies of the journal or box. In the "standard" type the rollers are in direct contact with the shaft; in the "heavy duty" type the specific pressures are greater and the shaft must be hardened by heat treatment at the place of contact with the rollers, or else a hard steel sleeve be interposed to form the bearing surface. For the standard type (*a*) the allowable pressure at speeds up to 500 r.p.m. is between 400 and 500 lb. per sq. in.; for line-shaft bearings up to $3\frac{15}{16}$ in. diam. running up to 600 r.p.m., 30 lb. per sq. in. For the high-duty type (*b*), allowable pressure at 1000 r.p.m. is 750 lb. per sq. in. Limiting maximum speeds are (*a*) 1500 r.p.m. and (*b*) 3000 r.p.m. The permissible loads fall off rapidly with increase of speed, for example, at 1500 r.p.m. the load on high-duty type should not exceed one-half that at 1000 r.p.m. Loads can be correspondingly increased at low speeds. Tables 62 and 63 give some dimensions of Hyatt bearings.

FIG. 123. Hyatt Roller Bearing.

In the **Norma roller bearing,** Fig. 124, the rollers are cylindrical and solid; the inner race is cylindrical while the outer race is slightly convex, giving some freedom for adjustment in case of flexure or imperfect alignment of the shaft. The capacities of these bearings at various speeds are shown in Table 64.

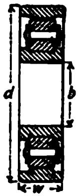

FIG. 124. Norma Roller Bearing.

Load Capacities of Roller Bearings. For rollers such as are used on bridge **turn tables** and in similar places where the speeds of rotation are slow, the safe load in pounds is $P = cnld$, in which n = number of rollers in the bearing, l and d the length and diameter of each roller, in., $c = 360$ for hard cast-iron rollers running on hard cast-iron tracks, and $c = 850$ for hard steel rollers on hard steel tracks. Where $l > 5d$, smaller values of c should be used. In case conical rollers are used, d is the mean diameter.

The Standard Roller Bearing Co. determines load capacities of roller bearings by the formula $P = 130{,}000d^2nl/3s$, in which P = load on bearing, lb.; d = diam. of roller, in.; n = number of rollers; l = length of each roller, in., and s = circumferential speed of each roller, ft. per min. In bearings with conical rollers d is the diameter of the roller at its mid-length. The safe load per inch of length of a solid roller is taken at 2000 lb., with the assumption that one-third the number of rollers take the whole load on the journal.

The above ratings are for steady loads and speeds; 50 per cent. temporary overload capacity can be added. External dimensions *d* and *w*, Fig. 124, are the same as for Hess-Bright bearings, Table 56. These bearings are also made with inside diameters (*b*) up to 215 mm. for the three types of service, with load capacities (at 300 r.p.m.) up to 34,300 lb. (light), 49,600 lb. (medium), and 67,500 lb. (heavy).

Another formula for the safe load on a roller bearing is $P = kld^2/(ND + 2000d)$, in which N = r.p.m. of the shaft; D = diam. of the sleeve or roller path, in.; and k = 1,200,000 to 2,000,000 for first-class workmanship, hardened steel rollers with $l = d$, running on hardened ground surfaces; k = 400,000 for ordinary workmanship and soft steel rollers running on a soft steel shaft.

GEARING

Spur Gears

Definitions. The various **parts of spur-gear teeth** are shown and named in Fig. 125. The **diametral pitch** (sometimes referred to as simply the pitch) is the ratio of the number of teeth in the gear to the diameter of the pitch circle measured in inches, or the number of teeth in the gear per inch of pitch circle diameter ($= \pi$/circular pitch in inches). The **line of action** of involute teeth is the tangent to the base circles of the two gears which passes through the point of tangency of their pitch circles; and the **angle of obliquity** (or **pressure angle**) is the angle included between the line of action and the common tangent to the pitch circles.

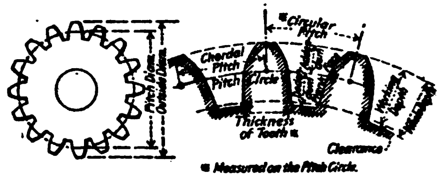

FIG. 125.—Spur Gear Teeth.

Outlines of Gear Teeth. The outlines of gear teeth are either involute curves or cycloidal curves. An **involute curve** is one generated by a point in a taut cord unwrapped from a **base circle**, or circle concentric with and inside the pitch circle. A cycloidal curve is one generated by a point on the circumference of a rolling circle. If the circle rolls on a straight line the curve is **cycloidal**; if on the outside of another circle, it is an **epicycloidal** curve, and if on the inside of another circle, a **hypocycloidal** curve.

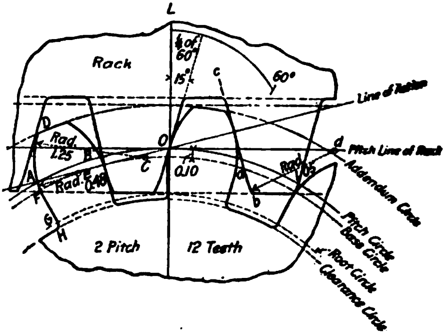

FIG. 126.—Grant's Odontograph for Involute Teeth.

The outlines of **involute teeth to be molded from patterns** may be laid out by means of Grant's **odontograph** for involute teeth, shown in Fig. 126. Referring to the figure, first draw the pitch, root, addendum and clearance circles. (For the relations of the latter three circles to the pitch circle, see p. 724.) Draw the base circle concentric with the pitch circle and with a radius of $^{29}/_{30}$ of the pitch circle radius. Lay off the circular pitch AO and thickness of tooth AB on the pitch circle. With a center C on the base circle and the face radius CA (obtained from Table 65) draw in the face outline AD of the tooth from the pitch circle to the addendum circle. With a center E on the base circle and the flank radius EA (obtained from Table 65) draw AF or that portion of the flank outline between the pitch circle and the base circle. From the base circle to the root circle the tooth outline FG is a radial line which rounds into the clearance circle at H. The outline of an **involute rack tooth** is drawn as follows: Draw a straight line ac making an angle of 15 deg. with the radius line OL. Draw ab from the center d on the rack pitch line with a radius equal to 0.67 in. multiplied by the circular pitch (or to 2.10 in.) divided by the diametral pitch. This arc establishes the necessary clearance in order to avoid interference.

The outlines of **epicycloidal teeth to be molded from patterns** may be similarly laid out by means of Grant's epicycloidal or three-point odontograph. See Fig. 127. Draw the pitch, addendum, root and clearance circles, and lay off the circular pitch and tooth thickness as before. Also lay off the face

Table 65. Grant's Odontograph for Involute Teeth

Pressure angle = 15 deg. Addendum = 0.3183 × circular pitch = 1/diametral pitch. Clearance = Addendum/8.

center and flank center circles with the distances from the pitch circle taken from columns 4 and 6 of Table 66. With radii for flanks and faces obtained from columns headed "Rad" in Table 66, draw the arcs forming the flanks and faces of the teeth. Fig. 127 shows the layout of a 20-tooth gear of 2 diametral pitch.

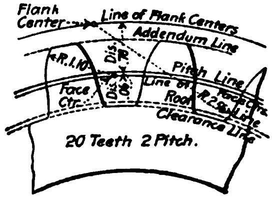

FIG. 127.—Grant's Odontograph for Epicycloidal Teeth.

Relative Proportions of Gear Teeth. In any set of interchangeable gears having cycloidal tooth outlines, the same rolling circle must be used for both faces and flanks of all the gears in the set. To avoid undercutting of the teeth, the rolling circle is made equal in diameter to one-half the pitch circle of the smallest gear in the set, which is usually limited to 12 or 15 teeth. Involute gears to be interchangeable must have the same angle of obliquity. Involute gears are usually preferred by manufacturers (one reason being that a slight change in the center distance does not impair the accuracy of their working), and the following relative proportions have been established (c.p. = circular pitch; d.p. = diametral pitch):

	Brown & Sharpe	C. W. Hunt Co.
Addendum	1/d.p. = 0.3183 c.p.	0.7854/d.p. = 0.25 c.p.
Dedendum	1.157/d.p. = 0.3683 c.p.	0.9424/d.p. = 0.30 c.p.
Working depth	2/d.p. = 0.6366 c.p.	1.5708/d.p. = 0.50 c.p.
Whole depth	2.157/d.p. = 0.6866 c.p.	1.7278/d.p. = 0.55 c.p.
Clearance	0.157/d.p. = 0.0500 c.p.	0.157/d.p. = 0.05 c.p.
Angle of obliquity	14½ deg.	14½ deg.

The proportions used by Wm. Sellers & Co., Inc. and the Grant Gear Works are the same as those given for Brown & Sharpe, excepting that the Sellers angle of obliquity is 20 deg. and the Grant 15 deg. The Fellows Gear Shaper Co. has established a stub-tooth standard having an angle of obliquity of 20 deg. Proportions are as given in Table 67.

Table 67. Fellows Stub-tooth System

Diametral pitch	Thickness of tooth	Addendum	Clearance	Whole depth of tooth	Diametral pitch	Thickness of tooth	Addendum	Clearance	Whole depth of tooth
4/5	0.3927	0.2000	0.0500	0.4500	8/10	0.1963	0.1000	0.0250	0.2250
5/7	0.3142	0.1429	0.0357	0.3214	9/11	0.1745	0.0909	0.0227	0.2045
6/8	0.2618	0.1250	0.0312	0.2812	10/12	0.1571	0.0833	0.0208	0.1875
7/9	0.2244	0.1111	0.0278	0.2500	12/14	0.1309	0.0714	0.0179	0.1607

Thickness of tooth same as for 14½-deg. gear of same pitch as numerator of stub tooth pitch fraction. Addendum equals reciprocal of denominator of stub tooth pitch fraction; clearance equals .25 divided by denominator of stub tooth pitch fraction.

Cutters for Gear Teeth. Standard cutters may be had for cutting either involute or cycloidal teeth of any system. For the stub-tooth system the Fellows gear shaper must be used. Gear teeth may also be hot-rolled, but for high-class work should be finished with a cutter.

The Brown & Sharpe Mfg. Co. has established **designations for rotating cutters** for gear teeth, which have become standard. These are given in Table 68.

Table 68. Standard Designations of Gear Cutters

Cutters for cycloidal teeth						Cutters for involute teeth			
Cutter	No. of teeth	Cutter	No. of teeth	Cutter	No. of teeth	Cutter	No. of teeth	Cutter	No. of teeth

G	18	*O*	34–37	*W*	250 & up	4	26– 29	8	12
H	19	*P*	38–42	*X*	Rack	4½	23– 25		

The Speed Ratios of Spur Gears are inversely proportional to their pitch diameters. The pitch diameters necessary for any given speed ratio and distance of shaft centers may be obtained in the following manner:

Let l = distance between shaft centers, in.; $r = \dfrac{\text{radius of smaller gear}}{\text{radius of larger gear}}$.

Then

Diam. of smaller gear (D_s), in. $= 2l/(1 + 1/r)$

Diam. of larger gear (D_l), in. $= 2l/(r + 1)$

Accordingly, if $l = 24$ in. and $r = 1/5$, $D_l = 48/(6/5) = 40$ in., and $D_s = 48/6 = 8$ in.

For **epicyclic gear trains,** see p. 657.

The speed ratios for the more common gear trains are as follows:

Fig. 128: r.p.m. of N = r.p.m. of $R \times \left(1 + \dfrac{\text{diam. of } F}{\text{diam. of } N}\right)$

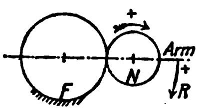

FIG. 128.

Fig. 131: r.p.m. of N = r.p.m. of $R \times \left(\dfrac{\text{diam. of } R}{\text{diam. of } R + \text{diam. of } F}\right)$
(with internal gear driving)

Fig. 132: r.p.m. of N = r.p.m. of $R \times \left(1 - \dfrac{\text{diam. of } F \times \text{diam. of } M}{\text{diam. of } S \times \text{diam. of } N}\right)$

Fig. 133: r.p.m. of N = r.p.m. of $R \times \left(1 + \frac{\text{diam. of } F \times \text{diam. of } M}{\text{diam. of } S \times \text{diam. of } N}\right)$

The shading in Figs. 128–133 shows the gear whose shaft has no motion.

Elliptical Gears (having the pitch curve in the form of an ellipse instead of a circle as with spur gears) are employed to obtain variable velocity throughout the revolution.

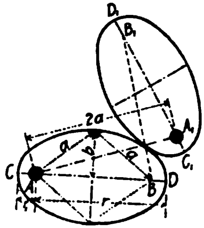

FIG. 134.—Elliptical Gears.

In Fig. 134, A = the axis of driving gear; A_1 = axis of driven gear; a = half major axis of ellipse; b = half minor axis of ellipse; A, B, A_1, B_1 are the focii of the ellipses; o = uniform angular velocity of the driving gear; o_1 = greatest angular velocity of the driven gear; o_2 = least angular velocity of the driven gear; r and r_1 as in figure.

Then $AA_1 = 2a$, and $b = 2a\sqrt[4]{V}/(\sqrt{V} + 1)$, where $V = o_1/o_2 = r^2/r_1^2$.

For strength of gear teeth, see p. 730; for efficiency of transmission by gears, pp. 247 and 733.

Bevel Gears

Bevel gears may be used to connect intersecting shafts in any given speed ratio. Referring to Fig. 135, let OA_1 and OA_2 represent the shafts to be connected and let a be the angle defined by their axes. Should it be required that OA_1 rotate at 100 r.p.m. while OA_2 rotates at 50 r.p.m., then the cones D_1OB and D_2OB defining the pitch surfaces of the bevel gears must have a common apex at O (the intersection of the shafts), and their common tangent must define the angles b_1 and b_2 whose ratio is 50 to 100 and whose sum is a. The tooth outlines will be generated by rolling cones having apexes at O. At the larger end of the larger gear the tooth outlines will be approximately those generated on a pitch circle of radius BA_2. BA_2 is drawn perpendicular to OB. The pitch circle for laying out the teeth at the smaller end is found in a similar manner.

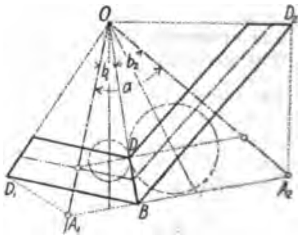

FIG. 135.—Bevel Gears.

Satisfactory relations for **proportioning the teeth of bevel gears** of the various inclinations shown in Figs. 136–139 are as follows:

Let P = diametral pitch
C = circular pitch
N = number of teeth in pinion
N_1 = number of teeth in gear
x = angle between shafts
$D(D_1)$ = pitch diam. of pinion (gear)
$O(O_1)$ = outside diam. of pinion (gear)
$J = 1/P = 0.3183C$
$K = 1.157/P = 0.3683C$

Then

$N = DP = \pi D/C$. $\quad N_1 = D_1P = \pi D_1/C$

$D = N/P = 0.3183CN$. $\quad D_1 = N_1/P = 0.3183CN_1$

$O = D + (2 \cos c/P) = D + 0.6366C \cos c$ [$= D + (1.4142/P) = D + 0.45C$ for the miter gear in Fig. 137]

$O_1 = D_1 + (2 \cos c_1/P) = D_1 + 0.6366C \cos c_1$
$= D_1 + (2 \sin c/P) = D_1 + 0.6366C \sin c$ for Fig. 136

$\tan c = \cos (x - 90°)/[(N_1/N) - \sin (x - 90°)]$ for Fig. 139
$= \sin x/[(N_1/N) + \cos x]$ for Fig. 138; $= N/N_1$ for Fig. 136

$c_1 = x - c$

$\tan s = 2 \sin c/N (= 1.4142/N$ for Fig. 137)

$2.314 \sin c/N (= 1.6362/N$ for Fig. 137)
$c + s\ (= 45° + s$ for Fig. 137); $a_1 = c_1 + s$
$c - f (= 45° - f$ for Fig. 137); $b_1 = c_1 - f$
$\frac{1}{2}O \cot a$; $M_1 = \frac{1}{2}O_1 \cot a_1$
$Y \cos a$; $H_1 = Y \cos a_1$.

ɡears. For Fig. 137 this equals $1.414N$.
h of bevel gears, see p. 732; for efficiency, pp. 247 and 733.

orm Gears

m-and-wheel gearing **y ratio** is the ratio number of teeth on the number of threads ı. Thus, a 30-tooth l meshing with a ed worm will have a o of 1 to 30, that is, ust make 30 revolu- to revolve the worm For a double- rm there will be 15 f the worm to one of ıeel, etc. High ve- are thus obtained y small wheels.

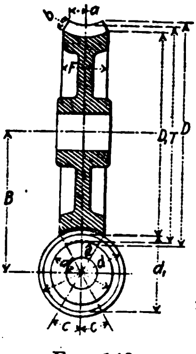

FIG. 140.

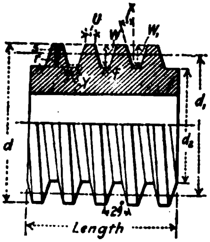

FIG. 141.

The following rules for **proportioning worm gears** are quoted from the "American Machinist Gear Book," by C. H. Logue, and refer to Figs. 140 and 141:

Let

N = number of teeth in worm wheel
n = number of threads in worm
p = circular pitch (dist. c to c. of teeth)
L = lead (advance of worm in 1 rev.)
D_1 = pitch diam. of worm wheel
T = throat diam. of worm wheel
D = outside diam. of worm wheel
F = face of worm wheel
a = distance from center line to point of tooth
b = length of side
d_1 = pitch diam. of worm
d = outside diam. of worm
d_2 = bottom diam. of worm
e = radius at throat of worm wheel
c = angle of sides of face, deg.
B = center distance
R = revs. of worm per rev. of wheel
x = angle of teeth in wheel with axis (used in gashing)
W = working depth
W_1 = whole depth
f = clearance
t = thickness of tooth at pitch line
t_n = normal thickness of tooth at pitch line
p_n = normal circular pitch
s = addendum
U = width of worm thread at top
Y = width of worm thread at bottom
P = diametral pitch

Then

$N = \pi D_1/p$
$T = 0.3183p(N + 2)$
$F = (0.5d + 0.17p) \sin c/0.5$
$a = F/2 - b \sin c$
$b = W_1 + 0.12p$
$d = d_1 + 2s$
$d_2 = d - 2W_1$
$e = \frac{1}{2}d_1 - s$
c = 30 to 35 deg.
$(\sin c = F/(d + 0.34p)$
$B = (D_1 + d_1)/2$
$D_1 = 0.3183Np$
$D = T + 2(e - e \cos c)$
$p = D_1/0.3183N$
$L = pn$
$n = N/R$
$\tan x = L/\pi d_1$
$t_n = t \cos x$, or
$t = t_n/\cos x$
$U = 0.335p = 1.0536/P$
$Y = 0.31p = 0.9744/P$
$p_n = p \cos x$, or $p = p_n/\cos x$

The formulæ for the tooth parts of spur gears apply also to worm gears. N, D, and p are calculated the same as for spur gears.

T has the same value as the outside diameter of a spur gear of the same pitch and number of teeth.

F will be sufficiently accurate when calculated from the formula in the parenthesis.

d_1. The efficiency of a worm gear drive depends greatly on the angle x of worm. When the lead is fixed, the angle is determined from $\tan x = L/\pi d_1$, and, in order to make it of a value that would indicate high efficiency, the diameter should be made as small as possible except when the angle approaches 45 deg., where either the worm or the wheel may drive. In such a case the conditions should be reversed and the diameter of the worm be made large enough to secure the desired angle, unless the wheel is to drive, which sometimes is the case.

c is generally from 30 to 35 deg., preferably 30 deg.

L = circular pitch × number of threads in the worm; *e.g.*, a double-threaded worm of 1½ in. circular pitch has a lead of 3 in.

n. The number of threads in a worm of given velocity ratio = number of teeth in the wheel divided by the ratio; *e.g.*, for a wheel with 60 teeth and a velocity ratio of 30 : 1, number of threads $= n = 60/30 = 2$.

W_1 should be proportioned from the normal pitch (p_n) rather than from the linear pitch (p), as is usually the case. It is wrong to take the depth from linear pitch even for single or double threads, and for quadruple and sextuple threads the error becomes so pronounced that it is likely to affect seriously the working of the gear.

t_n = thickness of tooth parallel with the axis of worm (= 0.5 × linear pitch) divided by the cosine of the helix angle x.

The **length of the worm** need be no greater than three times the circular pitch, as seldom are more than two teeth in contact at once. If the worm be made longer, how-

ɔan be shifted lengthwise when worn, as it always wears away more rapidly than d. It is common practice to make the length of worm = $6p$.
rength of worm gears, see p. 732; for efficiency, pp. 247 and 733.

Helical Gears

al gears (commonly misnamed "spiral" gears) may be used to connect llel shafts, (b) shafts at right angles and not intersecting, and (c) shafts at any angle to each other and not intersecting. Worm gears special case of (b). Fig. 142 represents two gears connecting non-intersecting shafts inclined other in plan at an angle of c degrees. Gear A, s R, has teeth of a pitch angle equal to x degrees, e pitch angle of the teeth of gear B is equal to x_1; the radius of gear B is R_1. Let n = r.p.m. of n_1 = r.p.m. of B; then the linear velocity of the urface of $A = 2\pi Rn$, and the component of the in the direction of the normal to the tooth pro- $\pi Rn \cos x$. Similarly, for gear B, the component velocity in the direction of the normal to the ofiles is $2\pi R_1n_1 \cos x_1$. When helical gears are in

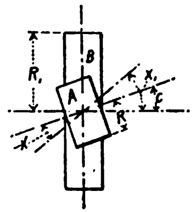

Fig. 142.

owever, the normals to the tooth profiles at the point of contact are nt and the velocities in the direction of the normals are identical in ence $2\pi Rn \cos x = 2\pi R_1n_1 \cos x_1$, or $n/n_1 = R_1 \cos x_1/R \cos x$.

oblem of connecting a pair of shafts by helical gears for any velocity ratio admits oer of solutions, since both the radii of the pitch surfaces and the angles of the tribute to establishing the velocity ratio. The formulæ given in Table 69 nd of assistance in the computation of helical gears. The notation used in this follows:

number of teeth in driver (follower)	a = tooth pitch angle of follower
pitch diam. of driver (follower)	b = tooth pitch angle of driver
circular pitch of driver (follower)	$L_1(L_2)$ = lead of driver (follower).
normal circular pitch for both gears	= lead of tooth helix
normal diametral pitch for both gears	$r_1(r_2)$ = r.p.m. of driver (follower)
outside diam. of driver (follower)	c = angle between shafts in plan
addendum of normal pitch	C = center distance.

Table 69. Formulæ for Helical Gear Calculations

Driver	Follower		Remarks
Formula	To find	Formula	
$\tan b = d_1r_1/d_2r_2$	a	90 deg. $- b$	Axes at right angles only.
$\tan b = p_1/p_2$	a	90 deg. $- b$	
$\cos b = p_n/p_1$	a	$c - b$	
$\tan b = \pi d_1/L_1$	a	$c - b$	
$\pi d_1 \cos b/N_1$	p_n	$\pi d_2 \cos a/N_2$	Same in both gears.
$\pi d_1/N_1$	p_2	$\pi d_2/N_2$	
$p_2N_1 = \pi d_1 \tan a$	L_2	$\pi d_2 \tan b = p_1N_2$	Axes at right angles only.
$d_1P \cos b$	N_2	$d_2P \cos a$	
$2C\Big/\left(\frac{r_1}{r_2}\tan a + 1\right)$	d_2	$2C\Big/\left(\frac{r_1}{r_2}\tan b + 1\right)$	Axes at right angles only.
$2C\Big/\left(\frac{r_1 \cos b}{r_2 \cos a} + 1\right)$	d_2	$2C - d_1$	
$0.3183N_1p_1$	d_2	$0.3183N_2p_2$	
$d_1 + 2S_n$	D_2	$d_2 + 2S_n$	
$d_1 + (2/P)$	D_2	$d_2 + (2/P)$	14½ deg. standard only.
$N_1/\cos^3 b$	Cutter*	$N_2/\cos^3 a$	

Center distance $C = (N_1/2P \cos b) + (N_2/2P \cos a)$

cutter to be used which is correct for the number of teeth given by the formulæ.

When helical gears are used to connect parallel shafts, the normal component of the tangential pressure on the teeth produces end thrust of the shafts. To remove this objection such gears are made with right-handed helical teeth on one side of the face and left-handed on the other, and are then known as **herringbone gears.** Correctly cut herringbone gears run much more smoothly than spur gears, and work silently and without vibration. They can also be run at higher speeds and higher velocity ratios. In the Wuest system, involute teeth with a 20-deg. angle of obliquity are employed, the pitch angle of the teeth being 23 deg. The face width is made equal to 6 × circular pitch p for gears with pinions of not less than 25 teeth, and from $6p$ to $12p$ for high ratios with small pinions. For convenience in manufacture the gears are grooved at the center of the face for a width equal to p and the two sets of teeth are stepped half the pitch apart. Pitch diam. $= n/p_1$ (for 20 teeth and over) $= (0.95n + 1)/p_1$ (for less than 20 teeth), where n = number of teeth and p_1 = diametral pitch. Addendum $= 0.8/p_1$; dedendum $= 1/p_1$; working depth $= 1.6/p_1$.

For strength of helical gears, see p. 732; for efficiency, p. 247.

Strength of Gear Teeth

Spur Gears. According to Wilfred Lewis (*Proc. Engr. Club of Phila.*, Jan., 1893), the load in pounds transmitted by spur gear teeth is

$$W = fbpy, \tag{1}$$

where f = intensity of stress of the material, lb. per sq. in.; b = width or face of gear, in.; p = circular pitch, in.; and y = a factor depending on the form of the tooth and the number of teeth in the gear. For involute teeth with an angle of obliquity of 20 deg., $y = 0.154 - (0.912/n)$, where n = number of teeth in the gear. For involute teeth with an angle of obliquity of 15 deg. and for cycloidal teeth, $y = 0.124 - (0.684/n)$. Values of y from these formulæ are given in Table 70.

Table 70. Values of Factor y in the Lewis Formula for Strength of Gears

No. of teeth	Value of factor y: Involute, 20 deg.	Involute 15 deg. and cycloidal	Radial flanks	No. of teeth	Value of factor y: Involute, 20 deg.	Involute 15 deg. and cycloidal	Radial flanks	No. of teeth	Value of factor y: Involute, 20 deg.	Involute 15 deg. and cycloidal	Radial flanks
12	0.078	0.067	0.052	20	0.102	0.090	0.060	43	0.126	0.110	0.068
13	0.083	0.070	0.053	21	0.104	0.092	0.061	50	0.130	0.112	0.069
14	0.088	0.072	0.054	23	0.106	0.094	0.062	60	0.134	0.114	0.070
15	0.092	0.075	0.055	25	0.108	0.097	0.063	75	0.138	0.116	0.071
16	0.094	0.077	0.056	27	0.111	0.100	0.064	100	0.142	0.118	0.072
17	0.096	0.080	0.057	30	0.114	0.102	0.065	150	0.146	0.120	0.073
18	0.098	0.083	0.058	34	0.118	0.104	0.066	300	0.150	0.122	0.074
19	0.100	0.087	0.059	38	0.122	0.107	0.067	rack	0.154	0.124	0.075

The 15-deg. involute system is the more universal in practice and further discussion of formula (1) will be confined to this particular case. If in (1) y be expressed as a function of the circular pitch, by writing $n = \pi D/p$, the formula becomes

$$p = D(0.28 - \sqrt{0.079 - (4.57W/bfD)}$$

Thus, for a gear of given diameter and given load, the circular pitch for any width of gear and limiting stress may be determined. In (1) the number of teeth and the circular pitch are both unknown. The application of this formula requires the selection of the width of gear and the working stress. It is usual to limit the width or face of gear to about 3 times the circular pitch, for under this assumption the strength of the tooth in case the load is applied at one corner will be equal to the strength when the load is uniformly distributed over the face. Table 71 gives values of the safe working stress f for different materials over a wide range of speeds. Metallic spur gears should not be run at a peripheral speed exceeding 2000 ft. per min.; above

Table 71. Values of the Factor f in the Lewis Formula for Strength of Gear Teeth

Material of gear	Speed of pitch circle, ft. per min.							
	100 or less	200	300	600	900	1200	1800	2400
Cast iron	8,000	6,000	4,800	4,000	3,000	2,400	2,000	1,700
Cast steel	20,000	15,000	12,000	10,000	7,500	6,000	5,000	4,300
Forged steel	25,000	20,000	16,000	13,000	10,000	7,500	6,300	5,400
Rawhide	5,000	4,000	3,000	2,500	2,000	1,600	1,200	......
Bronze	12,000	9,000	7,000	6,000	4,500	3,600	3,000	2,500
Rawhide*	....	3,600	3,500	3,100	2,700	2,400	1,900	......

* General Electric Co. practice.

1200 ft. per min. ordinary cut gears are objectionable on account of the noise made. The General Electric Co. uses the formula $C = WV/nb$, for **rawhide pinions**, in which V = velocity at pitch diameter, ft. per min., the maximum allowable values for C being as follows:

For diametral pitch =	1	1½	2	2½	3	3½	4
C =	1600	1400	1200	1000	900	800	600

The New Process Rawhide Co. (*Am. Mach.*, Apr. 6, 1911) states that the working stress of high-grade rawhide gears may be taken as $150bp$, but in no case should the pressure per inch of face exceed 250 lb. Pinions with bronze flanges cut through and forming part of the working face may have pressures from 10 to 25 per cent. greater, depending on the quality of the metal and the thickness of the flanges. Rawhide gears should be slightly lubricated with a mixture of graphite and lard oil or tallow. **Cloth pinions** (layers of cotton cloth soaked in machine oil and clamped between end flanges) generally have the same strength as cast-iron gears of the same dimensions. The face width of the pinion should equal that of its mating gear plus the sum of the end play of both shafts. The flanges should never engage with the mating gear.

Should it be required to determine the circular pitch, p, of a pinion having a given number of teeth to take the twisting moment (T) of the shaft on which it is keyed, the following expression may be used: $p^3 = 2\pi T/[nfe(0.124 - 0.684/n)]$, where $e = b/p$, or diametral pitch$^3 = 5nfe \times (0.124 - 0.684/n)/T$. For the particular case of a 15-tooth pinion the last formula reduces to: diametral pitch $= 2.6\sqrt[3]{f/T}$, where the width of the gear is 3 times the circular pitch, that is, $e = b/p = 3$. T = in.-lb.

The **strength of stub teeth** cannot be computed by the Lewis formula. An 8–10 stub-tooth gear is one whose diametral pitch is 8 and whose addendum and dedendum circles are those of a standard 10-pitch gear. A stub-tooth gear will carry a greater load than a standard-tooth gear in the ratio of the two pitches dimensioning the stub tooth, that is, the 8–10 stub tooth will take 10/8 of the load of a standard 8-pitch tooth.

Bevel Gears. The strength of bevel-gear teeth is determined on the basis that a spur-gear tooth having the same face width and form and size as the bevel gear at the middle of its face, has the strength of the bevel-gear tooth.

Let Fig. 143 represent a bevel gear, in which p' = circular pitch at larger end; p = circular pitch at middle of gear face = $p'(A + a)/2A$; b = width of gear face; W_M = mean value of load on bevel-gear tooth per in. length of contact line. W_R = resultant of all unit pressures in bevel-gear tooth; W' = load which if applied at greatest pitch radius of gear (A) would produce the same torque in gear shaft as the actual load acting along face. Then $W_M = 3A(A^2 - a^2)W'/2(A^3 - a^3)b$. Assume that the pressure varies directly as the radius. After the bevel gear has been laid out so that A, a, R and c become known, the circular pitch at the middle of the gear face can be determined from the relation $p = D(0.28 - \sqrt{0.079 - 4.57\,W_M/bfD})$, where $D = 2R$ and W_M is found as above. Then $p' = 2Ap/(A + a)$.

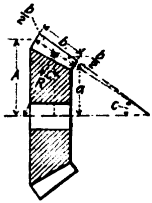

FIG. 143.

The strength of bevel-gear teeth may also be determined by using the following modification of the Lewis formula for spur-gear teeth: $W = fbpyd/D$, in which d and D are respectively the pitch diameters at the smaller and larger ends of the gear. This formula applies only when $d \geq 0.66D$.

Shrouding the teeth increases their strength very considerably, and it is safe to assume that full **shrouding** will give double the strength and half shrouding an increase in strength of nearly 50 per cent.

Herringbone Gears. Safe working pressure (lb.) on the teeth of Wuest gears = $W = 0.4pbk$, where p = circular pitch, b = width of face (both in in.) and k has the following values determined by experiment:

	Velocity of pitch circle, ft., per min.							
	200	400	800	1200	1600	2000	2400	2800
High-carbon-steel forgings	....	....	1550	1440	1320	1220	1120	1050
Steel castings	1300	1200	1100	1100	920	820	770	700
Phosphor bronze	1100	1040	920	830	750	690	630	590
Gun metal	960	880	750	650	580	530	500	460
Cast iron	760	690	590	500	450	410	390	370
Brass	600	520	440	400	360	330	310	300

Also W = h.p. × 33,000/V, where V = velocity of pitch circle, ft. per min.

Worm Gears. The allowable load (lb.) on worm-gear teeth = $W = cbp$, where b = width of tooth and p = circular pitch—both in in., and c = constant = 285 to 425 for cast-iron cut teeth = 455 to 711 for phosphor-bronze wheel and hardened steel worm such as are used for high speeds. These values are for the strength of the teeth only. For continuous running where heating and wear must be taken into consideration, c should have about the following values in the case of a phosphor-bronze wheel and a hardened and polished worm running in an oil bath:

For peripheral velocity of worm, ft. per sec. =	3.3	8.2	13.1	18	23
c =	426–570	356–426	285–340	213–256	142–170

Helical Gears. According to Unwin, $W = 0.0833bpf\cos^2 x$, where x = pitch angle of teeth, and f has the same values as for spur-gear teeth.

Proportions of Gear-wheel Parts

Gear Arms of **elliptical section** may be conveniently proportioned by means of the following equations:

Let Z = section modulus of arm at hub; p = circular pitch, in.; d.p. = diametral pitch; b = width of face; $R = b/p$; n = number of teeth in the gear; N = number of arms;

D = thickness of arm at base; $2D$ = width of arm at base. Then, upon equating the strength of the tooth to that of the arm considered as a cantilever and taking an equal share of the load, there results

$$Z = p^3R(n - 7)/50N = \pi^3R(n - 7)/[50N(\text{d.p.})^3]$$

$$\text{and } D = \sqrt[3]{p^3R(n - 7)/20N} = \sqrt[3]{1.57R(n-7)/N(\text{d.p})^3}.$$

In case **arms of cruciform or T section** are desired, find the dimensions of an arm of elliptical section as above and then determine a cruciform or T section of equal section modulus. The section moduli of elliptical, T and cruciform sections of the proportions shown respectively in Figs. 144, are $0.4E^3$, $0.04E^3$ and $0.04E^3$, respectively. The **number of arms** may be 6 for gears up to 60 in. in diam., 8 for 60 to 80 in., and 10 for gears over 80 in. in diam.

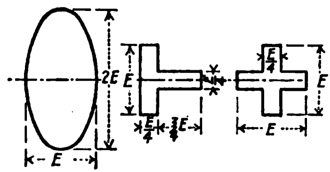

FIG. 144.—Gear-arm Sections.

Rims of gear wheels may be made of a thickness equal to half the circular pitch, tapering to an increased thickness where they join to the arms. Generally, **face width** = $2\frac{1}{2}\ p$ to $3p$.

Hubs may have an outside diam. equal to $1\frac{1}{2}$ to 2 times the shaft diameter, with a reinforcement at the keyway equal to one-half the key thickness.

Efficiency of Gearing in Power Transmission

(See p. 246)

Spur and Bevel Gears. The efficiency of power transmission by the use spur gears and bevel gears varies from 90 per cent. to 98 per cent. The conditions tending to a low efficiency are (1) high ratio of gear diameters; (2) non-lubrication of the tooth surfaces; (3) inaccurate tooth outlines; and (4) inaccuracy in alignment.

The efficiency of **worm gearing,** when the friction of the thrust bearing is neglected, is $E = (\tan a)(1 - f \tan a)/(\tan a + f)$ approx., where a = angle of thread, and f = coefficient of friction. With values of $f = 0.025$ and 0.05 the variation of efficiency with thread angle is as shown in Fig. 145.

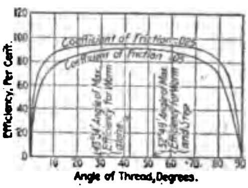

FIG. 145.—Efficiency of Worm Gearing.

Self-locking worms are obtained when $f = \tan a$. The efficiency resulting with such angles can never be as much as 50 per cent. In practice, $\tan a$ can be made greater than f and the gear will be self-locking because of the friction in other parts of the drive.

To find the **pitch** of worm-wheel teeth and the largest pitch diameter of worm **to transmit a given horse power** at a given speed at maximum efficiency the diagram shown in Fig. 146 may be employed (*Machy.*, May, 1912). To transmit 7 h.p. with a single thread worm at 360 r.p.m. there is required, as shown by the diagram, a worm pitch diam. of 3 in. and a circular pitch of worm-wheel teeth of $1\frac{1}{4}$ in. For cast-iron worm wheels and worms with **unfinished teeth,** the pitch should be $1\frac{1}{2}$ times that obtained from the diagram.

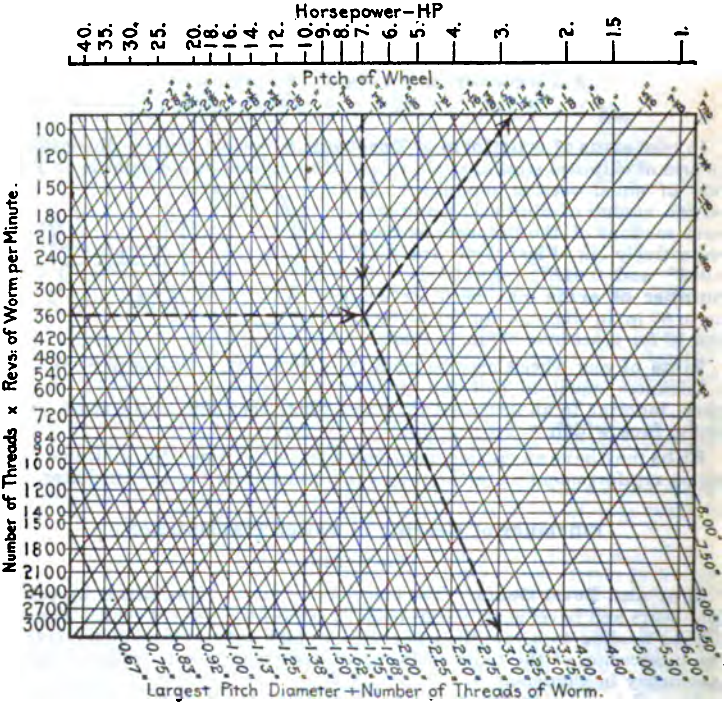

FIG. 146.—Diagram for Designing Worm Gearing of Maximum Efficiency.

Materials for Gears

(See also pp. 541 for phosphor bronze)

For cast-iron gears the compositions given in Table 72 are used. For phosphor-bronze worm wheel with steel worm, a satisfactory composition is: Cu, 89.5 per cent. Sn, 10 per cent., P, 0.5 per cent.

For **alloy steels for automobile transmission gears,** see S.A.E. specifications, p. 465.

Table 72. Compositions of Cast Iron for Gears

	Si	S	P	Mn	Total carbon
Large gears........................	1.00-1.50	0.08-0.10	0.30-0.50	0.80-1.00	Low
Medium gears.....................	1.50-2.00	under 0.09	0.40-0.60	0.70-0.90	....
Small gears........................	2.00-2.50	under 0.06	0.50-0.70	0.60-0.80	....

Friction Gearing

Friction gearing of either the spur or bevel gear type may be used for the transmission of power. In either case it is good practice for the driver to be of paper, leather, or pulp composition, and the driven wheel of metal, which may be iron, type metal, aluminum, etc. Goss (*Trans. A. S. M. E.*, vol. 29, 1907), reports as follows on the characteristics of friction drives:

The **safe working pressures** in lb. per sq. in. are as follows: Straw fiber, 150, leather fiber, 240; tarred fiber, 240; sulphite fiber, 140; leather, 150. They are taken as 20 per cent. of the ultimate resistance of the material to crushing.

The safe working values of the **coefficient of friction** may be 60 per cent. of the values found from laboratory experiments. The frictional and power coefficients in Table 73 are calculated upon this basis.

Table 73. Frictional and Power Coefficients for Friction Gearing

H.p. transmitted $= kwdN$

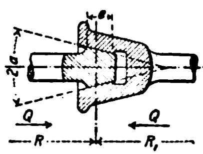
where $w =$ width of face of driver, in.; $d =$ diam. of driver, in.; $N =$ r.p.m.

Driver	Driven wheel	Coefficient of friction	k	Driver	Driven wheel	Coefficient of friction	k
Straw fiber.....	Iron........	0.25	0.00030	Tarred fiber....	Type metal.	0 16	0.00031
Straw fiber.....	Aluminum..	0.27	0.00033	Sulphite fiber...	Iron........	0.33	0.00037
Straw fiber.....	Type metal.	0.18	0.00022	Sulphite fiber...	Aluminum..	0.32	0.00035
Leather fiber...	Iron........	0.31	0.00059	Sulphite fiber...	Type metal..	0.31	0 00034
Leather fiber...	Aluminum..	0.30	0.00057	Leather........	Iron........	0.13	0 00016
Leather fiber...	Type metal.	0.18	0.00035	Leather........	Aluminum..	0.21	0.00026
Tarred fiber....	Iron........	0.15	0.00029	Leather........	Type metal.	0.25	0.00029
Tarred fiber....	Aluminum..	0.18	0.00035				

In the case of **bevel friction gears** the horse power may be had from the above values by taking for N a value which will correspond to the average velocity and radius of the pitch surface. In the case of **wedge-surface friction gears**, as shown in Figs. 147 and 148, the tangential force P for a given normal force Q pressing the wheels together is $P \leq Qf/(\sin a + f \cos a)$, where f is the coefficient of friction. Generally, $a = 10$ to 15 deg. The radial depth of contact of the surfaces e (Fig. 147) should not exceed ¼ in. The **efficiency** of friction drives, according to Ernst, may range from 88 to 90 per cent. In **disk drives** the distance between the face of the driver and the center of the driven wheel should not be less than 12 times the face width of the driver, otherwise the power capacity will be decreased due to slip.

PULLEYS, FLYWHEELS, SHEAVES, DRUMS

Pulleys for the transmission of power by belting may be purchased in the market in the following types and sizes.



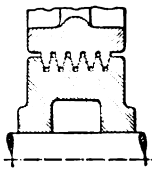


FIG. 147. FIG. 148.
Wedge-surface Friction Gears.

Cast-iron Pulleys, solid or split or with solid rims and split hubs, may have rims of the construction shown in Fig. 149. The **dimensions** to which the several forms of construction are made by the Hill Clutch Co., are as shown in Table 74. The **number of arms** is usually as follows: For pulleys less than 15 in. in diam., 4 arms; for 15-in. to 40-in. pulleys, 6 arms; for 40-in. to 150-in. pulleys, 8 arms. Pulleys with faces less than 20 in. wide, 1 set of arms; with faces from 20 to 50 in. wide, 2 sets; with faces over 50 in. wide, 3 sets. These proportions apply to thin-rim cast-iron belted pulleys and not to flywheels or heavy band wheels. The Medart Patent Pulley Co., of St. Louis, Mo., makes **pulleys with wrought-iron rims** and cast-iron spiders which are adapted to higher speeds than cast-iron pulleys.

Table 74. Face Widths of Standard Cast-iron Pulleys
(Letters refer to Fig. 149)

Diam., in.	A Max. face, in.	C Face, in.	Diam., in.	A Max. face, in.	C Face, in.	Diam., in.	A Max. face, in.	C Face, in.	Diam., in.	A Max. face, in.	C Face, in.

16	17	18	21	20	21–26	36–47	22	23–36	....	......	......

Wood Split Pulleys may be obtained from a number of makers with diameters from 3 in. to 96 in. and with a large range of face widths, at prices approximately 20 per cent. less than for cast-iron pulleys. Wooden pulleys should be avoided in damp places and for high speeds.

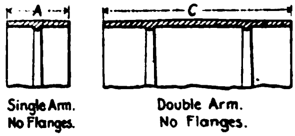

Fig. 149.—Pulley Rim Constructions.

Paper Pulleys transmit power at less loss than cast-iron-face pulleys.

Pressed-steel Pulleys are adapted to use at higher speeds than are cast-iron pulleys.

Stresses in Pulleys, Sheaves and Flywheels—Proportions

Arms of pulleys, sheaves and flywheels are subjected to stresses due to conditions of founding, to details of construction (such as split or solid), and to conditions of service, which do not readily admit of analysis. For this reason no accurate stress relations can be established, and the following formulæ must be understood to be only approximately correct. It has been established experimentally by Benjamin (*Am. Mach.*, Sept. 22, 1898) that thin-rim pulleys do not distribute equal loads to the several pulley arms. For these, it will be safe to assume the tangential force on the pulley rim as acting on half the number of arms. Pulleys with comparatively thick rims, such as engine band wheels, have all the arms taking the load. Furthermore, while the stress action in the arms is similar to that in a beam fixed at both ends, the amount of restraint at the rim depending on the rim's elasticity, it may, nevertheless, be assumed for purposes of design that cantilever action is predominant. The bending moment at the hub in arms of thin-rim pulleys will be $M = PL/\frac{1}{2}N$, where M = bending moment, in.-lb.; P = tangential load on the rim, lb.; L = length of the arm, in., and N = number of arms. For thick-rim pulleys and flywheels, $M = PL/N$.

For arms of elliptical section having a width of two times the thickness, where E = **width of arm section** at the rim, in., and f_t = intensity of tensile stress, lb. per sq. in.,

$$E = \sqrt[3]{40PL/f_tN} \text{ (thin rim)} = \sqrt[3]{20PL/f_tN} \text{ (thick rim)}$$

For single-thickness belts P may be taken as 50 B lb. and for double-thickness belts P = 75 B lb., where B is the width of pulley face, in. Then $E = k \times \sqrt[3]{BL/f_tN}$, where k has the following values: For thin rim, single belt, 13; thin rim, double belt, 15; thick rim, single belt, 10; thick rim, double belt, 12.

For cast iron of good quality f_t due to bending may be taken at 1500 to 2000. The arm section at the rim may be made from $\frac{2}{3}$ to $\frac{3}{4}$ the dimensions at the hub.

For high-speed pulleys and flywheels it becomes necessary to check the arm for tension due to rim expansion. It will be safe to assume that each arm is in tension due to one-half the centrifugal force of that portion of the rim which it supports. That is, $T = Af_t = Wv^2/2NgR$ (lb.) where T = tension in arm, lb.; N = number of arms; v = speed of rim, ft. per sec.; R = radius of pulley, ft.; A = area of arm section, sq. in.; W = weight of pulley rim in lb. and f_t = intensity of tensile stress in arm section, lb. per sq. in. Whence $f_t = WRn^2/5800NA$, where n = r.p.m. of pulley.

Arms of flywheels having heavy rims may be subjected to severe stress action due to the inertia of the rim at sudden load changes. There being no means of predicting the probable maximum to which the inertia may rise, it will be safe to make the arms equal in strength to $\frac{3}{4}$ of the shaft strength in torsion. Accordingly, for elliptical arm sections,

$$N \times 0.5E^3f_t = \tfrac{3}{4} \times 2f_sd^3, \text{ or } \quad E = 1.4d\sqrt[3]{f_s/f_tN}$$

For steel shafts with $f_s = 8000$ and cast-iron arms with $f_t = 1500$,

$$E = 2.4d/\sqrt[3]{N} = 1.3d \text{ (for 6 arms)} = 1.2d \text{ (for 8 arms)}$$

where E = width of elliptical arm section at hub, in. (thickness = $\frac{1}{2}E$) and d = shaft diameter, in.

Rims of belted pulleys cast whole may have the following proportions (see Fig. 150):

$$t_2 = \tfrac{3}{4}s + 0.005D; \quad t_1 = 2t_2 + C; \quad w = \tfrac{9}{8}B \text{ to } \tfrac{5}{4}B;$$

where s = belt thickness, $C = \frac{1}{24}w$, and B = belt width, all in inches.

Engine band wheels, flywheels and pulleys run at **high speeds** are subjected to the following stress actions in the rim:

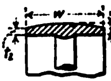

FIG. 150.

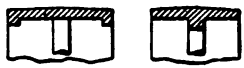

FIG. 151.

Rims for Belted Pulleys.

Considering the rim as a free ring (*i.e.*, without arm restraint) and made of cast iron or steel, $f_t = v^2/10$ (approx.), where f_t = intensity of tensile stress, lb. per sq. in. and v = rim speed, ft. per sec. For beam action between the arms of a solid rim, $M = Pl/12$ (approx.), where M = bending moment in rim, in.-lb.; P = centrifugal force of that portion of rim between arms, lb., and l = length of rim between arms, in.; from which $f_t = WR^2n^2/450N^2Z$, where W = weight of entire rim, lb.; R = radius of wheel, ft.; n = r.p.m. of wheel, and Z = modulus of rim section, in.^{3}. In case the rim section is of the forms shown in Fig. 151, care must be taken that the flanges do not reduce the section modulus from that of the rectangular section. For **split rims** fastened with bolts as shown in Fig. 152, the stress analysis is as follows:

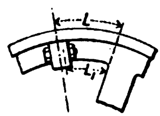

FIG. 152.

Let w = weight of rim portion L inches in length, lb.; w_1 = weight of lug, lb.; L_1 = lever arm of lug, in., and f_t = intensity of tensile stress in rim section joining arm. Then $f_t = 1.25n^2R(w_1L_1 + wL/2)/Z$, where n = r.p.m. of wheel; R = wheel radius, ft.; and Z = modulus of rim section. The above equation gives the value of f_t for bending when the bolts are loose, which is the worst possible condition that may arise. On this basis of analysis f_t should not be

47

greater than 8000. The stress due to bending in addition to the stress due to rim expansion as analyzed previously will be the probable maximum intensity of stress for which the rim should be checked for strength. The flange bolts, because of their position, do not materially relieve the bending action. In case a tie rod leads from the flange to the hub it will be *safe* to consider it as an additional factor of safety. When the tie rod is kept tight it very materially strengthens the rim.

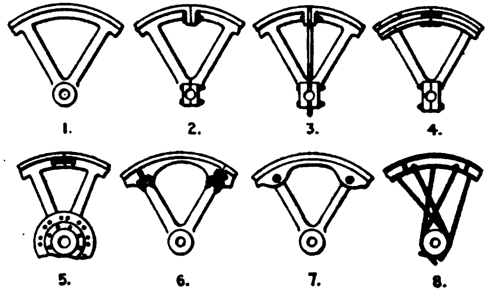

FIG. 153.—Types of Flywheel Construction (see Table 75).

The Relative Strengths of Different Types of Wheel Construction are shown by the results of Benjamin's experiments on the bursting of flywheels (*Trans. A. S. M. E.*, 1899, 1902). The types of wheels experimented with and the speeds at which they burst are shown in Fig. 153 and Table 75.

Table 75. Test Data on the Flywheels of Fig. 153

Number.*	1	2	3	4	5	6	7	8
Number of arms	6	6	6	6	8	6	6	24

Comparative rim speeds at failure	100	49	57	77	65	56.5	100	107
Apparent rim tension at failure, lb. per sq. in. = $v^2/10$	15,625	3,764	5,062	9,302	6,502	4,973	15,445	17,978
Efficiency† of construction	0.85	0.19	0.265	0.49	0.34	0.26	0.84	0.94

Flywheels of the shrunk-link-joint type may be constructed as shown in Fig. 154 and to the dimensions given in Table 76. With cast-iron flywheels the bearing pressure on the link may be 20,000 lb. per sq. in. and the maximum shear on the head of the link 5600 lb. per sq. in. The length of the link may be made 0.999D, which gives an initial tension in the link of 30,000 lb. per sq. in. Proportions of **rims and arms of engine band wheels** are given in Tables 77 and 78.

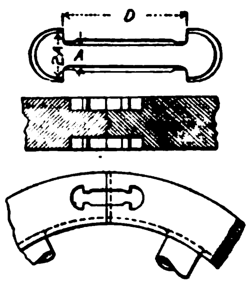

FIG. 154.—Shrunk-link Joint for Flywheels.

Allis-Chalmers Co. has a two-part cast-iron hub, between which parts are bolted hollow cast-steel arms each cast integral with its proportion of a narrow, deep rim. The rim sections are connected by shrink links and the rim is reinforced on each side by several layers of steel plates riveted to it, the plates being arranged to break joints. A wheel made by the Westinghouse Elec. & Mfg. Co. for use in a rolling mill has a cast-steel spider with two sets of rectangular-section arms. The face of the spider is machined parallel to the shaft with dovetailed grooves, into which laminated steel sheets are fitted (the joints overlapping) and bound together by bolts passing through cast-steel end plates to form the rim.

Rims of Pulleys for Cotton and Manila Rope Drives may be made as shown in Fig. 155 and 156 and to the dimensions given in Table 79, which represent the practice of the Allis-Chalmers Co.

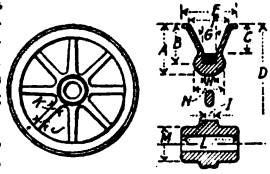

FIG. 157.—Sheaves for Wire Rope.

In the American (continuous) system of rope driving (see Rope Drives) of the Dodge Mfg. Co. the rim grooves have an angle of 60 deg., and for 1-in. rope, the dimensions *D*, *E*, *B* and *L* (see Fig. 155) are 11/16, 13/16, 1 1/8 and 5/8 in., respectively.

The practice of the Brown Hoisting Machinery Co. in the proportioning of **sheaves for iron and steel ropes** is given in Fig. 157 and Table 80.

[4] Straight ribbed arms.

For **hoisting sheaves,** see p. 1107.

Sheaves for ordinary **link chains** may be proportioned as shown in Figs. 158 and 159. The pitch diameter D is given by the equation

$$D^2 = (r/\sin a)^2 + (d/\cos a)^2$$

where a = 90 deg. divided by the number of teeth in the wheel. Values of sin a and cos a are given in Table 81.

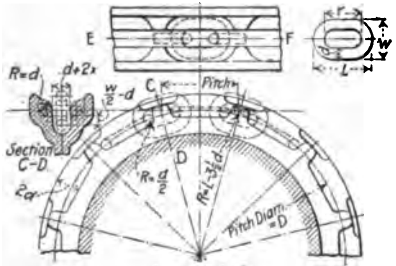

FIG. 158.—Sheave for Link Chain.

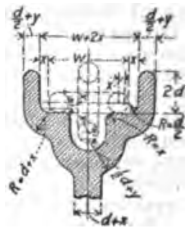

FIG. 159.

Table 81. Sprocket Wheels for Ordinary Link Chains

(Values of a, sin a and cos a for use in the formula:

Pitch diam. $D = \sqrt{(r/\sin a)^2 + (d/\cos a)^2}$. See Figs. 158–159)

Table 82. Dimensions of Sprocket Wheel Chains

(Letters refer to Fig. 158. d = diam. of stock in link, in.; L and W = outside length and width of link, in.)

d	L	W	d	L	W	d	L	W	d	L	W
3/16	1 3/8	13/16	1/2	2 1/2	1 3/4	13/16	4	2 11/16	1 1/4	6	4 1/4
1/4	1 1/2	1	9/16	2 7/8	1 15/16	7/8	4 1/4	3	1 3/8	6 1/2	4 3/4
5/16	1 3/4	1 3/16	5/8	3 1/4	2 1/8	15/16	4 1/2	3 1/4	1 1/2	7 1/4	5 1/4
3/8	2	1 3/8	11/16	3 1/2	2 5/16	1	4 3/4	3 1/2	1 5/8	7 7/8	5 3/4
7/16	2 1/4	1 9/16	3/4	3 3/4	2 1/2	1 1/8	5 1/2	3 7/8	......	......	......

The value of r, the internal length of the link, is given by $r = L - 2d$, where L is the outside length of the link and d is the diameter of chain stock. These last quantities and the width of the link W are given in Table 82. In Figs. 158 and 159, x = 3/32 in. for d = 1/4 to 1/2 in.; = 1/8 in. for d = 1/2 to 1 1/8 in.; = 5/32 in. for d = 1 1/4 to 1 5/8 in. y is 3/32 in. for d = 3/16 to 7/16 in., and 1/16 in. for d = 1/2 to 15/16 in.

Drum Scores for Cables and Chains may be made as illustrated in Figs. 160–162, with the dimensions given in Table 83.

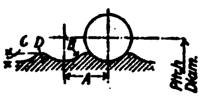
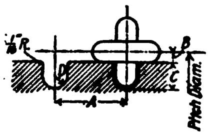
Strength of Hoisting Drums. Let W = total load to be hoisted, lb.; l = distance c. to c. of bearings, in.; d = diameter of drum at bottom of grooves, in.; d_1 = inside diameter of drum, in.; Z = section modulus = $0.0982\,[d^3 - (d_1^4/d)]$; M = bending moment on drum = $Wl/4$; P = tension in each





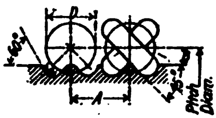


FIG. 160. FIG. 161. FIG. 162.

Drum Scores for Cables and Chains.

rope or chain supporting the load, lb.; p = pitch of grooves, in.; $t = \frac{1}{2}(d - d_1)$ = thickness of drum at bottom of grooves, in. Then, for cast-iron drums, to resist bending stresses, M/Z should not exceed 3000 lb. per sq. in.; to resist crushing stresses, $K = \sqrt{(M/Z)^2 + (P/pt)^2}$ should not exceed 6000 lb. per sq. in. For example, assume W = 10,000 lb., P = 5000 lb. (2 ropes), d = 15 in., l = 80 in., and $p = \frac{3}{4}$ in. Taking 12.5, 13 and 13.5 in. as trial values of d_1, the formula of K works out respectively as 5550, 6813 and 9060. The economical value (6000) therefore results when d_1 lies between 12.5 and 13 in. Taking d_1 = 12.75 in., K = 6060 and M/Z = 1263, both of which practically fulfill the conditions stated.

For **hoisting drums,** see p. 1107.

BELT DRIVES

(For the properties of belt materials, see p. 621)

Leather Belts of the best quality are those made from the "butt" of the hide. The ultimate tensile **strength** of leather used in belts varies from 3000 to 5000 lb. per sq. in. Average values of the breaking strength of good oak-tanned belting, as determined by Benjamin, are as follows:

	Breaking strength per inch of width, lb. Single belts	Double belts
Solid leather	900	1400
At riveted joint	600	1200
At laced joint	350	....

The **weight** of leather belting is about 0.035 lb. per cu. in. Single belts average from 0.22 in. to 0.25 in. in **thickness**, and double belts from 0.33 to 0.35 in. Rawhide, semi-rawhide, (*i.e.*, surface-tanned rawhide), and chrome-tanned (green) belts are not as serviceable in dry places as oak-tanned belts. Rawhide and chrome-tanned belts give good service in damp places, such as dye-houses.

Cotton and Canvas Belts weigh from 0.026 to 0.05 lb. per cu. in., the heavier qualities containing more sizing and frequently being waterproofed. Cotton belts are made in 2-ply from 1 to 24 in. wide; 3-ply, from 1½ to 24 in.; 4-ply, from 2 to 24 in.; 5-ply, from 4 to 24 in., and 6-ply, from 6 to 24 in. The widths increase by ½ in. from 1 in. up to 4 in., by 1 in. from 4 in. to 10 in., and by 2 in. from 10 in. to 24 in. Canvas belts are obtainable in 4-ply from 1½ to 18 in. wide; in 6-ply from 3 to 30 in.; in 8-ply from 4 to 48 in., and in 10-ply from 12 to 60 in. The widths increase by ½ in. from 1½ to 5 in.; by 1 in. from 5 to 14 in.; by 2 in. from 14 to 32 in.; widths above 32 in. are 36, 40, 48, 54 and 60 in. Canvas belting has about the same **strength** as leather belting.

Rubber Belts are specially adapted for use in damp places and out of doors. The rubber, however, when poor or softened by animal oil or grease, is liable to peel off, especially on belts which are frequently shifted. Rubber belting **weighs** about 0.045 lb. per cu. in. Four-ply belting, according to Benjamin, has an ultimate tensile **strength** of from 890 to 930 lb. per sq. in. Bach recommends a **working tension** of from 100 to 150 lb. per sq. in. Rubber belts are made in the following widths and thicknesses: 2-ply, 3-ply and 4-ply, from 1 to 60 in. wide; 5-ply, from 1½ to 60 in.; 6-ply from 2 to 60 in.; 7-ply, from 4 to 60 in.; 8-ply, from 6 to 60 in. The widths increase by ¼ in. from 1 in. to 2 in.; by ½ in. from 2 to 5 in.; by 1 in. from 5 to 16 in.; by 2 in. from 16 to 60 in.

Steel Belts have been used with success in Germany during the past few years, in thicknesses ranging from 0.008 to 0.044 in. and up to 10 in. in width. They are made from a special steel, tempered, and fitted with a joint fastened by screws. The belts are made at the factory to a length just enough less than the exact length around the pulleys where they are to be used to produce the proper initial tension when in working position. The pulleys on which they run are cylindrical—without crown—with cork-faced canvas cemented around them, which practically does away with slip. The effect of centrifugal force is negligible, and speeds up to 19,000 ft. per min. have been reported. The cross-section per h.p. transmitted at a speed around 3000 ft. per min. is about 0.00072 sq. in.

Belt Joints. Cemented joints when properly made have a strength equal to that of the solid leather. **Leather-laced and riveted joints** are about ½ and ⅔ as strong respectively as the solid leather. **Wire-laced joints** have from 85 to 90 per cent. of the strength of solid leather. Heavy metal belt joints should not be used on belts run at high speeds.

Arrangements for Belt Drives. In belt drives the center line of the belt advancing on the pulley should lie in a plane passing through the mid-section of the pulley at right angles to the shaft. Shafts inclined to each other require connection as shown in Fig. 163. In case **guide pulleys** are needed, their positions can be determined as shown in Figs. 164, 165 and 166. In Fig. 165 the center circles of the two pulleys to be connected are set in correct relative position in two planes, a being the angle between the planes (= supplement of angle between shafts). If any two ıs E and F be assumed on the line of intersection MN of the planes, and ts EG, EH, FJ and FK be drawn from them to the circles, the center of the guide pulleys must be so arranged that these tangents are also

63.

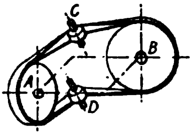

FIG. 164.

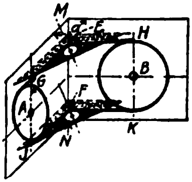

FIG. 165.

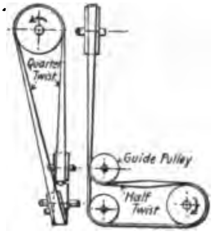

FIG. 166.

Arrangements for Belt Drives.

;s to them, as shown. In other words, the middle planes of the guide must lie in the planes GEH and JFK. When these conditions are ꜿ belts will run in either direction on the pulleys.

void the necessity of taking up the **slack** in belts which have become ꜿd and permanently lengthened, a **belt tightener** ı shown in Fig. 167 may be employed. It should ꜿed on the slack side of the belt and nearer the pulley than the driven pulley.

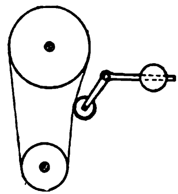

FIG. 167.—Belt Tightener.

;th of Belt for a Given Drive. The length of an **elt** for a given drive is equal to $L = \frac{1}{2}\pi D + \frac{1}{2}\pi d$ $c^2 + (R - r)^2$, where L = length of belt, in.; D = of large pulley, in.; d = diam. of small pulley, $= \frac{1}{2}D$; $r = \frac{1}{2}d$, and x = distance between pulley ı.

n a **crossed belt** is used, the length is

$$L = \tfrac{1}{2}\pi D + \tfrac{1}{2}\pi d + 2\sqrt{x^2 + (R + r)^2}.$$

Pulleys. In the case of belts operating on cone pulleys, the pulley ꜿrs must be such that the belt will fit over any pair with equal tightness. **·ossed belts,** it will be apparent from the equation for length of belt that ı of the pulley diameters need only be constant ıe belt may fit with equal tightness on each pulleys. With open belts the length is a function both the sum and the difference of the pulley ꜿrs, hence no direct solution of the problem is ꜿ.

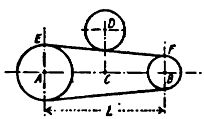

FIG. 168.

ıphical method devised by C. A. Smith (*Trans.* Γ. *E.*, vol. 10) is shown in Fig. 168. Let A and ıe centers of any pair of pulleys in the set, the diameters of which are or assumed. Bisect AB in C and draw CD at right angles to AB. $D = 0.314$ times the center distance L and draw a circle tangent to the e EF. The belt line of any other pair of pulleys in the set will then ʒent to this circle. If the angle EF makes with AB is greater than ., draw a tangent to the circle D making an angle of 18 deg. with AB ›m a center on CD distant $0.298L$ above C draw an arc tangent to this 18-deg. line. All belt lines with angles greater than 18 deg. will be tangent to this last-drawn arc.

A very slight error in a graphical solution drawn to any scale much under full size, will introduce an error seriously affecting the equality of belt tensions on the various pairs of pulleys in the set, and where much power is to be transmitted it is advisable to calculate the pulley diameters from the following **formulæ** derived from Burmester's graphical method ("Lehrbuch der Mechanik").

Let D_1 and D_2 be respectively the diameters of the smaller and larger pulleys of a pair, $n = D_2/D_1$, and l = distance between shaft centers, all in in. Also let $m = 1.58114l - D_0$, where D_0 = diam. of both pulleys for a speed ratio $n = 1$. Then $(D_1 + m)^2 + (nD_1 + m)^2 = 5l^2$. First settle on values of D_0, l and n and then substitute in the equation and solve for D_1. The diam. D_2 of the other pulley of the pair will then be nD_1. The values thus obtained are correct to the fourth decimal place.

The speeds given by cone pulleys should increase in a **geometrical ratio**, that is, each speed should be multiplied by a constant a in order to obtain the next higher speed. Let n_1 and n_2 be respectively the lowest and highest speeds (r.p.m.) desired and k the number of speed changes. Then $a = \sqrt[k-1]{n_2/n_1}$. In practice, a ranges from 1.25 up to 1.75 and even 2. The ideal value for a in machine-tool practice, according to Carl G. Barth, would be 1.189. In the example below this would mean the use of 18 speeds instead of 8.

Example. Let $n_1 = 16$, $n_2 = 400$, and $k = 8$, to be obtained with four pairs of pulleys and a back gear. From formula, $a = \sqrt[7]{25} = 1.584$, whence speeds will be 16, $(16 \times 1.584 =) 25.34$, $(25.34 \times 1.584 =) 40.14$, and similarly 63.57, 100.7, 159.5, 252.6, and 400. The first four speeds are with the back gear in, hence the back-gear ratio must be $100.7 \div 16 = 6.29$.

Transmission of Power by Belts. The turning force (tangential) on the rim of a pulley driven by a flat belt is equal to $T_1 - T_2$, where T_1 and T_2 are respectively the tensions in the driving (tight) side and following (slack) side of the belt. (For the relations of T_1 and T_2 at low peripheral speeds, see p. 248.) $\text{Log}\,(T_1/T_2) = 0.0076fa$ when the effect of centrifugal force is neglected. When the speeds are high, however, the relations of T_1 to T_2 are modified by centrifugal stresses in the belt, in which case $\log\,(T_1/T_2) = 0.0076f(1 - x)a$, where f = coefficient of friction between the belt and pulley surface, a = angle of wrap, in degrees, and $x = 12wv^2/gt$, in which w = weight of 1 cu. in. of belt material, lb.; v = belt speed, ft. per sec.; g = 32.2 ft. per sec.^{2} and t = allowable working tension, lb. per sq. in. Values of x for leather belting (with w = 0.035 and t = 300) are as follows:

For v =	30	40	50	60	70	80	90	100	110	120	130
x =	0.039	0.070	0.118	0.157	0.214	0.279	0.352	0.435	0.526	0.626	0.735

Researches by Barth (*Trans. A. S. M. E.*, 1909) seem to show that f is a function of the belt velocity, varying according to the formula $f = 0.54 - 140/(500 + V)$ for leather belts on iron pulleys, where V = belt velocity in ft. per min. For practical purposes of design, however, the following values of f may be used: For leather belts on cast-iron pulleys, f = 0.30; on wooden pulleys, f = 0.45; on paper pulleys, f = 0.55. The treatment of belts with belt dressings, pulleys with cork inserts, and dampness are all factors which greatly modify these values, tending to make them higher. Canvas belts operate satisfactorily with effective tensions on pulley rims varying from 20 lb. to 23 lb. per inch width per ply. Balata belting will take tensions 15 per cent. greater. These belts should not be laced.

horse power transmitted by a leather belt is

$$\text{h.p.} = (T_1 - T_2)V/33{,}000$$

$T_1 - T_2$ is the difference in belt tensions, lb., and V is the belt velocity, min. It is good practice to allow 35 lb. per in. of width for single id 50 lb. for double belts in roughly estimating the allowable values of ₂. Also, in estimating T_1, it is custo-) allow 70 lb. per in. of width for single id 110 lb. for double belts. When using leather belts it will be found advisable to ie pulley not less than 12 in. in diam.; le belts, not less than 20 in. in diam. 169 gives the **horse power transmit-· inch of belt width** at various speeds arc of contact of 180 deg., according to ctice of Wm. Sellers & Co., Inc. (based ie experiments of Wilfred Lewis, *Trans. I. E.*, vol. 7 and 20) and according to ommendation of C. G. Barth (*Trans. I. E.*, vol. 31). Barth's curves are in-to insure maximum durability of belts applicable to belts with any good joint. ("Handbook for Machine Designers") ends the use of the Sellers curves (*S*) ing belts and of Barth's (*B*) for ma-lts.

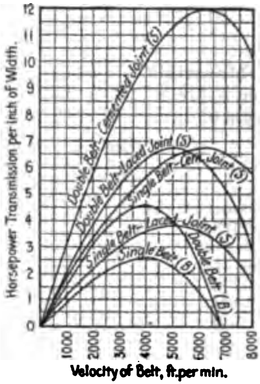

Fig. 169.—Power Transmitted by Belting.

an arc of contact differing from 180 values taken from Fig. 169 should be ed by a factor given in the following table:

con-g.) =	90	100	110	120	130	140	150	160	170	180	190	200	210
=	0.65	0.70	0.75	0.79	0.83	0.87	0.91	0.94	0.97	1.00	1.03	1.05	1.07

rc of contact on the smaller of two pulleys connected by an open belt, s, is approximately equal to $181 - [60(D - d)/l]$, where D and d are r and smaller pulley diameters and l the distance between their shaft all in in. This formula gives an error not exceeding 0.5 per cent.

ral Notes on Belting. The following conclusions are those arrived W. Taylor (*Trans. A. S. M. E.*, vol. 15) after 9 years of experimental machine-shop belting:

, thick belts give better satisfaction than wide, thin belts. Thickness should rith width.

st economical speed is from 4000 to 4500 ft. per min.

t distance between shaft centers is from 20 to 25 ft.

joints should be spliced and cemented. Double belts less than 10 in. wide ve a splice 10 in. long; belts wider than 10 in. should have a splice length he belt width. Rubber belts should have stepped splices, coated with rubber nised in place.

leather belts will last well when repeatedly tightened to an initial tension of 71 of width (= 240 lb. per sq. in.) but will not long maintain this tension.

ening belts, belt clamps with spring balances between them for weighing the ould be used. When their use is impracticable a double belt should be short-; in. for every 10 ft. of length for the ordinary rule of 110 lb. per in. of width 65 lb. per in. of width for the effective pull $T_1 - T_2$), and (*b*) 1 in. for every the more economical rule of 54 lb. for T_1(= 26 lb. for $T_1 - T_2$). Under (*a*) double belts should, with care, last 7 years; under (*b*), 18 years.

In figuring the total expense of belting, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

Oak-tanned and fulled leather double belts should not have the effective pull in excess of 35 lb. per in. of width. At this value the number of linear feet of 1-in. double belt passing around a pulley per min. required to transmit 1 h.p. is 950. For other types of leather belts and 6- and 7-ply rubber belts the corresponding values are 30 lb. and 1100 ft.

ROPE DRIVES

Textile Rope Drives

Materials. Textile ropes are made from cotton, hemp, and Manila hemp fibers, see p. 629. The ultimate **strength,** working strength, and **weight** per ft. of such ropes are approximately as given in Table 84. The

Table 84. Weight and Strength of Textile Ropes

Diam. of rope, in.	Ultimate strength, lb.		Working strength, lb.		Weight, lb. per ft.	
	Cotton	Manila Hemp	Cotton	Manila Hemp	Cotton	Manila Hemp
½	1,150	1,900	50	50	0.06	0.08
⅝	1,800	2,900	78	78	0.10	0.13
¾	2,600	4,100	112	112	0.15	0.18
⅞	3,500	5,500	153	153	0.20	0.24
1	4,600	7,100	200	200	0.26	0.32
1¼	7,200	10,900	312	312	0.40	0.50
1½	10,400	15,000	450	450	0.58	0.72
1¾	14,000	19,800	612	612	0.79	0.98
2	18,400	25,100	800	800	1.04	1.28

values in the table are determined from the following formulæ, which agree with the results of tests and practice:

		Cotton	Hemp and Manila
Ultimate strength in lb.	=	$4600d^2$	$100d^2(81 - 9d)$
Working strength in lb.	=	$200d^2$	$200d^2$
Weight, lb. per ft.	=	$0.26d^2$	$0.32d^2$

Transmission Rope is made with three, four or six strands, the last two having an inner core. Three-strand rope is used for small drives where the rope diameter is less than ⅞ in. or where the rope is subject to much bending. Four and six strands are preferable for larger drives. Cotton rope is more flexible than Manila hemp and may be used for small installations where small pulleys are necessary. It is less desirable than Manila, less strong, more difficult to splice, more expensive, and less resistant to weather.

Transmission ropes **wear** out usually by internal friction, the wear being more rapid as the pulley sizes are diminished. For satisfactory wear the rope must be laid with a lubricant such as graphite. If run in a hot or dry place or exposed to the weather, a slight application of tallow to the rope when in motion will be found beneficial. The **pulley diameter** should never be less than 36 times the rope diameter. The use of a few large ropes, when consistent with the diameter of the smallest sheave, is the better practice, as there are fewer splices to be made, wear is less, and breakdowns are less likely to occur. In general, however, ropes larger than 1¾ in. in diameter should only be used on drives of great magnitude.

Capacity of Ropes for Power Transmission. Good three-strand cotton ropes with an arc of contact of 180 deg. will transmit power in accordance with the values given in Table 85 (Edward Kenyon, *Trans. S. Wales Inst.*

1909). These values correspond to those obtained from the formula: each rope = $0.003265Vd^2$, in which V = rope velocity, ft. per min., = diam. of rope, in. This formula may be used for intermediate ›s and rope sizes. Fig. 170 (from the catalog of the American Mfg.

ms of Rope Driving. There are two general systems of rope driving on use: the multiple, or English, system, and the continuous, or American tem. The **multiple system** consists of one or more independent ınning side by side in the grooves of the sheave wheels or pulleys and is adapted to the transmission of large powers. It is unlikely that ın one rope will fail at a time, and the system therefore is comparacure against a general breakdown. Power may be easily transmitted to the different floors of a mill and the amount of power transmitted may be easily increased by adding new ropes. The ropes always bend in the same direction and therefore wear less rapidly than in the continuous system. Disadvantages are the number of splices needed, unsuitability for outdoor use and for vertical drives. In the **continuous system** (Fig. 171), one rope is wound around the driving and driven sheaves several times, the rope from an outside groove of the driving sheave being guided by an independent sheave around a weighted tightener sheave, thence to the outside groove of the driven sheave. The tightener sheave or **tension carriage** produces a uniform tension in the rope and automatically regulates the slack due to stretch, inequalities of load, etc. The continuous system is especially adapted to vertical and quarter-turn drives (see Fig. 171), where shafts are inclined at an angle to each other, where rope is exposed to the weather, and in cases of complicated transmission. In general, it should also be used where the shafts to be connected are nearer together than 30 ft., as in the multiple system a small amount of stretch will decrease the initial tension to such an extent that the centrifugal force will lift rope from its groove, thereby lessening its driving capacity.

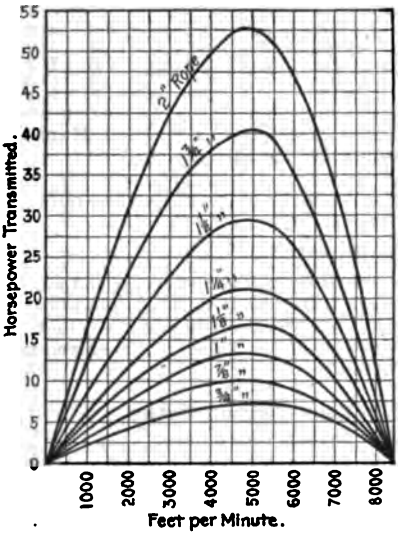

FIG. 170.—Power Transmitted by Cotton Rope.

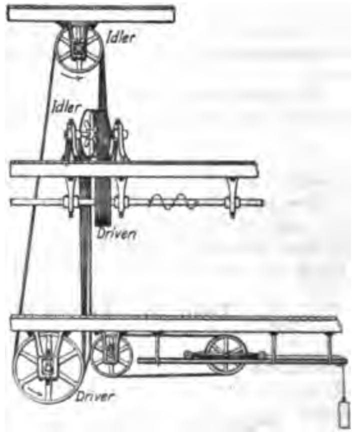

FIG. 171.—Continuous System of Rope Driving.

Rope Sheaves. Proportions for rope sheaves are shown in Figs. 155 and 156 and dimensions therefor are given in Table 79. The **groove angle** generally employed is 45 deg., larger angles permitting the rope to slip slightly under varying loads or overstress. In **idler or carrier sheaves** either 45-deg. or U-shaped grooves may be used. When the drive runs outdoors and the rope is exposed to the wind, the deep U-shaped groove should be used. This groove is $d + \frac{1}{4}$ in. wide at the periphery and slightly deeper than d, where d = rope diameter. Satisfactory driving may be done over distances up to 175 ft. without the use of idlers.

Tension Carriage. For drives over short center distances not more than laps of rope should be cared for by one tension sheave. For longer he number of laps should be reduced in proportion to the length and of the ropes between the driving and driven sheaves. Ordinarily, the m length of rope to be governed by a tension carriage should not 000 ft.

f Ropes. The sag on the driving side of both multiple and continu- ems, measured in feet, $= S = WL^2/8T$, where W = weight of 1 ft. , lb.; L = distance between shafts, ft.; T = maximum allowable in the rope, lb. per sq. in., taken as $200d^2$. The sag on the slack side nined by the same formula, using, however, the tension in the slack place of the maximum allowable tension. Table 88 gives values cal- from the formula. See pp. 147 to 151 for formulæ and tables for th of rope, etc., under various conditions.

Table 88. Sag in Power Transmission Ropes

ing Transmission Rope. Splices should have the same diameter ope itself, should be smooth and free from lumps, and should so be at the fastenings or "tucks" will not wear away and allow the rope to 1. The following instructions for making the English transmission r a 4-strand rope spliced on sheaves in the multiple system, are l from the American Mfg. Co.'s "Blue Book of Rope Transmission:"

t place the rope around the sheaves and stretch it taut with a tackle, the ing each other from 6 to 7 ft., and the passing point being marked with twine ope. Then slip the rope off the sheaves to give sufficient slack for making the . Unlay the strands in pairs as far back as twines M and M', crotch the four trands thus opened (Fig. 172), the cores c having been drawn out together on side. 3. Remove twine M and unlay strands 6 and 8 in pairs back 2 ft. to A rands 1 and 3 carefully in their place. Next unlay 5 and 7 to A' and replace nd 4 (see Fig. 173). 4. Separate strands 6 and 8, unlaying 8 four feet back to 6 at A (Fig. 174). 5. Separate strands 1 and 3, leaving 3 at A as a companion laying 1 in place of 8 until they meet at B. 6. Separate 2 from 4 and 5 from similarly, taking care that the original twist and lay of the strands is main- Trim all projecting strands to 2 ft. in length. 7. Tucking in the Strands. This for strands 2 and 7 (identical for the other three pairs) is performed as follows: nd 7 for 12 to 14 in. (Fig. 175), divide each in half by removing its cover yarns, ends 2′ and 7′ with twine; then, leaving cover 2, relay 2′ until near 7 and 7′, point join 2′ and 7′ with a simple knot (Fig. 176). Divide cover yarns 7 and hrough them, continuing on through the rope *under* the two adjacent strands, the core, thus locking 2′ (Fig. 177). In no event pass 2′ over these or any other At the right of knot made with 2′ and 7′, raise 2′ slightly with a marlinspike or tuck 7′ around it two or three times, these two thus forming a whole strand. lf-strand 7′ until cover is reached, the yarns of which are divided and 7′ rough them and drawn under the two adjacent strands, again forming the t off the strand ends at both locks, leaving about 2 in. so that the yarns may

draw slightly without unlocking (Fig. 178). After a few days service the projecting ends will wear away.

Splicing of Power Transmission Rope.

Efficiencies of Rope Drives. Results of extensive tests reported by E. H. Ahara (*Jour. A. S. M. E.*, Aug., 1913) show that the efficiency of both the multiple and continuous systems falls off slightly with an increase in speed, but is not affected by changes in center distances between 25 and 150 ft. Two types of drive were tested: the "open" (horizontally, over two sheaves) and the "up and over" (upward from driver, horizontally over two idlers, downward and then around driven wheel, upward a short distance, horizontally over two idlers, and thence downward around driver to point of beginning), with from one to eight 1-in. Manila ropes. The multiple system sheaves had 45-deg. grooves and the continuous system 60-deg. grooves in which the ropes lay freely and withdrew without effort. The following efficiencies at ¾ load were obtained on 100-ft. centers and at a rope speed of 4500 ft. per min.:

No. of ropes	1	2	3	4	6	8
Continuous system (American):						
Effy. of open drive, per cent	91	93	94	94	94	94
Effy. of up and over drive, per cent	58	72	79	80	80	81
Multiple system (English):						
Effy. of open drive, per cent	73	80	84	86	86	86
Effy. of up and over drive, per cent	56	67	71	72	75	77

Comparative Costs of Belt and Rope Drives. According to the Plymouth Cordage Co., belts cost 2½ times as much as Manila ropes of equal capacity, while rope sheaves cost about ⅓ more than belt pulleys.

Wire Rope Drives

The general **characteristics** and commercial **sizes** of wire ropes are given on p. 843.

Bending Stresses in Wire Ropes. Wire ropes when transmitting power are subjected to bending stresses in passing around pulleys or sheaves. The intensity of stress in any case may be determined by means of the formula

$$f = Ea/[2.06(R/d) + C]$$

where f = stress, lb.; E = modulus of elasticity of the material = 28,500,000 (average); a = aggregate cross-sectional area of the wires in the rope, sq. in.; R = radius of bend, in.; d = diam. of wire, in; C = 9.27 for ropes of six 7-wire strands (for which d = ⅑ rope diam.) = 15.45 for ropes of six 19-wire strands (for which d = 1/15 rope diam.). Ropes with six 7-wire strands are those generally used in power transmission, and their bending stresses are given in Table 89.

Table 89. Bending Stresses of Transmission Rope of Six 7-wire Strands, Lb.

(Trenton Iron Co.)

Sheaves. The necessity for keeping bending stresses within safe limits has occasioned the establishment of minimum sheave diameters for the various sizes of rope. Table 90 is representative of good practice in this regard. The first cost of large sheaves is high but they conduce to long life for the rope and hence to low operating cost. For proportions of sheaves, see Fig. 157 and Table 80. Ordinarily, the best filling for the grooves consists of segments of leather and rubber soaked in tar and packed alternately in the groove. Where the pressure of the rope is very great, hardwood blocks are preferable. Sheaves should be as light as is consistent with strength, and well balanced.

Transmission of Power by Wire Rope. In wire-rope transmission the **working tension** on the rope should not exceed the difference between the maximum safe load and the bending load as obtained from Table 89 (for 7-wire rope) or from the formula given for f. Ordinarily, where the work is approximately uniform, the maximum safe load may be taken as 0.4 × ultimate load for cast steel and about 0.33 for plow steel. Thus, the ultimate load of a 1-in. cast-steel rope of six 7-wire strands is given in manufacturers' tables as 62,000 lb., whence maximum safe load = 24,800 lb. The bending load for this rope around a 96-in. sheave is (Table 89) 12,869 lb., or working tension = 24,800 − 12,869 = 11,931 lb. The usual **rope velocities** are from 50 to 100 ft. per sec., and centrifugal tension is generally neglected in power calculations. In the present case, centrifugal tension, lb., $= wv^2/32.2$, where w = weight of 1 ft. of rope, lb. For a 1-in. rope w = 1.58 lb., whence centrifugal tension = 490 lb. for v = 100 ft. per sec.

To avoid slipping, a certain ratio must exist between the tension T_1 in the tight side and T_2 in the slack side of the rope. This ratio is

$$T_1/T_2 = e^{fn\pi}$$

in which e = Napierian logarithmic base = 2.718, f = coefficient of friction between the rope and the material used in filling the sheave grooves, n = number of half laps of the rope about the sheaves at either end of the line. Following are values of f given by the Trenton Iron Co. for dry, wet, and greasy ropes running in various tracks:

	Grooved iron drum	Wood-filled sheaves	Sheaves with rubber and leather filling
For dry ropes f =	0.170	0.235	0.495
For wet ropes f =	0.085	0.170	0.400
For greasy ropes f =	0.070	0.140	0.205

The force available in transmitting power is the difference between the tensions T_1 and T_2, or $T_1 - T_2 = T_2\,(e^{fn\pi} - 1)$ and to obtain this the rope must be tightened when at rest so that the initial tension $= \frac{1}{2}(T_1 + T_2)$, or

$$\text{Initial tension} = \tfrac{1}{2}T_2(e^{fn\pi} + 1) = \tfrac{1}{2}(T_1 - T_2)\,(e^{fn\pi} + 1)/(e^{fn\pi} - 1)$$

Values of $e^{fn\pi}$ and of $(e^{fn\pi} + 1)/(e^{fn\pi} - 1)$ for various values of f and n are given in Table 91.

* Specially flexible rope of 6 strands, each strand having 19 wires (9 on 9 on 1) the intermediate wires of which are of smaller cross-section.

Table 92 gives the horse power transmitted by cast-steel ropes making a single lap on wood-filled sheaves, and is calculated on the assumption that the sheaves are of equal diameters and of a size not less than the minimum diameters given in Table 90. It is impracticable to transmit more than 250 h.p. with filled sheaves. since the rope tension is so great that the filling material is rapidly cut out, and the frictional grip of an iron surface by the rope is insufficient with but a single lap at either end of the line. In this case the rope must be lapped several times about a pair of grooved drums at each end, or about sheaves so arranged in pairs that the rope makes a half lap about each and a final half lap at one end about the sheave of a tension carriage for taking up the slack.

Sag of Wire Ropes. The sag or deflection S of a wire rope at the center of the span may be calculated by the formula $S = WL^2/8T$, where W is the weight of 1 ft. of rope, lb.; L = span, ft. and T = tension in the rope, lb. Substituting for T the values of T_1 and T_2 in the tight and slack sides and expressing W in terms of the rope diameter, the following values are obtained:

		Steel rope	Iron rope
Deflection of still rope at center, ft.	=	$0.00004L^2$	$0.00008L^2$
Deflection of driving rope at center, ft.	=	$0.000025L^2$	$0.000025L^2$
Deflection of slack rope at center, ft.	=	$0.0000875L^2$	$0.000175L^2$

For sags, length of wire, etc., see pp. 147–151.

Span Lengths. For spans under 60 ft. in length, a heavier rope should be used than that actually required to transmit the power. This is made necessary by the difficulty of splicing short ropes so as to give the exact deflection required. The maximum length of span depends on the contour of the ground and the available height of the terminal sheaves. The lower side of the rope should always be the tight or driving side. The **maximum limit of span** is often determined by the sag of the upper side when running; for 10-ft. sheaves and towers of ordinary height it is about 600 ft., though transmissions have been built with spans of as much as 1700 ft. in length. In **long-distance transmissions,** when the distance exceeds the maximum for a single span, the rope is supported and its direction changed (if necessary) by intermediate sheaves having plain unfilled grooves. In very long transmissions slower speeds are necessary and the rope must be lapped about a grooved drum several times.

Splicing Wire Ropes. The general method for splicing wire ropes resembles closely that described for textile ropes. The length of splice used ranges from 16 ft. for ½ in. ropes up to 30 ft. for large sizes. Twelve strands have to be cared for instead of eight in the case of the textile rope. The ends for tucking in are left about 12 in. long. Tucking in is accomplished by untwisting the rope by means of long-armed wooden clamps, cutting out the hemp core for a sufficient distance and then forcing the ends into the space formerly occupied by the core. The rope is then smoothed and rounded with a wooden mallet.

CHAIN DRIVES

Chains may be used to advantage in the transmission of power when a positive, high-efficiency drive is desired and when the distances between the shaft centers are too short to use belts and too long for toothed gearing. They occupy but little space and will work satisfactorily in hot or damp places.

FIG. 179.—Roller Chain.

Roller Chains are made as shown in Fig. 179. The Diamond Chain & Mfg. Co. manufactures this type of chain in the following sizes and strengths:

Pitch, in.	2	1¾	1½	1¼	1	¾	⅝	½
Ultimate tensile strength, lb.	40,000 to 34,000	30,000 to 24,000	21,000 to 18,000	18,000 to 13,000	10,000 to 8000	5000	3500 to 1200	1200

For light and steady loads a **speed** of 2000 ft. per min. has been attained with this type of chain. As the loads become heavier and more irregular, however, the speed should be lower. About 1000 ft. per min. is a usual speed for a wide range of applications. The safe **working load** varies from ⅙ to ¹⁄₁₀ of the ultimate strength of the chain, according to the severity of the service and conditions of drive.

Block Chains (Fig. 180) are made by the Diamond Chain and Mfg. Co. with widths of ⅛, ³⁄₁₆, ¼, ⁵⁄₁₆, ½ and 1 in., and with pitches of ½, ⅝, 1, and 1½ in. The strength of the 1-in. pitch chain varies from 1200 to 2500 lb.; that of the 1½-in. pitch chain is 5000 lb. These chains are usually employed for speeds under 700 ft. per min.

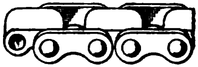

Fig. 180.—Block Chain.

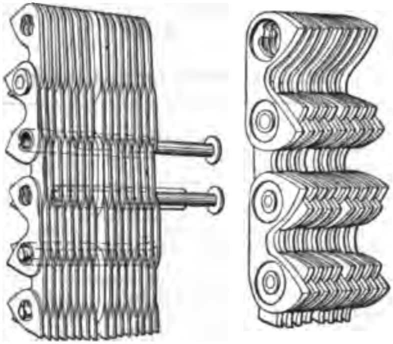

Fig. 181.—Renold Silent Chain.

Renold Silent Chain. The standard sizes, working loads and wheel widths of this chain (shown in Fig. 181) are given in Table 93. Speeds from 800 to 1200 ft. per min. are usual. One of the chief characteristics of this chain is that wear is automatically compensated for, and hence it operates with little noise and wear as compared with the roller and block types.

Morse Silent Chain. The principal feature of construction of this chain (Fig. 182) is the rocker joint, which requires but little oil for lubrication. These chains may therefore be run at speeds above which the oil is thrown off. Difficulty will be experienced if the wedges get out of alignment. When this occurs the destruction of the chain is very rapid. Table 94 gives the principal data on this type of chain.

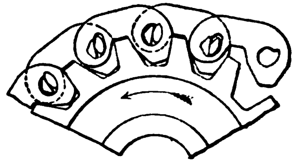

FIG. 182.—Morse Silent Chain.

C_1 for armed sprockets	0.16	0.25	0.35	0.45	0.7	1.0	2.0	4.0

Approximate Weights for Solid and Armed Sprockets. T = number of teeth. F = face in in. C and C_1 = constants in lb. per in. in face per tooth as per table. Weight of armed sprocket = $T \times F \times C_1$. Add 25 per cent. for split and 50 per cent. for spring and split sprockets. Weight of solid pinion = $T^2 \times (F + 1) \times C$.

Note 1.—Number of teeth = T. Exact outside diam. = D. For T less than 20 teeth, D = pitch diam. For T more than 20 teeth, D = pitch diam. + (2 × addendum).

Note 2.—Under special conditions a larger number of teeth than shown may be cut in large sprocket.

Thickness of sprocket rim, including teeth should be at least 1.2 times the chain pitch. The number of grooves in the sprocket, their width and distance apart, vary according to pitch and width of chain. The width of the sprocket should be ⅛ to ¼ in. greater on small drives, and ¼ to ½ in. greater on large drives than nominal width of the chain. An even number of links in the chain and an odd number of teeth in the wheels are desirable. Horizontal drives are preferred; tight chains on top are necessary for short drives without center adjustment, and desirable for long drives with or without center adjustment. Adjustable wheel centers are desirable for horizontal drives and necessary for vertical drives. Avoid vertical drives. Allow a side clearance for chain (parallel to axis of sprockets and measured from nominal width of chain) equal to the pitch. Maximum linear velocity for commercial service, 1200 to 1600 ft. per min. These data are for use in preliminary design. Engineering features should always be submitted to the company for approval before ordering.

Length of Chain. Referring to Fig. 183,

P = pitch of chain, in.

R and r = pitch radii of larger and smaller sprockets, respectively, in.

N and n = number of teeth on larger and smaller sprockets, respectively.

$(180° + 2a)$ and $(180° - 2a)$ = angles of contact on larger and smaller sprockets respectively.

$a = \sin^{-1}[(R - r)/D]$. $A = D \cos a$.

Then, **length of chain** in in. is equal to

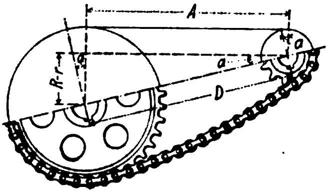

FIG. 183.

$$L = NP\left(\frac{180° + 2a}{360°}\right) + nP\left(\frac{180° - 2a}{360°}\right) + 2\,D\cos a$$

For a block chain the total length ordered should be a multiple of the pitch, while for a roller chain it should be a multiple of twice the pitch, since an outside and inside link are required for joining the ends.

Proportions of Sprockets. Sprocket wheels for **block chains** are designed as follows: In Fig. 184 let N = number of teeth; h = diam. of round part of chain block, in.; B = distance from center to center of holes in chain block, in.; A = distance from center to center of holes in side links, in. Then $a = 180°/N$, $\tan b = \sin a/[(B/A) + \cos a]$. Pitch diam. = $A/\sin b$; bottom diam. = $(A/\sin b) - h$; outside diam. = $(A/\sin b) + h$. Sprocket wheels (see p. 742) for **roller chains** are proportioned as follows: In Fig. 185, let N = number of teeth, P = pitch of chain, in., and D = diam. of roller, in. Then $a = \frac{1}{2} \times (360/N)$, pitch diam. = $P/\sin a$, bottom diam. = $(P/\sin a) - D$. For sprockets of 17 teeth and over, outside diam. = $(P/\sin a) + D$. For sprockets under 17 teeth, outside diam. = $(P/\sin a) + D - E$, in which E has the following values:

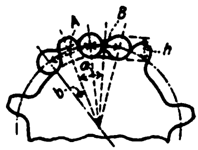

FIG. 184.

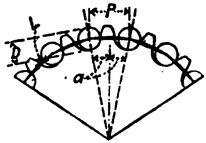

FIG. 185.

Pitch	E: 8 to 12 teeth	E: 13 to 16 teeth
½ in. to ¾ in.	0.062 in.	0.031 in.
1 in. to 2 in.	0.125 in.	0.062 in.

The **teeth for** both **roller and block chain sprockets** should have the following proportions: Referring to Fig. 186, let W = width of chain rollers or blocks, in. Then $A = W/2$; $B = W - \frac{1}{64}$ in. when $W = \frac{1}{4}$ in. or less, $= W - \frac{1}{32}$ in. when $W = \frac{5}{16}$ in. to ⅝ in., $= W - \frac{1}{16}$ in. when W = ¾ in. and over.

When the sprocket is flanged the following values of C obtain:

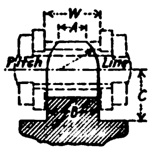

FIG. 186.

Roller, in.	A	B	1	1¼	1½	1¾	2
C, in., not less than	¼	11/32	½	9/16	⅝	13/16	15/16

A = 1-in. block and 1-in. twin roller, or ½-in. block and ⅝-in. roller.
B = 1½-in. block and ¾-in. roller.

The **pitch line clearance** for roller sprockets (see L, in Fig. 185) should be as follows:

Pitch, in.	1/2	5/8	3/4	1	1 1/4	1 1/2	1 3/4	2
Clearance, in.	1/32	1/32	1/16	3/32	3/16	7/32	1/8	5/32

Notes on Chain Drives. Short pitch is preferable to longer pitch for durability. The center-to-center distance between sprockets should not be less than 40 times the pitch of the chain. It is better to have the slack side of the chain at the bottom. Large sprockets and a large number of teeth give less wear. The ratio of sprockets should not be greater than 5 to 1 for roller chains, or 8 to 1 for block chains. Sprockets should not have less than 16 teeth. An odd or "hunting" tooth is advantageous on the pinion. Vertical drives, if impossible to avoid, should be short. A long vertical chain will tend to drop away from the lower wheel, resulting in bad chain action. Means should be provided for adjusting the distance between the shafts. Where the load is irregular or impulsive the use of a spring sprocket is advisable.

CRANE CHAINS, HOOKS, ETC.

Crane Chains. The researches of Goodenough and Moore (*Bulletin*, No. 18, Univ. of Ill. Exp. Station) on the strength of chain links results in the following formulæ:

$$P = 0.4d^2S \text{ for open links;} \qquad P = 0.5d^2S \text{ for stud links}$$

Table 95. Weights, Dimensions and Safe Loads* of Chains as Given by Standard Manufacturers

* Safe loads based on one-half proof tests, or one-fourth of the approximate breaking load of chain.

where P = safe load on chain, lb.; d = diameter of bar from which chain is made, in.; and S = maximum permissible intensity of tensile stress, lb. per sq. in. Chains made of wrought iron may be designed for values of S from 15,000 to 20,000 according to the nature of the service. Standard **proportions for chains** are given in Table 95, the dimension letters of which refer to Fig. 187.

FIG. 187.

The load at which permanent deformation begins in wrought-iron **rings** used **on chain slings** is P(lb.) = $42{,}000d^3/D$, in which d = diam. of stock from which ring is forged, in., and D = mean diam. of ring, in. = inside diam. + d (W. Worsdell, *Engg.*, May 6, 1910). For safe load take $P = 14{,}000d^3/D$.

For proportions of **chain sheaves,** see p. 742. For **hoisting chains,** see p. 1109.

Crane Hooks may be designed to the proportions given in Fig. 188 (Axel K. Pedersen, *Am. Mach.*, Nov. 24, 1910). Letting P_1 = load on hook in tons (2000 lb.), $D_1 = \sqrt{P_1}$; $D_2 = \frac{7}{8}D_1$; $W = 1.5A$; $h = \frac{3}{4}H$; $L_1 = 2.3A$ to $2.6A$; $L_2 = 4.3A$ to $4.5A$. Values of A used by the Pawling & Harnischfeger Co. are as follows:

Capacity, lb.	6000	10,000	15,000	20,000	30,000	40,000
A, in.	1½	1⅞	2⅛	2½	3	3½
Capacity, lb.	50,000	60,000	80,000	100,000	120,000	
A, in.	3¾	4	4¾	5	5½	

At the section M–M, $b = 2A \tan 0.5\,T$, $B = b(x + 1)$, and $H = Ax$, where T = angle included between the side faces, deg., and x is a factor obtained from the curve in Fig. 188 and depending on the value of F. This latter value is determined from the equation

$$F = SA^2 \tan(0.5T)/P$$

where P = load on hook, lb., and S = maximum allowable intensity of tensile stress in the metal, lb. per sq. in. S may be taken at 17,000 lb. per sq. in. for a high grade of iron. Values of tan $(T/2)$ may range from 0.22 to 0.32. For the theory upon which the curve in Fig. 188 is based, together with experimental verifications, see p. 440 and the papers of Andrews and Pearson (Drapers' Company Research Memoirs, Technical Series, I), Goodman (*Proc. Inst. C. E.*, vol. clxvii), and Rautenstrauch (*Am. Mach.*, Oct. 7, 1907, and *Trans. A. S. M. E.*, vol. 31).

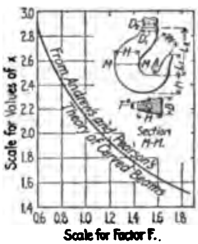

FIG. 188.

Open-side Machine Frames for punches, shears, presses, riveters, etc., are generally made of box or I-section, and should be designed as curved beams, using the analysis of Andrews and Pearson (Rautenstrauch, *Trans. A. S. M. E.*, vol. 31) instead of the ordinary formulæ for bending. The Andrews-Pearson formulæ, however, are difficult of application, and Mr. Andrews has accordingly amended the simple formulæ of the ordinary bending theory, as follows (*Am. Mach.*, Sept. 5, 1912): Corrected combined tensile stress at inner edge of section (lb. per sq. in.) $= t = P[1 + (Kld_1/k^2)]/A$; corrected combined compressive stress (lb. per sq. in.) at outer edge of section $= c = P[(Cld_2/k^2) - 1]/A$, where P = load or pressure (lb.) applied at the distance l (inches) from the neutral axis of the section; d_1 (d_2) = distance from neutral axis to inside (outside) edge, in.; k = radius of gyration of section about the neutral axis, in inch units; A = area of cross-section of frame, sq. in. K and C are correcting factors given by Mr. Andrews in the form of curves

(*The Engineer*, Apr. 19, 1912), from which the following formulæ have been derived (C. M. Sames, *Eng. Digest*, June, 1912, p. 477): $K = (7.84s + 0.42)/(8s - 3)$; $C = (s - 0.16)/(s + 0.2)$, in which $s = R/H$, where R = radius of curvature of the neutral axis and $h = d_1 + d_2$ = depth of section, both in inches. The working stresses employed should be based on the results of transverse breaking tests of cast iron rather than upon tensile tests.

ENGINE DETAILS

Cylinders

(See p. 1039 for the cylinders of gas engines; p. 1193 for automobile engines; and p. 1241 for marine engines)

Steam-engine Cylinders may have walls of the thickness

$$t(\text{in.}) = (PD/2000) + 0.3 \text{ in.}$$

where P = steam pressure, lb. per sq. in., and D = diam. of bore, in. The thickness thus obtained allows for reboring. For jacketed cylinders the **liner** when of cast iron may be of the thickness: $t_0 = [PD/(5125 + 10P)] + 0.4$ in.

The **thickness of** the **jacket** may be equal to that of the liner minus the 0.4 in. allowed for reboring. The space between the liner and jacket must not be less than ¾ in. and in large cylinders should be as much as 1¼ in. **Wrought-steel liners** need have but from 30 to 35 per cent. of the thickness of cast-iron liners. For compound engines the high-pressure cylinder is to be designed to withstand full boiler pressure, and the other cylinders as follows: Intermediate (triple) $P = 0.5 \times$ boiler pressure; low (triple), $0.3 \times$ boiler pressure; low (double), $0.4 \times$ boiler pressure.

Cylinder Flanges should not be thicker than $1.2t$ to $1.25t$. Heavier flanges cause severe cooling strains which materially weaken the casting.

Cylinder Heads (see also p. 1242) when flat may be proportioned as flat plates supported at the edges. $t_1 = 0.5D\sqrt{5P/6f}$, where t_1 = thickness of plate, in., and f = intensity of stress, lb. per sq. in. = 3000 for cast iron and 8000 for cast steel. When **heads** are **dished and ribbed** the same formula may be used for determining the maximum limit of dimension and the actual thickness made from 20 to 40 per cent. less, depending on the ribbing.

See also **Diaphragms, Casings** and **Heads**, p. 788.

Valve-chest Walls (see also Strength of Flat Plates, p. 420) when flat may have the following thickness (in in.): $t_2 = b\sqrt{a^2P/(a^2 + b^2)2f}$, where b = unsupported width of wall, in.; a = unsupported length of wall, in.; f = 6500 for cast iron.

Steam-chest Cover Plates for flat valves may have a thickness in inches given by $t_3 = b\sqrt{3a^2P/4(a^2 + b^2)f}$.

Large cover plates are usually dished and ribbed for added strength. A steam-chest cover such as shown in Fig. 189, when tested to destruction, cracks along a diagonal. The maximum intensity of stress will be $f = M/Z = Pb^2a^2/12Z\sqrt{b^2 + a^2}$, where M is the bending moment at the diagonal and Z is the modulus of the cross-section along a diagonal, or the moment of inertia of the section divided by the distance from the neutral axis to the outer fiber.

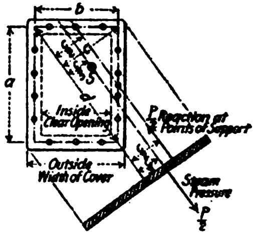

FIG. 189.

Bolts for holding down cylinder heads and steam-chest covers should never be less than ⅝ in. and preferably ¾ in. in diameter to prevent their being twisted off in tightening. The intensity of stress based on steam-pressure load should be limited to 6000 lb. per sq. in. and the spacing should not be greater than 6½ in. or less than 3½ times the diameter of the bolt. Stud holes should be tapped to a depth equal to 1½ times the diameter of stud, but never allowed to enter a steam space. The **strength** of the bolts should be much less than the strength of the frame or cylinder with load application along the center line of the engine. This will insure the safety of the more expensive castings in case of unusual loading such as may be caused by water in the cylinder. For **gas-engine cylinders**, see p. 1041.

Hydraulic Press Cylinders may be proportioned for strength by Lamé's formula (see p. 395). For cast-iron cylinders f is 6000; for cast steel, 15,000. For very high pressures cast iron is too porous and permits leakage through the cylinder walls. For pressures above 3000 lb. per sq. in. it is advisable to use steel castings, although a close-grained iron may serve up to 3500 lb. per sq. in. Pipe connections to press cylinders should be bossed. Press-cylinder bottoms should be hemispherical and not flat, in order to diminish shrinkage stresses.

Pistons and Piston Rods

Small Steam-engine Pistons may be made to the form and dimensions given in Fig. 190 and Table 96. A new piston, however, must be provided with each reboring of the cylinder. **Built-up pistons** may be made to the form and proportions given in Fig. 191 and Table 97. With the use of this type of piston, a reboring of the cylinder calls for a new bull ring and new piston rings, but permits the use of the same spider and follower plate.

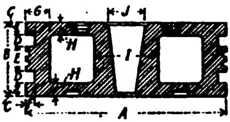

FIG. 190.—Small Steam-engine Piston.

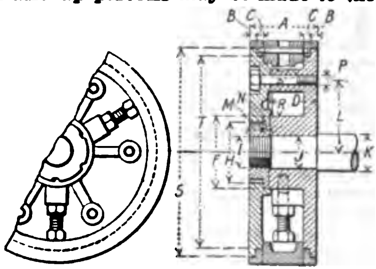

FIG. 191.—Built-up Engine Piston.

Conical Pistons for use in vertical engines may be proportioned for strength according to the formulæ given by Kraft (*Proc. Inst. C. E.*, vol. 127, p. 259):

$$T = p(R^2 - x^2)/2fx \sin a; \qquad t = px'/f \sin a$$

where p = steam pressure, lb. per sq. in.; f = maximum allowable stress, lb. per sq. in. (= 3000 for cast iron and 9000 for steel); T and t = minimum thickness of metal at sections near boss and rim, respectively, in.; x, x', a and R have the significance given in Fig. 192.

Bauer gives proportions for **cast-steel pistons** as found in Fig. 193

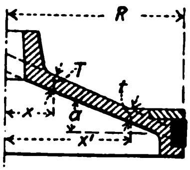

FIG. 192.

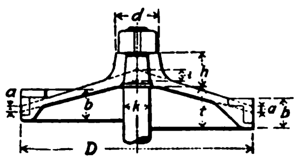

FIG. 193.—Conical Engine Piston.

and Table 98. Thickness of boss $d = 1.5k$ to $1.7k$. For small pistons and for heavily built engines use $1.7k$; for large pistons and light engines, $1.5k$. Height of the boss $= h = 1.1k$. The thickness of the steel at the middle or

mean radius may be $i = k \times c$ where c may have the following values: $c = 1$ for flat pistons or those in which the inclination measured in the inside is very slight (angle 0 deg. to 6 deg.), $= 0.85$ to 0.95 when angle is 6 to 18 deg., $= 0.75$ to 0.85 when angle is 18 to 28 deg. $= 0.65$ to 0.75 when angle is 28 to 35 deg.; also $a = 0.45i$ to $0.55i$. For **marine-engine pistons,** see p. 1242; for **gas engines,** p. 1041; for **automobile engines,** p. 1242.

Piston Rings. Steam-engine piston rings up to 20 in. in diameter may be made to the forms and proportions given in Figs. 194 and 195 and Table 99. (For gas-engine piston rings, see p. 1043.) The eccentric rings give a more uniform pressure against the cylinder walls. This pressure should be from 3 to 4 lb. per sq. in. The ring is preferably in segments for large engines, each segment being pressed against the cylinder walls by a spring.

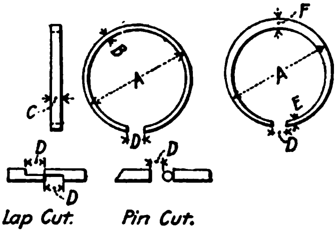

FIG. 194. FIG. 195.
Piston Rings.

Piston Rods are subjected mainly to compressive stresses and may be designed as round, free-ended columns, Euler's formula for which reduces to $P = 0.485Ed^4/sl^2$, in which P = total load, lb.; E = modulus of elasticity ($= 30{,}000{,}000$ for mild steel); d = diam. of rod, in.; l = length of rod, in.; [For hollow piston rods, substitute $(d_2^4 - d_1^4)$ for d^4 in formula, d_2 and d_1 being respectively the outer and inner diameters.] The factor of safety s has the following values: For vertical engines $s = 8$ to 11 for load fluctuating between P and 0; $s = 15$ to 22 for load fluctuating between $+P$ and $-P$. In horizontal engines the rods are also subjected to bending stress due to the combined weight of the piston and rod. In small engines with light pistons the formula for vertical engines may be used with $s = 11$ to 22. In large engines with heavy pistons and rods running through glands in both heads (as in tandem steam and gas engines), the rod must be of such stiffness that it will not deflect at mid-length between its points of support more than 0.08 in. In this case the piston diameter must be from 0.12 to 0.16 in. less than that of the bore. Deflection in in. $= l^3(W_1 + 0.625W_2)/48EI$, where l = length between supported points, in.; W_1 and W_2 = weights of piston and rod respectively, lb.; I = moment of inertia of rod section $= \pi d^4/64$. For **rods for marine engines,** see p. 1242; for **gas-engine piston rods,** see p. 1042. Most reliable values of d may be found by the use of Ritter's long-column formula. This reduces to the following form for mild-steel rods: $d^2 = P(1 + \sqrt{1 + fl^2/190P})/1.57f$, where f = allowable working stress, usually 5000 lb. per sq. in., l = rod length in inches, P = load on rod, lb.

Table 100. Dimensions for Ends of Locomotive Piston Rods
(All dimensions in in. Letters refer to Figs. 196 and 197)

To check for stress in an existing design the formula is more conveniently written as: $f = P[1 + (16SL^2/\pi^2Ed^2)]/A$, where A = area of rod section, sq. in.; E = modulus of elasticity in tension = 30,000,000 for mild steel; S = elastic limit of material = 30,000 lb. per sq. in. for mild steel.

Successful locomotive practice in the design of **piston-rod ends** is shown in Figs. 196 and 197, dimensions being given in Table 100.

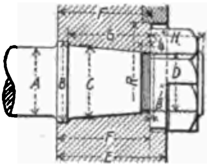

FIG. 196.

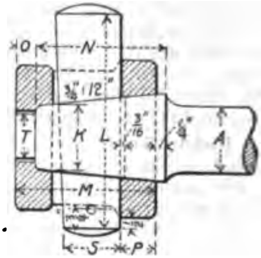

FIG. 197.

Piston-rod Ends.

Cross Heads

Engine Cross Heads of the **wing type** may have the features of construction shown in Fig. 198. The **box type** of cross head may be designed as shown in Fig. 199. The substitution of pin shoulders on the cross head and straight bores in the box for the taper construction reduces the cost of machining. The shoulders should bear on the face of the side opposite to which the nut holding the pin is seated in order that screwing up the nut will not tend to bind the connecting-rod end in the box and thus cause heating. It is well to flatten the top and bottom portions of the pin where wear is a minimum to prevent the pin wearing to an oval shape. It is sometimes the practice to give the pin a quarter turn occasionally to promote more uniform wear. In locomotive and marine service the type of cross head shown in Fig. 200 is frequently used.

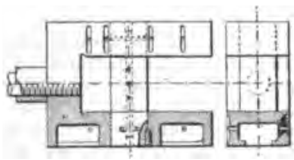

FIG. 198.—Wing Type of Cross Head.

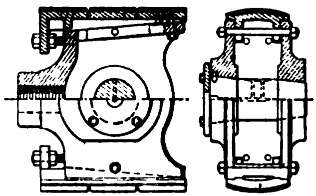

FIG. 199.—Box Type of Cross Head.

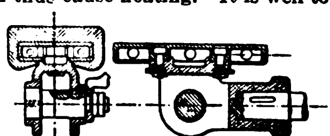

FIG. 200.—Marine-engine and Locomotive Type of Cross Head.

Cross-head Pins. In steam-engine practice the cross-head pin is designed for a bearing pressure of 1000 to 1500 lb. per sq. in. According to Barr, American practice in proportioning cross-head pins is as follows: $dl = CA$, $l = Kd$; where d = pin diam., in.; l = bearing length of pin, in.; A = piston area, sq. in., C = 0.08 (0.07) for high (low) speeds, and K = 1.25 (1.3) for high (low) speeds.

Shoes. The area of the shoes for stationary steam-engine cross heads should be such as to limit the maximum pressure to from 25 to 40 lb. per sq. in. The total maximum pressure of the cross-head shoes on the guide is $P \tan a$, where P = maximum steam-pressure load behind the piston, lb., and a = maximum angle of connecting rod with engine center line.

In **marine practice** (see also p. 1243) the area of the shoes, according to Bauer, is based in the following limiting pressures: 55 to 65 lb. per sq. in. for cargo and slow-running passenger vessels; 70 to 85 lb. per sq. in. for iron-clads and large cruisers; 65 to 80 lb. per sq. in. for mail steamers; 85 to 120 lb. per sq. in. for small cruisers and torpedo boats.

In **locomotive practice** the limiting pressure on the cross-head shoe is about 85 lb. per sq. in.

Connecting Rods

Connecting rods for **locomotive** service may be made to the form shown in Fig. 201. For **small stationary engines**, rods of the form shown in Fig. 202 are used. For **marine-engine rods**, see p. 1242; for **automobile engines**, p. 1193.

According to Haeder, **gas-engine connecting rods** may be proportioned as shown in Fig. 203 and Table 101.

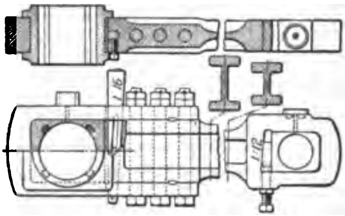

FIG. 201.—Locomotive Connecting Rod.

Shanks for connecting rods may be designed as long columns with round ends, using Ritter's formula (see p. 765), $d^2 = CP[1 + \sqrt{1 + (l^2kf/KCP)}]/kf$, where P = load on rod, lb.; f = maximum allowable stress, lb. per sq. in.; l = length of rod, in. For **rods of circular cross-section**, d = rod diam., in., C = 1.00, k = 1.57, and K = 300. For **rods of rectangular cross-section** having height of section equal to 2.7 times the thickness, d = height of rod section, in.; C = 1.35, k = 1, and K = 420. These constants are for rods of mild steel having an elastic limit of 30,000 lb. per sq. in. and a modulus of elasticity in tension of 30,000,000 lb. per sq. in. In high-speed steam-engine practice, f may be 4000. In slow-speed steam engines, gas engines and pumps, f may be 5000 to 5500. In general, the **working stress** for connecting rods should be from 1/6 to 1/8 the stress at the elastic limit of the material, when designing for long-column action. Rods for high-speed engines having important inertia stresses should be designed with a factor of 1/8. The sum of the stresses due to long-column action and to inertia (whipping action) should not exceed 1/3 the stress at the elastic limit of the material.

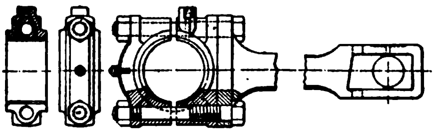

FIG. 202.—Connecting Rod for Small Engines.

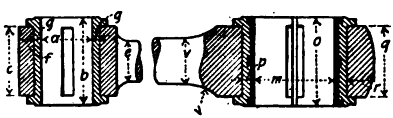

FIG. 203.—Gas-engine Connecting Rod.

The **maximum inertia stress** in a connecting-rod shank may be closely approximated by use of the following formulæ:

For round rods, $f' = l^2wv^2/(0.098d^3 \times 16gR)$, where f' = stress due to inertia, lb. per sq. in.; w = weight of 1 in. length of rod, lb; v = velocity of crank pin, ft. per sec.; g = 32.2 ft. per sec.^{2}; R = crank radius, ft.; d = mean diam. of rod, in. For rectangular rods, $f' = l^2wv^2/(0.167bh^2 \times 16gR)$, where b = thickness of rod section, in., and h = height of rod section, in.

Table 101. Dimensions of Connecting Rods

Connecting-rod Ends as in Fig. 202 should have their bolts designed such that each may take 5/8 the maximum load on the cap with a stress of 5000 lb. per sq. in. for wrought iron and 6000 lb. per sq. in. for steel. In steam engines the maximum load producing tension in the bolts may be occasioned by the steam pressure or the inertia of the reciprocating masses. In single-acting gas engines the load on the bolts is caused by the inertia forces. **Strap ends** as shown at the crank-pin end of the rod in Fig. 201, should have the side straps designed to carry 5/8 the load, with a limiting stress of 5000 to 6000 lb. per sq. in. The ends are made from 1 to 1.6 times the thickness of the sides for both milled and strap ends. Connecting-rod ends consisting of **strap and cotter fastenings** may be proportioned, according to Molesworth, as follows (see Fig. 204): $b = D + 1.4a$, $c = 0.3D + 0.06$ in., $e = 0.33D + 0.06$ in., $f = 0.37D + 0.12$ in., $g = 0.35D + 0.12$ in., $h = D$, $j = 0.5D + 0.4$ in., $k = 0.9D$, $l = 0.2D + 0.06$ in. Taper of cotter, 1 in 16.

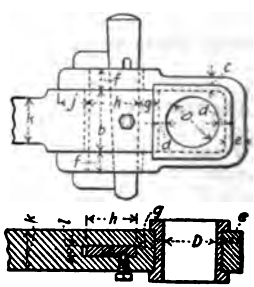

FIG. 204.—Connecting-rod End.

Stuffing Boxes

Stuffing boxes of the ordinary **bolted flange type** suitable for steam engines may be proportioned as shown in Fig. 205, where d = rod diam., in.; $d_1 = 1.22d + 0.6$ in.; $l_1 = 0.4d + 1$ in.; $l_2 = d + 1$ in.; $l_3 = 0.75l_2$; d_2 = bolt diam. = $0.12d + 1/2$ in. when 2 bolts are used, = $1.6\,(0.12d + 1/2 \text{ in.})/\sqrt{n}$ where the number of bolts n is greater than 2; $t = 0.1d + 0.6$ in.; $t_1 = 1.4t$; $t_2 = t$; $t_3 = 0.04d + 0.2$ in. (not to exceed 1/2 in.); $t_4 = 0.1d + 0.13$ in. (not to exceed 1 in.). All glands are to be of brass.

The **screw type of stuffing box** may be made as shown in Fig. 206, with

$d_1 = 1.3d + 0.6$ in. $\quad l_3 = 0.6d + 1$ in. $\quad h = 0.6d + 1$ in.
$d_2 = 0.15d + 0.5$ in. $\quad t = 0.1d + 0.3$ in. $\quad h_1 = 0.14d + 0.4$ in.
$l_1 = 0.4d + 1$ in. $\quad t_1 = 0.15d + 0.5$ in. $\quad h_2 = 0.67d + 1.2$ in.
$l_2 = d + 1.5$ in. $\quad t_2 = 0.13d + 0.4$ in. $\quad h_3 = 0.3d + 0.7$ in.

The gland is of brass.

Packings for Hydraulic Cylinders.

Packings for Hydraulic Cylinders may be proportioned as shown in Figs. 207 and 208. The construction shown in Fig. 208 is adapted to pressures of 2500 to 3000 lb. per sq. in., and **hemp packing** is used.

24	22½	24	1⅞	¼	24	25½	1⅞	3/16	24	2	28	¼

Sometimes the ram of the press cylinder is **packed with leather,** as shown in Figs. 209–212. The proportions may be as given in Table 102. For high-pressure and superheated steam, stuffing boxes are usually provided with metallic packing.

For **gas-engine stuffing boxes,** see p. 1042.

Labyrinth Packing. Leakage past dummy or balance pistons of steam turbines of the Parsons type may be reduced to a small amount by a labyrinth packing (Fig. 213), where the steam pressure is throttled down by passing through a succession of very small clearances, c, formed by rings fitting alternately in grooves in the stator and rotor. These rings are usually composed of short brass strips with clearance between their ends in order to prevent them from being forced out by expansion when heated. The clearance edges of the rings are made from 0.01 to 0.015 in. thick. The number of rings n required to limit the leakage of steam to a given weight per second may be determined from the formula

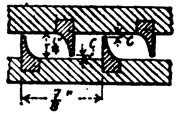

FIG. 213.

$$n = [40p - 2600(w/a)]/[540(w/a) - p]$$

where p = absolute pressure of steam, lb. per sq. in., w = permissible leakage of steam, lb. per sec., and a = cross-sectional area of the steam passage at the clearance rings, sq. in. This formula is derived from a chart given in Morrow's "Steam Turbine Design," p. 293.

Example. Let dummy piston circumference = 70 in.; pressure before passing through labyrinth = 180 lb. per sq. in. abs.; pressure after passing labyrinth = 85 lb. abs.; clearance c = 0.01 in.; leakage w not to exceed 0.7 lb. per sec. Here $a = 70 \times 0.01 = 0.7$ and $w/a = 0.7/0.7 = 1$. Substituting in formula, number of rings for 180 lb. = 13; also, number of rings for 85 lb. = 2; whence, number of rings for leakage of 0.7 lb. per sec. between the two pressures = 13 − 2 = 11.

CRANK GEARING

Analysis of the Motion of the Reciprocating Parts. Let r = crank radius, in.; R = crank radius, ft.; $s = 2r$ = stroke, in.; l = length of connecting rod, in.; x = displacement of piston from dead center, in.; a = crank angle corresponding to x; b = connecting-rod angle corresponding to x; v = crank-pin velocity, ft. per sec.; c = piston velocity, ft. per sec.; N = rev. per min. of the crank. Then, when the center lines of the piston rod and crank shaft lie in the same plane, as is customary,

$x = r(1 - \cos a) \pm l(1 - \cos b) = r(1 - \cos a \pm r \sin^2 a/2l)$ approximately, where the + sign is used for displacements from head-end dead center and the − sign for displacements from crank-end dead center. Table 103 gives **piston positions corresponding to different crank angles.** See also Table 18, p. 968, for crank angles corresponding to various piston positions.

When, however, the center line of motion of the reciprocating masses is located a distance h from the center of rotation of the crank, as shown in Fig. 214, the dead centers are unsymmetrical and the stroke is less than $2r$, having the value

$$s = \sqrt{(l + r)^2 - h^2} - \sqrt{(l - r)^2 - h^2}$$

Determination of the Velocity of the Reciprocating Parts. The velocity of the reciprocating parts is

$$c = v(\sin a + r \sin 2a/2l) \text{ approx.}$$

when the center lines of the piston rod and crank shaft lie in the same plane. When, however, the crank rotates about a center off the center line, as in Fig.

Table 103. Piston Positions for Various Crank Angles
(From beginning of stroke *toward* crank shaft. To find distance of piston from beginning of stroke, multiply tabular value by length of stroke)

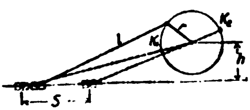

Fig. 214.

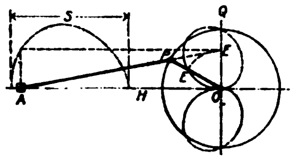

Fig. 215.

214, the above formula does not hold, and a graphical solution such as that shown in Fig. 215 may be resorted to. AH is the center line of the piston rod produced, AP is the connecting rod, OP the crank with center at O. Draw OQ

at right angles to AH. For any position AP of the connecting rod cutting OQ in E, the length OE represents the velocity of the reciprocating parts to the same scale to which OP represents the crank-pin velocity. The graphical construction of Fig. 215 shows how to construct velocity ellipses for the whole revolution.

Determination of the Acceleration of the Reciprocating Parts. The acceleration, p, of the reciprocating parts is given by the equation

$$p = v^2(\cos a \pm r \cos 2a/l)/R, \text{ approx.}$$

Table 104. Inertia Factors

The **inertia force** in lb. per sq. in. of piston is $f = Mp/A = Wv^2(\cos a \pm r \cos 2a/l)/AgR = 0.00034WN^2R(\cos a \pm r \cos 2a/l)/A$, where W = total weight of reciprocating masses, lb.; A = piston area, sq. in. The value of W for any given engine is to be taken as the weight of the piston, piston rod, cross head and a portion of the connecting rod. It is usual to include from ½ to ⅔ the connecting-rod weight as part of the reciprocating masses. Values of $\cos a \pm (r/l) \cos 2a$ are given in Table 104.

Trooien shows that the **weight of reciprocating parts for steam engines** may be expressed by the formula $W = KD^2/SN^2$, where K = 1,370,000 to

Table 105. Tangential Factors

3,400,000, with average value of 2,000,000; W = weight of parts, lb.; D = cylinder diam., in.; S = stroke, in., and N = r.p.m. For **gas engines**, see p. 1046.

Relation Between the Force in the Line of Piston Travel and the Tangential Reaction at the Crank Pin. In Fig. 216, if P is the force in the line of piston travel the force acting along the connecting rod is $C = P/\cos b$, and that on the guides $N = P \tan b$. The force tangent to the crank-pin circle at the crank pin is $T = C \sin (a + b) = P \sec b \sin (b + a) = P \sin a\,(1 + r \cos a/\sqrt{l^2 - r^2 \sin^2 a})$. Table 105 gives values of $\sec b \sin (b + a)$ for various values of l/r.

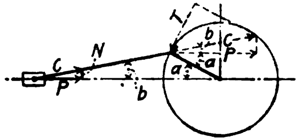

FIG. 216

DETERMINATION OF FLYWHEEL WEIGHT

Tangential Effort Curves. In Fig. 217 are shown the indicator cards $ABCD$ and $A'B'C'D'$ for the forward and return strokes of a single-cylinder double-acting steam engine. The total steam pressure on the piston at each instant is obtained by subtracting from the pressures on one face (*e.g.*, ABC) the corresponding pressures ($C'D'A'$) on the other face of the piston, giving such diagrams as abc and $a'b'c'$. The inertia effect of the reciprocating parts per sq. in. of piston area is represented by the ordinates to the curves xyz and $x'yz'$ for the forward and return strokes, respectively. The ordinates between the total steam pressure and the inertia curves (p_1, p_2, p' and p'') give the resultant pressures acting along the center line of the engine. The tangential reactions at the crank pin can be obtained as shown in the preceding paragraph. These tangential reactions are shown plotted against crank positions in Fig. 218.

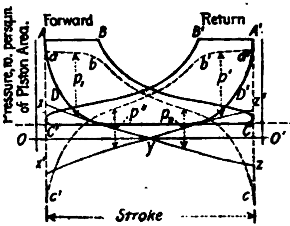

FIG. 217.

In engine design it is usual to construct the tangential effort curve from the cards obtained at normal or rated engine load and to assume that the engine is working against a constant and uniform torque. The uniform resisting torque is represented in Fig. 218 by XX, which is so located that the shaded areas above and below it are equal to one another. The areas BCD and FGH represent in ft.-lb. per sq. in. of piston area the amount of energy which is effective in accelerating the moving masses; and the areas DEF and HAB represent the energy per sq. in. of piston area liberated in the retardation of the moving masses.

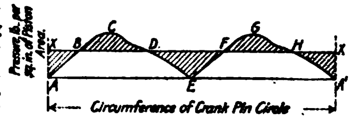

FIG. 218.

Determination of Flywheel Weight. Let M = mass of wheel rim. W = weight of wheel rim, lb. v_1 = maximum linear rim velocity, ft. per sec. v_2 = minimum rim velocity, ft. per sec. $v = \frac{1}{2}(v_1 + v_2)$ = average rim velocity, ft. per sec. $k = (v_1 - v_2)/v$ = coefficient of energy fluctuation. D = mean diam. of rim, ft. N = r.p.m. A = piston area, sq. in. E_m = energy represented by area BCD or FGH or DEF (Fig. 218) = maximum energy in ft.-lb. per sq. in. of piston area which must be absorbed or liberated by the wheel rim with velocity variation between v_1 and v_2. Then

$$E_m \times A = M\frac{v_1^2}{2} - M\frac{v_2^2}{2} = \frac{W}{g}kv^2 = \frac{kWD^2N^2}{11,744}; \text{ or } W = \frac{11,744\, E_m A}{kD^2N^2}$$

About 9/10 W may be placed in the rim to account for the flywheel effect of the arms and other rotating masses. Acceptable values of k are as follows: Pumps, 1/30 to 1/50; machine shops, 1/35 to 1/40; looms and paper mills, 1/40; spinning mills, 1/60; direct-current generators (lighting), 1/150; alternating-current generators, 1/300.

Approximate methods for determining **flywheel weights for steam engines** are as follows (for gas-engine flywheels, see p. 1047; for automobile engines, p. 1194): $W = \text{h.p.} \times C/kNv^2$, where h.p. = i.h.p. of the engine, other symbols as before. C has values as given in Table 106 (Theiss, *Am. Mach.*, Sept. 14, 1893).

* p = compression to initial steam pressure; $0.7p$ = compression to $0.7 \times$ initial pressure; 0 = no compression.
† Mean values.

In the operation of alternators in parallel, resonance must be avoided and the angular displacement must be within 2.5 deg. of the electrical circuit either side of the mean. To insure the time period of the alternator being 40 per cent. greater than that of the impulses of the prime mover (steam or gas engine), the following formula may be used:

$$WR^2 = T^2/P_0 \times 684{,}000/N^2,$$

where W = weight of flywheel, field and rotating parts, lb.; R = radius of gyration of combined rotating parts, ft.; T = time period of engine impulses, sec. = 60 ÷ ($N \times$ impulses per revolution); N = r.p.m. of engine; f = frequency of the system = No. of poles $\times$ r.p.m. ÷ 120; and P_0 = rated capacity of generator in kilowatts $\times$ shunt-circuit current ÷ full-load current. The above formula will ensure a lack of resonance but not necessarily a proper angular variation. The following formula insures an angular variation not more than 2½ electrical degrees either side of the mean: $WR^2 = \text{kw.} \times C \times 10^9/N^4$, where kw. = kilowatt rating of generator, and C has the following values:

	Type of Engine		
	Horizontal single crank	Vertical cross comp.	Horizontal cross comp.
25 cycles........	315	275	250
40 cycles........	505	440	400
50 cycles........	630	550	500
60 cycles........	755	660	600
125 cycles........	1575	1380	1250

Wittenbauer's Analysis for Flywheel Performance. Let the crank-pin velocity be represented by v_r and the velocity of any moving masses (m_1, m_2, m_3, etc.) at any instant or phase be represented by v_1, v_2, v_3, etc. The kinetic energy of the entire system of moving masses may then be expressed as

$$E = \tfrac{1}{2}(m_1v_1^2 + m_2v_2^2 + m_3v_3^2 \ldots.) = \tfrac{1}{2}M_rv_r^2$$

where the single reduced mass M_r at the crank pin which possesses the equivalent kinetic energy is

$$M_r = [m_1(v_1/v_r)^2 + m_2(v_2/v_r)^2 + m_3(v_3/v_r)^2 + \ldots]$$

In an engine mechanism sufficiently accurate values of M_r can be obtained if the weight of the connecting rod is put half at the crank pin and half at the cross head. M_r is a variable in engine mechanisms on account of the reciprocating parts, and should be found for a number of crank positions. It should include all moving masses, except the flywheel.

The total energy E used in accelerating reciprocating parts from the beginning of the forward stroke up to any crank position can be obtained by finding from the indicator cards the total work done in the cylinder (on both sides of the piston) up to that time and subtracting from it the work done in overcoming the resisting torque, which may usually be assumed constant. The mean energy of the moving masses is $E_0 = \tfrac{1}{2}M_rv_r^2$.

In Fig 219 the reduced weights of the moving masses $G_p + G_{rs}$ are plotted on the X axis corresponding to different crank positions. $G_p = gM_p$ is the reduced flywheel mass and $G_{rs} = gM_{rs}$ is the sum of the other reduced masses. Against each of these abscissæ is plotted the energy E available for acceleration measured from the beginning of the forward stroke. The curve 0123456 is the locus of these plotted points.

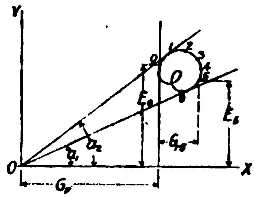

FIG. 219.

This diagram possesses the following property: Any straight line drawn from the origin O to any point in the curve is a measure of the velocity of the moving masses; tangents bounding the diagram measure the limits of velocity between which the crank pin will operate. The maximum linear velocity of the crank pin in ft. per sec. is $v_2 = \sqrt{2g \tan a_2}$, and the minimum velocity is $v_1 = \sqrt{2g \tan a_1}$. Any desired change in v_1 and v_2 may be accomplished by changing the value of G_p, which means a change in the flywheel weight or a change in the flywheel weight reduced to the crank pin. As G_p is very large compared with G_r, the tangents are best found by direct calculation.

GOVERNORS*

Governors are mechanisms designed to maintain the speeds of prime movers (r.p.m.) within reasonably constant limits, whatever the load may be. Nearly all governors depend for their action upon centrifugal force, and consist of a pair of masses rotating about a spindle driven by the prime mover and kept from flying outward by a controlling force. With an increase in speed this controlling force is overcome and the masses move outward until the controlling force is increased to balance their action, and this motion is transmitted to valves supplying the prime mover with its working fluid or fuel. (See also p. 215.)

Conical Pendulum Governor (Fig. 1). In this governor, invented by **Watt,** the revolving masses are balls attached to a vertical spindle by link arms, and the controlling force consists of the weights of the balls themselves. There is a definite ball position for any particular speed, and the governor is said to be "static." For any position of the balls the height of the cone of revolution of the balls and their arms is h (in.) $= 35{,}200/n^2$, where n = r.p.m. Energy (in.-lb.) $= 2wh$, where w = weight of one ball, lb. The sensitiveness of this governor, or the sleeve movement for a given change in speed, rapidly falls off as n increases.

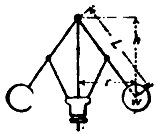

FIG. 1.

Loaded Governor. The **Porter governor** (Fig. 2) is a Watt governor with the addition of a heavy movable weight surrounding the spindle. For a given variation of speed the height h (in.) is greater than with the Watt governor, being, when the four arms are of equal length, $h = [(w + w_1)/w] \times (35{,}200/n^2)$, where w = weight of one ball and w_1 = weight surrounding spindle, both in lb. This type of governor can be run at much higher speeds than the Watt, and it is much more powerful with the same weights of balls. Energy (in.-lb.) $= 2wh + w_1h_1$, where h_1 = vertical rise of center weight, in.

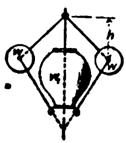

FIG. 2.

Crossed-arm Governor. This is a conical pendulum governor in which each arm is suspended from a pin placed at the opposite side of the spindle to that of its ball. By proper proportioning the balls may be made to move along an approximately parabolic path, and the height h made practically constant for the whole range of the governor, resulting in extreme sensitiveness.

Spring-loaded Governors are those in which the controlling force is wholly or partly produced by springs. This permits the use of a horizontal or inclined axis of rotation.

Shaft Governors consist essentially of a wheel keyed to the main shaft of the engine and carrying weights pivoted near its circumference, which are free to move outward under the influence of centrifugal force, this tendency being resisted by springs. In steam engines the movement of the weights is communicated by links to an eccentric, thus varying the travel of the valve.

In **inertia shaft governors** a weight arm is so pivoted and has its weight so distributed that its inertia assists in making the eccentric adjustment, and the more sudden the change in load the greater the assistance it renders. Thus, when the engine speeds up the weight tends to rotate at its old speed by reason of its inertia, and hence lags behind the wheel. Also,

* Staff contribution.

if the load is suddenly increased, the engine will slow down, but the weight arm will continue at its old speed, gaining on the wheel and again assisting the centrifugal force in altering the position of the eccentric with respect to the crank. In the Rites inertia governor the weight arm is a long bar with heavy ends which is pivoted off its center to a pin some distance from the center of the shaft. In the Armstrong governor a weight attached to the end of a laminated spring fixed to the hub of the governor wheel is acted on both by centrifugal force and inertia.

Helical **springs** for shaft governors may be calculated as follows: Let x = distance (ft.) from c. of g. of weight to center of pin around which the weight turns; x_1 = distance (ft.) from center of pin to point of attachment of spring. Then, pull P_1 on spring due to centrifugal force of weight W(lb.) $= 0.00034WR_1^2n_1^2\,x/x_1$, where R_1 = distance (ft.) from center of shaft to c. of g. of weight when running at n_1 r.p.m. Also, at n_2 r.p.m., $P_2 = 0.00034WR_2^2n_2^2x/x_1$. Then (see p. 429) P_2 = maximum tension (or compression) on spring, lb. $= f\pi d^3/8D$, where d = diam. of wire in spring, in.; D = mean diam. of coil, in.; and f (safe) = 50,000. After obtaining d from the equation for a given diameter D and pull P_2, the number of active coils z required to give the necessary extension or compression S (in.) of the spring may be obtained from the formula $z = Cd^4S/8(P_2 - P_1)D^3$, where P_1 is the initial tension or compression on spring, lb. and C = 12,000,000 for round steel wire. If with springs thus calculated the governing is too fine, reduce the number of active coils in order to stiffen spring and bring about a greater fluctuation in speed. If the governing is too coarse, a larger number of active coils is required. The **powerfulness** K of the two springs of a shaft governor depends upon the energy stored in the springs by extending them the amount S (from tension P_1 to tension P_2).

Stability, Isochronism, Hunting. The controlling force in a governor (whether gravity or that of springs) may be considered as a force F acting on each weight in the direction of the radius toward the axis of revolution. If w/g be the mass of the weight and r the radius of its c. of g., the governor will revolve in equilibrium when $F = 4\pi^2r(n/60)^2w/g = 0.00034rn^2w$. In order to insure stability F must increase more rapidly than r as the balls move outward. The frictional resistance to the action of a governor may be considered as a force f acting radially on each ball so that the whole controlling force is $F + f$ when the balls are moving out and $F - f$ when they are moving in. The corresponding speeds are given by the equation $F + f = 4\pi^2r[(n + \Delta n)/60]^2w/g$ and $F - f = 4\pi^2r[(n - \Delta' n)/60]^2w/g$. As a result of friction the speed may change from Δn above to $\Delta' n$ below the normal speed n while the position of the balls is unchanged. It is apparent that a stable governor cannot maintain an absolutely constant speed in the engine it controls. If a change takes place in the load on a steam engin, it is necessary for the weights or balls to be displaced a certain amount in order to alter the steam supply, and the weights can retain their new position only at a changed speed. The maximum range of speed depends on that amount of change of n which is required to alter the configuration of the governor between the limits of no steam supply and full steam supply. If this range is but a small percentage of n, the governor is said to be sensitive.

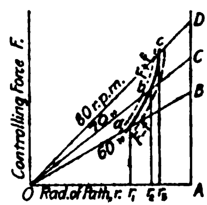

Fig. 3.

The **configuration** of a governor at any speed within its range may be determined as in Fig. 3, a numerical example of a Watt governor being taken, in which $w = 10$ lb. Assuming the upper end of ball arm (Fig. 1) to be pivoted at the axis of spindle, $r^2 + h^2 = L^2$ = constant, or, for any position, $r = \sqrt{L^2 - h^2}$. Now, $h = 35{,}200/n^2 = 9.78$ in. for 60 r.p.m., 7.19 in. for 70 r.p.m., and 5.5 in. for 80 r.p.m. Assuming radius $r = 10$ in. at 60 r.p.m., L^2 = constant = 195.6, whence $r = 12$ in. at 70 r.p.m. (for $h =$ 7.19 in.) = 12.8 in. at 80 r.p.m. In Fig. 3, at any radius greater than 12.8 in., say 16 in., erect an ordinate AD. Calculate the values of $F = 0.00034rn^2w$, taking $r = 16$ in., $w = 10$ lb. and $n = 60$, 70 and 80 respectively, and lay these values off to scale, as AB, AC, AD. Draw OB, OC and OD. Take $r_1 = 10$ in. by scale and erect an ordinate cutting OB or the 60 r.p.m. line at a; locate points b and c similarly, using radii r_2 and r_3 of 12 in. and 12.8 in. respectively, and connect a, b and c by a smooth curve. This is the **curve of controlling force** of the governor, and the ball path radius for any intermediate speed may be obtained by suitably scaling AD, drawing a line from the desired speed value on this scale to O and dropping an ordinate to the radius scale from its intersection with the curve abc. When a tangent to any point makes a greater angle with OA than does a line drawn from O through the same point, the governor is stable throughout its range. The influence of friction can be readily seen by plotting $F + f$ and $F - f$ curves.

A governor is said to be **isochronous** (or astatic) when the speed of rotation is the same for all positions within its limits of movement. On account of the frictional resistances of the joints, however, the speed must always increase slightly before any additional centrifugal force is available, and this will move the weights to their extreme outward position; conversely, when the speed falls sufficiently for gravity or spring force to overcome the frictional resistance, the weights will move to their extreme inward position. In this way the engine will fall into a state of speed oscillation or **hunting**, which is obviously objectionable and may be avoided by giving the governor a fair degree of stability, by reducing the frictional resistances as much as possible, and by the use of dash pots which offer great resistance to sudden movements but allow comparatively slow changes of position to take place freely.

ELEMENTS OF HIGH-SPEED MACHINES

BY

L. C. LOEWENSTEIN

DISK-WHEEL STRESSES

The wheels of steam turbines and the impellers of centrifugal pumps and centrifugal compressors are frequently subjected to high centrifugal forces. The correct mathematical determination of the stresses produced by these forces along the three principal axes of the given wheel is in general too laborious for practical purposes. As the axial width, however, of such wheels (usually spoken of as disk wheels) is generally small in comparison to their radial dimensions, the axial stresses are considered as negligible, and the computations, thus greatly simplified, are confined to the radial and tangential stresses.

The profiles of disk wheels are usually made up of straight lines and of circular arcs. For computation purposes, however, it is preferable to represent such profiles by one or more hyperbolas of the general form

$$t = br^{a} \tag{1}$$

in which t = thickness of disk at radius r, in.; a = shape constant, and may be either zero, positive, or negative; b = dimension constant, and does not enter into the stress computations unless the wheel is subjected to other centrifugal loads besides its own. For an hyperbola from radius r_1 to radius r_2, where the thicknesses are t_1 and t_2, respectively,

$$a = \log(t_1/t_2)/\log(r_1/r_2) \tag{2}$$

and

$$\log b = \log t_1 - a \log r_1 = \log t_2 - a \log r_2 \tag{3}$$

For the computations of the centrifugal radial and tangential stresses in a disk it is necessary to know besides its shape, as given by (1), either two stresses at the same radius (radial and tangential) or one stress of either kind at two different radii. Thus, if the radial stresses R_1 and R_2 at the radii r_1 and r_2, respectively, of the same hyperbolic section are given (or assumed), the corresponding tangential stresses T_1 and T_2 are found from the equations

$$T_1 = Ar_2^2 - BR_1 + CR_2 \tag{4}$$

$$T_2 = Dr_2^2 - ER_1 + FR_2 \tag{5}$$

The factors A, B, C, D, E, and F are functions only of the shape constant a and of the ratio of radii $K = r_1/r_2$, and are given by the following relations:

$$\left.\begin{aligned}
B &= -\frac{m_2K^{m_1-1} - m_1K^{m_2-1}}{K^{m_2-1} - K^{m_1-1}} & A &= -\frac{7.956\left(\frac{N}{1000}\right)^2}{8 + 3.3a}[1.9K^2 + 3.3(K^2B - C)] \\
E &= -\frac{m_2 - m_1}{K^{m_2-1} - K^{m_1-1}} & D &= -\frac{7.956\left(\frac{N}{1000}\right)^2}{8 + 3.3a}[1.9 + 3.3(K^2E - F)] \\
C &= \frac{E}{K^{a+2}} & m_1 &= -\frac{a}{2} - \sqrt{\frac{a^2}{4} - 0.3a + 1} \\
F &= B + a & & \\
N &= \text{r.p.m.} & m_2 &= -\frac{a}{2} + \sqrt{\frac{a^2}{4} - 0.3a + 1}
\end{aligned}\right\} \tag{6}$$

In formulæ (6) a density of 0.28 lb. per cu. in. and a ratio of lateral contraction to radial elongation (Poisson's ratio) of 0.3 have been assumed. When these functions have been computed in a given problem for a particular value of a and a particular ratio of radii r_1/r_2 their values may be preserved for future problems involving the same a and K, even though the actual dimensions may be entirely different. The values of A and D should be recorded for 1000 r.p.m.

Example. Fig. 1 shows the half-section of a turbine wheel designed to run at 3600 r.p.m. As at any given radius there is only one thickness, there is also only one set of values of T and R at any particular radius; so that T_{23} and R_{23} at the end of the third section are equal respectively to T_{14} and R_{14} at the beginning of the fourth section, and may be so equated by the use of formulæ (4) and (5). [In the notation used the first number of the subscript indicates the inner surface (1) or the outer surface (2) of a ring; the second number is the number of the ring. Thus, T_{23} indicates the tangential stress at the outer surface of the third ring.] At 3600 r.p.m. the shrink fit with which the wheel is forced on the shaft is supposed to have been almost entirely neutralized by the centrifugal expansion of the bore, so that the radial stress in the bore R_{11} may be taken as zero. By trial it is found that five hyperbolas give a sufficiently close approximation to the actual profile between the inner radius of 3¼ in. and the outer radius of 18¾ in. at which the buckets may be assumed as attached. The radial stress R_{25} produced by the pull of the buckets on the outer surface of the wheel (r = 18¾) is, say, 156.1 lb. per sq. in. at 1000 r.p.m. The available data may be summarized as follows:

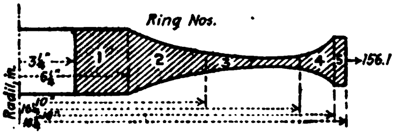

FIG. 1.

Ring No.	1	2	3	4	5
r_1 =	3.25	6.25	10.00	16.25	18.00
r_2 =	6.25	10.00	16.25	18.00	18.75
t_1 =	4.00	4.00	1.024	0.544	2.514
t_2 =	4.00	1.024	0.544	2.514	2.514
r_1/r_2 =	0.520	0.625	0.615	0.903	0.960
t_1/t_2 =	1.00	3.91	1.88	2.17	1.00
a =	0.0	−2.9	−1.3	15.0	0.0
R_1 =	0.0	......	......	......	......
R_2 =	......	......	......	......	156.1
A =	6.93	5.91	6.53	8.06	7.84
B =	1.74	4.08	2.94	3.90	24.5
C =	2.74	1.48	2.27	21.45	25.5
D =	3.17	3.31	3.57	7.04	7.44
E =	0.74	2.26	1.59	3.55	23.5
$F = B + a$ =	1.74	1.18	1.64	18.9	24.5

Equating the tangential stress at the end of each ring with that at the beginning of the adjoining ring, gives the following equations [from (4) and (5)]:

At $r = 6\frac{1}{4}$, $T_{21} = T_{12}$, or $3.17 \times (6\frac{1}{4})^2 - 0.74 \times 0 + 1.74R_{21} = 5.91 \times (10)^2 - 4.08R_{12} + 1.48R_{22}$.

At $r = 10$, $T_{22} = T_{13}$, or $3.31 \times (10)^2 - 2.26R_{12} + 1.18R_{22} = 6.53 \times (16\frac{1}{4})^2 - 2.94R_{13} + 2.27R_{23}$.

At $r = 16\frac{1}{4}$, $T_{23} = T_{14}$, or $3.57 \times (16\frac{1}{4})^2 - 1.59R_{13} + 1.64R_{23} = 8.06 \times (18)^2 - 3.90R_{14} + 21.45R_{24}$.

At $r = 18$, $T_{24} = T_{15}$, or $7.04 \times (18)^2 - 3.55R_{14} + 18.9R_{24} = 7.84 \times (18\frac{3}{4})^2 - 24.5R_{15} + 25.5 \times 156.1$.

The solution of these equations, considering that $R_{21} = R_{12}$, $R_{22} = R_{13}$, $R_{23} = R_{14}$ and $R_{24} = R_{15}$, gives the following stresses at 1000 r.p.m.:

For r =	3.25	6.25	10.00	16.25	18.00	18.75
R =	0.	462.	1500.	1652.	237.5	156.1
T =	1536.	927.	1060.	1265.	910.	860.

For 3600 r.p.m., all the stresses should be multiplied by $(3600/1000)^2 = 12.96$, giving

R =	0	5,990	19,440	21,410	3,080	2,020
T =	19,910	12,010	13,740	16,400	11,790	11,150

If the modulus of elasticity of the material is, say, 29,000,000, the radial stretch L at any radius is

$$L = (T - 0.3R)r/29{,}000{,}000 \tag{7}$$

making the radial elongation at the various radii as follows:

For r =	3.25	6.25	10.00	16.25	18.00	18.75
L =	0.00224	0.00220	0.00277	0.00560	0.00676	0.00682

For intermediate points in any ring, R_2 can be computed by (4) from the known values of T_1 and R_1, and then T_2 can be computed by (5) from the known values of R_1 and R_2.

Average Stress. Frequently it is desired to know only the average tangential stress for a given section of wheel disk without going through the computations for finding the local stresses. The formula for average tangential stress T_a in a wheel, due to its own weight alone, is

$$T_a = 28.42(N/1000)^2 SI/A_0 \tag{8}$$

in which N = r.p.m.; S = density of material, lb. per cu. in.; I = moment of inertia of the half-section about the axis of the shaft, in.^{4}; and A_0 = area of the half-section, sq. in. For hyperbolic cross-sections of the form $t = br^a$,

$$I = b\,(r_2^{a+3} - r_1^{a+3})/(a + 3) \tag{9}$$

and

$$A_0 = b\,(r_2^{a+1} - r_1^{a+1})/(a + 1) \tag{10}$$

For the preceding example the values in (9) and (10) are as follows:

Ring No.	1	2	3	4	5
b =	4.00	814.0	20.4	37.26×10^{-20}	2.514
A_0 =	12.00	7.8	4.6	2.3	1.9
I =	280.	471.	772.	686.	637.

Total $A_0 = 28.6$; total $I = 2846$.

The average tangential stress, due to the disk's own weight, at 3600 r.p.m. is $T_a = 28.42 \times (3.6)^2 \times 0.28 \times (2846/28.6) = 10{,}300$ lb. per sq. in.

If at the outer radius of 18¾ in. there is a radial stress of 2023 lb. per sq. in. at 3600 r.p.m. caused by the attached buckets and the non-continuous portions of the turbine wheel itself, the additional average stress caused by this dead load is $2023 \times 18.75 \times 2.514/28.6 = 3340$ lb. per sq. in. The total average tangential stress in the wheel disk section is therefore $10{,}300 + 3340 = 13{,}640$ lb. per sq. in. By plotting the local tangential stresses against total area of section counted from the inside of the bore (instead of against radii), and drawing on this curve of stresses a horizontal line to represent the average tangential stress as just found, the equality of areas above and below this horizontal line will serve as a very sensitive check on the correctness of the computations. In case there are bolt holes or other non-continuous portions in the section, the (projected) area of these holes should be subtracted from the gross area of the section, and all tangential stresses should be multiplied in the ratio of the gross area to the net area of the section.

Impellers. In impellers for centrifugal pumps such as shown in Fig. 2, the dead load caused by the blades cannot be regarded as acting at any particular radius. The usual procedure is to compute the local radial and tangential stresses by the method described above, on the assumption of zero radial stress both inside the bore and at the outer radius, thus leaving the dead load all out of account temporarily. Then the average tangential stress T_a in the section, and the total centrifugal force F in lb. exerted by all the blades are computed. If the weight of all the blades is W lb. and the radius of their center of gravity is R in., then, at N r.p.m., $F = 28.42(N/1000)^2WR$, and if the area of the impeller section on one side of the shaft line is A_0 sq. in., the additional average tangential stress T_e caused by the dead load is $T_e = F/2\pi A_0$. If there are any holes in the section, the sum of T_a and T_e should be multiplied in the ratio of the gross area to the net area of the section to give the corrected total average tangential stress in the impeller. The ratio of this total average stress to the original value of T_a is then applied as a correction factor to the values of the local tangential stresses as previously computed. The correction of the radial stresses is laborious and uncertain.

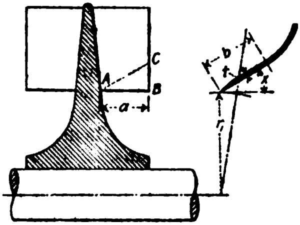

FIG. 2.

In connection with Fig. 2 it should be noted that if the width a of the impeller blade is excessive, the lower corner of the blade is subject to a crumpling stress on the section through AC. Referring to the lettering in the figure, if N = r.p.m. and S = density of the material (lb. per cu. in.), the crumpling stress in lb. per sq. in. is

$$C = 28.42\left(\frac{N}{1000}\right)^2 Sr_1 \cos x \frac{a^2b^2}{t(a^2+b^2)}$$

In case the value of C is too high, the blade must be reinforced by annular shrouds, or the radial inlet construction must be changed to that of the axial inlet type.

CRITICAL SPEEDS OF SHAFTS

The critical speed of a rotating shaft is the speed at which its elastic forces are completely neutralized so that it is incapable of offering any resistance to a deflecting force. This speed is equal numerically to the frequency of vibration of the shaft with the masses mounted on it, if deflected by an external force while the shaft is at a standstill. Its value depends on the length of the shaft, its various diameters, the manner in which it is supported, and on the magnitude and distribution of the loads it carries, but it is independent of whether the shaft is horizontal or vertical.

Shafts of Uniform Diameter. If a shaft carrying loads W_1, W_2, W_3, W_4. . . (lb.) has such dimensions and is so supported that the static deflections at those loads, if the shaft were horizontal (although actually it may be vertical), would be y_1, y_2, y_3, y_4 . . . (in.), respectively, the first or lowest critical speed N_c in r.p.m. is given by the formula

$$N_c = 187.7\sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + W_4y_4 + \ldots}{W_1y_1^2 + W_2y_2^2 + W_3y_3^2 + W_4y_4^2 + \ldots}} \quad (1)$$

The value obtained by using in this formula the static loads W and the corresponding deflections y is generally within 1 per cent. of the correct value. By repeating the calculation, using W_1y_1, W_2y_2, W_3y_3, W_4y_4 . . . as the concentrated loads acting on the shaft and finding the corresponding deflections y_{1e}, y_{2e}, y_{3e}, y_{4e}, and then writing for the correct value N_c

$$N_c^1 = N_c\sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + W_4y_4 + \ldots}{W_1y_{1e} + W_2y_{2e} + W_3y_{3e} + W_4y_{4e} + \ldots}} \quad (2)$$

a closer approximation to the true critical speed will be obtained, as the values y_{1a}, y_{2a}, . . . will correspond more nearly to the elastic curve of the shaft *at the critical speed.* Similarly, by repeating the calculation again with W_1y_{1a}, W_2y_{2a} . . . as loads and finding corresponding deflections y_{1b}, y_{2b} . . . ., a still closer approximation to the true critical speed will be obtained. Unless, however, extreme care is taken to avoid cumulative errors of computation, the increased accuracy obtained for successive trials is likely to be to a large extent illusory, and of no practical value. If the shaft carries any distributed loads, they should be replaced by approximately equivalent concentrated loads before using formula (1). In case the loads W_1, W_2, W_3, W_4 . . . are not all on the same span (*e.g.*, on a three-bearing shaft), the loads on one span must be assumed as acting vertically downward, and those on the other vertically upward, so as to preclude the possibility of a zero deflection at any point except at the bearings. The same rule applies when the shaft has three or more spans.

In practice, the loads are usually shrunk on the shaft so that its stiffness (or its moment of inertia) at the loads is greatly increased; the loads are not exactly concentrated at the assumed points; and, finally, the gyroscopic action of the loads on the bent shaft, especially toward the bearings, tends to straighten out the shaft. For these reasons, the value of N_c as computed by (1) will usually be found to be somewhat low.

If a single load W_1 alone is acting on the (weightless) shaft, (1) becomes

$$N_c = 187.7/\sqrt{y} \tag{3}$$

and in this form it is occasionally applied to single-span shafts carrying more than one load by taking for y the *maximum* deflection of the shaft, no matter where it occurs.

A shaft may have as many critical speeds as the number of loads it carries. A shaft carrying a distributed load may therefore have an infinite number of critical speeds. For engineering purposes, only the first critical speed is usually of importance, while the second critical speed is only occasionally reached. For shafts of uniform or average diameter d (in.), carrying one or two concentrated loads or a uniformly distributed load (lb.), formulæ for the critical speed can be written down directly. Tables 1, 2, and 3 are for steel shafts having a modulus of elasticity E = 29,000,000. Table 1 gives the single critical speed N_c. Table 2 gives the first critical speed N_{c1} and R the ratio of successive critical speeds to the first. Table 3 gives directly or indirectly the two critical speeds N_{c1} and N_{c2}. In all cases, the weight of the shaft itself is either neglected, or a part of it (one-half to two-thirds) is added to the concentrated loads. Shafts with very short or self-aligning bearings are considered as *supported* at the bearings, and those with long, rigid bearings as *fixed*.

As defined above, a shaft at its critical speed is in a state of maximum sensitiveness (or indifferent equilibrium), so that the smallest force may, if allowed sufficient time, deflect it to infinity and break it. The minutest deviation, however, from the mathematically exact critical speed is sufficient to restore to the shaft a considerable amount of its elastic resistance. In the neighborhood, therefore, of its critical speed a shaft merely undergoes more or less intense vibrations, which are generally transmitted also to the supporting frame. The deflecting force may be due to some external cause, but it is usually supplied by the almost unavoidable deviations of the centers of gravity of the various loads from the center line of the shaft. By reducing these deviations to a minimum by fine workmanship and very careful balancing, the vibration at the critical speed may be made scarcely noticeable.

Table 1. Critical Speeds of Shafts with a Single Concentrated Load

(Bearings R_1 and R_2; distance c. to c. = l)

* One bearing, R_1; load W distributed uniformly from R_1 to end of shaft, distant l from bearing.

Shafts of Variable Diameter. When the diameter of the shaft is too variable to assume a satisfactory average, or when the total number of loads is greater than two, no general critical speed formulæ are available, and each case must be worked out independently. For the deflections y_1, y_2, y_3 . . . in (1) the following general formula may be used:

$$Ey_x = \int\int_0^x \frac{M}{I}\,dx + C_1x + C_2$$

in which E = modulus of elasticity (taken as 29,000,000 for steel); y_x = deflection at point x, in.; x = distance of point x from origin, in.;

Table 3. Critical Speeds of Shafts Carrying Two Concentrated Loads

General formula: N_{c1} and $N_{c2} = \sqrt{\frac{1}{2A}\left[U^2 + V^2 \mp \sqrt{(U^2+V^2)^2 - 4AU^2V^2}\right]}$

For N_{c1} use minus sign; for N_{c2} use plus sign. The values of A, U, and V are given in the table below, whenever N_{c1} and N_{c2} are not given directly. y_1 and y_2 = static deflections at W_1 and W_2 (shaft horizontal).

1		$A = 1 - \left(\frac{l^2 - a_1^2 - a_2^2}{2(l-a_1)(l-a_2)}\right)^2$ $U = 387{,}500\frac{d^2}{a_1(l-a_1)}\sqrt{\frac{l}{W_1}}$; $V = 387{,}500\frac{d^2}{a_2(l-a_2)}\sqrt{\frac{l}{W_2}}$
2		$N_{c1} = 548{,}000\frac{d^2}{a_1(l-2a_1)}\sqrt{\frac{l}{W_1}}$ $N_{c2} = 548{,}000\frac{d^2}{a_1}\sqrt{\frac{l}{W_1(3l-4a_1)}}$ $y_1 = \frac{W_1a_1^2}{6EI}(3l-4a_1)$
3		$A = 1 - \frac{(l+a)^2}{4l(l+c)}$ $U = 387{,}500d^2\sqrt{\frac{l}{W_1a^2b^2}}$; $V = 387{,}500\frac{d^2}{c\sqrt{W_2(l+c)}}$ $y_1 = \frac{W_1a^2b^2}{3EIl} - \frac{W_2ac}{6EIl}(l^2-a^2)$ $y_2 = \frac{W_2c^2}{3EI}(l+c) - \frac{W_1ac^2}{6EIl}(l^2-a^2)$
4		$A = 1 - \frac{9}{16}\,\frac{l}{l+c}$ $U = 1{,}550{,}000\frac{d^2}{l\sqrt{W_1l}}$; $V = 387{,}500\frac{d^2}{c\sqrt{W_2(l+c)}}$ $y_1 = \frac{W_1l^3}{48EI} - \frac{W_2cl^2}{16EI}$; $y_2 = \frac{W_2c(l+c)}{3EI} - \frac{W_1cl^2}{16EI}$
5		$C_1 = \frac{(l_1+a_1)^2}{4l_1(l_1+l_2)}$ $C_2 = \frac{(l_2+a_2)^2}{4l_2(l_1+l_2)}$ $A = 1 - \frac{C_1C_2}{(1-C_1)(1-C_2)}$ $U = 387{,}500\frac{d^2}{a_1b_1}\sqrt{\frac{l_1}{W_1(1-C_1)}}$; $V = 387{,}500\frac{d^2}{a_2b_2}\sqrt{\frac{l_2}{W_2(1-C_2)}}$
6		N_{c1} and $N_{c2} = 1{,}405{,}000\frac{d^2}{l\sqrt{W_1l}}\sqrt{1+m\mp\sqrt{1+m^2-1.388m}}$
7		$N_{c1} = 1{,}550{,}000\frac{d^2}{l\sqrt{W_1l}}$ $N_{c2} = 2{,}340{,}000\frac{d^2}{l\sqrt{W_1l}}$ $y_1 = \frac{7Wl^3}{768EI}$

M represents the moments at successive points on the shaft, lb.-in.; I represents the moments of inertia at the points where M is found, in.^{4}; C_1 = tangent at origin ($x = 0$) and C_2 = deflection at origin. In practice, the origin is taken at one of the bearings, where the deflection is zero; M and I are found at the points where the shaft diameter changes (generally designated as shoulders) and at the points where the loads are applied; values of dx are the finite (often large) distances between the successive points at which M and I are computed; and the integration indicated is in reality a mechanical summation.

If the total length of the span (between successive points where $y = 0$) is l, then

$$C_1 = -\frac{1}{l}\iint_0^l \frac{M}{I}\,dx$$

If M_1 and M_2 are the moments at the points x_1 and x_2, respectively, these points being separated by a piece of shaft of constant diameter d and moment of inertia I, then, for this piece of shaft,

$$\int_{x_1}^{x_2} \frac{M}{I}\,dx = \frac{M_1 + M_2}{2} \times \frac{x_2 - x_1}{I}$$

and proceeding step by step, the integral $\int_0^{x_1} \frac{M}{I}\,dx$ from the origin up to any point x_1 in. from the origin may thus be found. The double integral for the above piece of shaft of constant I is

$$\iint_{x_1}^{x_2} \frac{M}{I}\,dx = (x_2 - x_1)\int_0^{x_1} \frac{M}{I}\,dx + \frac{(2M_1 + M_2)(x_2 - x_1)^2}{6I}$$

so that the double integral $\iint_0^{x} \frac{M}{I}dx$ up to any point x in. from the origin may be found by a step-by-step process. If the distances $x_2 - x_1$ are very small, it is near enough to write for each individual step

$$\iint_{x_1}^{x_2} \frac{M}{I}\,dx = (x_2 - x_1)\int_0^{x_1} \frac{M}{I}dx$$

For critical-speed purposes, zero deflections are permissible only at the bearings, so that an overhanging load must be assumed as acting in an opposite direction from that of the loads between the bearings, and in a two-span shaft the loads on one span must be assumed as acting oppositely to (increasing the deflections of) those on the other span. The values of the reactions at the bearings of a single span, or two-bearing, shaft, are found in the usual way by taking moments. For a two-span, or three-bearing, shaft, one of the bearings is at first assumed as removed, and the deflections at the various loads, and also at the point of removal, are computed by the process outlined above. Then all the loads are supposed removed, a load of say 1000 lb. is assumed as applied at the point of bearing removal, and the deflections at all points for this condition are computed again. If the ratio of the deflection at the point of removal due to the actual loads to that due to the assumed 1000-lb. load is m, then $1000m$ is the desired third reaction, and the total deflections at all points can now be found with very little additional work. The same process may evidently be extended to the case of a four-bearing shaft by assuming two of the bearings removed and a 1000-lb. load applied successively at each of the points of removal.

For an illustration of the method of using the above principles and formulæ, see Loewenstein and Crissey, "Centrifugal Pumps," p. 203.

Long Drums. In addition to the deviation of the center of gravity of a load from that of the shaft on which it is carried, the axis of the load may be out of parallel with that of the shaft. When the shaft is put in rotation, a turning moment is developed which tends to increase the obliquity, but this is resisted by the elasticity of the shaft. Under certain conditions, however, a critical speed may be reached at which the elastic resistance of the shaft may be neutralized, and the increasing obliquity may strain the shaft to the breaking point. In Fig. 3, a continuous rigid drum is shown mounted on a steel shaft so that its principal axis AA deviates from the center line of the shaft by an angle t (shown greatly exaggerated). Let the diameter of the shaft be d, the span l, the distance of each end of the drum from the nearest bearing, a, (all in in.), the moment of inertia of drum about the principal axis AA, I_1, and that about the principal axis BB, I_2, both in in.^{4}. Then the critical speed N_{ct} due to the obliquity alone is $N_{ct} = 13{,}950 d^2 l/a\sqrt{a(I_2 - I_1)}$. The value of the angle of obliquity t does not enter into this formula, and the danger of this critical speed exists even when there is no initial obliquity. In impulse turbine wheels and in the impellers of centrifugal pumps and compressors, $I_2 - I_1$ is negative, and any initial obliquity to the center line of the bearings tends to decrease rapidly as the speed increases.

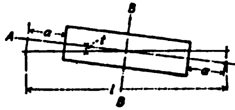

Fig. 3.

DIAPHRAGMS, CASINGS AND HEADS

The stationary parts of steam turbines, centrifugal pumps, and centrifugal compressors, such as diaphragms, casings and heads, are frequently subjected to high static pressures. Since a mathematical determination of the local stresses from point to point produced by these pressures is generally impracticable on account of the too irregular shape of such parts, the designer must depend on his judgment to avoid too sudden changes of contour or portions which are obviously too weak. If the general shape of the cross-section is satisfactory, the following method may be employed for determining the average stress in the extreme fiber.

The uniform static pressure of p lb. per sq. in. may be considered as resisted by the uniformly distributed reaction at the bolt circle (of diam. D in.) where the part in question is held to the adjoining parts. The total load W on the part, and also the total reaction, is $0.7854\ D^2p$ lb., and the distance L between the centers of gravity of the load and of the reaction is $0.1061\ D$ in. If the section modulus of the diametral cross-section is Z (in.^{3}), the average stress S at the extreme fiber is

$$S(\text{lb. per sq. in.}) = \tfrac{1}{2}W \times L/Z \qquad (1)$$

The following **graphical method for** finding the **section modulus of an irregular cross-section** will generally be found both convenient and sufficiently accurate. The heavy lines in Fig. 4 represent the half cross-section of a dished diaphragm on one side of the shaft line AB. The center line of gravity of the cross-section is assumed as nearly as possible, and two arbitrary lines at a distance K in. on each side of it are laid off outside of, but preferably close to, the cross-section. The cross-section is massed about AB (or any line parallel to it) by drawing a number of meridian lines perpendicular to AB and laying off their intercepts on the cross-section from AB; as replacing the intercept CD by the equal length $C'6$. The greater the number of these lines (especially furthest from the center of gravity line) the more accurate is the process; but it is always very important that such a line be taken wherever there is a sudden change of section. From the intersections $0'$ of the two arbitrary lines with AB, lay off the distances $0'1'$, $0'2'$, etc., equal respectively to the distances 01, 02, etc. From $5'$ draw a line to point a, which is the intersection of line 5 with the outline of the massed cross-section. Line $5'a$ intersects the arbitrary line at b. Connect b to 0 by a straight line, intersecting line 5 at c. Similarly, connect points $1'$ to $10'$ to the corresponding points of intersection of the meridian lines 1 to 10 with the boundary of the massed cross-section. Where these connecting lines intersect the arbitrary line are points to be connected to the origin 0. The intersection of each of these lines to the origin 0 with the original meridian lines will give intersection points on each meridian line similar to that of c. By connecting all these points the cross-hatched section as shown in the figure is found. If the center line of gravity was correctly chosen the area of the cross-hatched portion above the center line of gravity is equal to that below. If this is not the case, a new center line must be taken and the work repeated. If the diaphragm has been properly designed, the cross-hatched figure on each side of the center line of gravity will be very nearly a triangle. Therefore, any very marked deviations of the outer periphery of this figure from a straight line should give warning of a local excess or of a local deficiency of material. Also, the section selected for treatment in this way should be, as far as possible, a representative section, and must not be taken through a part where the body is specially strengthened by ribs or otherwise.

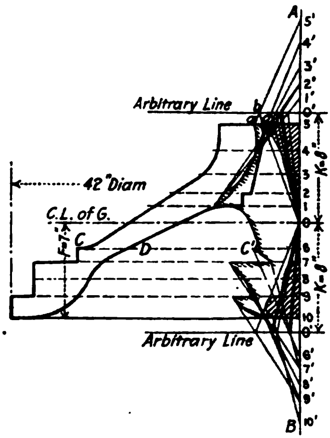

FIG. 4.

In Fig. 4, the total cross-hatched area on both sides of the center line of gravity of the half section is 12.69 sq. in. (after allowing properly for the scale of the drawing). As the diaphragm is symmetrical about the shaft line AB, the cross-hatched area A corresponding to the total diametral cross-section is 25.38 sq. in. If the distance F from the center line of gravity to the remotest fiber is 7 in., and the distance K on each side is 8 in., the modulus of the section $Z = AK^2/F = 232$ in.^{3} If the diameter of the bolt circle is 42 in., and the unbalanced pressure on the diaphragm is 100 lb. per sq. in., then $W = 0.7854 \times 42^2 \times 100 = 138{,}545$, and $L = 0.1061 \times 42 = 4.456$, so that from (1), $S = \frac{1}{2} \times 138{,}545 \times 4.456/232 = 1330$ lb. per sq. in. For safe design S should not exceed 3000 lb. per sq. in. for cast iron and 9000 lb. for cast steel.

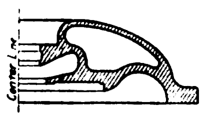

FIG. 5.

If the casing is hollow, as in the half cross-section of the centrifugal-pump casing shown in Fig. 5, the procedure is the same, the massing about the center line being the sum of the two intercepts for the hollow part of the casing.

PIPE AND PIPE FITTINGS

BY

C. W. HAM

CAST-IRON PIPE

Cast-iron Pipe is extensively used for water, gas, sewage, culverts, drains, etc., in a wide range of sizes and for varying pressures, and is particularly **adapted to underground and submerged service** because of its comparatively high corrosion-resisting qualities. It is more durable than wooden-stave, wrought-iron or steel pipe, but its first cost is greater for the ordinary sizes required in a pressure pipe line or in a distributing system. The tensile strength of commercial cast-iron pipe is uncertain, and, due to its low elasticity, it is not suitable for lines subject to the strains of expansion, contraction, and vibration, unless it is of very heavy weight. This pipe may be had in various thicknesses and weights with either **flanged ends** or **bell-and-spigot ends.** The latter are generally used for underground work, making a tight joint when properly put together, calked and leaded. For exposed piping, flanged ends are used, the joints being made up with gaskets. Flanged pipe has superior strength and tightness of the joint and is used where pipe

lines can be well supported. The bell-and-spigot joint possesses greater flexibility, provides for expansion and contraction, and is therefore especially suitable for water pipe and almost exclusively used for that purpose. Fig. 1 shows the standard form of the joint for ordinary pressures. Other forms rarely used in the United States are the bell-and-plain-spigot and the turned-and-bored joints. Plain-end pipe with couplings for high-pressure gas mains and threaded pipe for corrosive liquids are also manufactured. Cast-iron pipe, fittings, and valves have not been found suitable for superheated steam service. German authorities state that cast iron should not be used for temperatures above 480 deg. fahr. Other authorities specify temperatures as high as 575 deg. fahr.

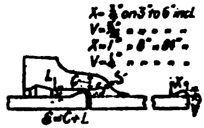

Fig. 1.

The **specifications** adopted by the American Water Works Association, May 12, 1908, are now used generally as the manufacturer's standard throughout the United States. The standards of the New England Water Works Association do not differ materially. Brackett's formula for the thickness of cast-iron pipe is $T = 0.25 + (P + P')r/3300$, in which T is the thickness in inches, P the maximum static pressure in lb. per sq. in. for which the pipe is designed, P' the allowance made for water ram, and r the radius in inches. This gives a large factor of safety to cover inequalities of the castings, strains brought on the pipe from other causes than the water pressure, and to give sufficient thickness to insure the pipe against breakage in shipping and laying. For ordinary water-works conditions for pipes, from 42 to 60 in. diameter, inclusive, 70 lb. per sq. in. is enough for P', but for smaller pipe Brackett allows the following values:

Diam. of pipe, in = 36	30	24	20	16	12	10 to 3
P', lb. per sq. in. = 75	80	85	90	100	110	120

For city work where great damage would be caused by breakage, and for single lines with no reserve where an interruption of the supply would be a very serious matter, the pipes may be made thicker than computed by this formula.

Cast-iron pipe should be made of a soft and tough quality of iron and should be subjected to a test pressure of at least twice the working pressure. A good grade of cast iron shows the following properties: Tensile strength, 20,000 lb. per sq. in.; a test bar 1 × 2 in. in section should support a central load of 2000 lb. when placed flatwise on supports 24 in. apart; if loaded to breaking, should show a deflection of not less than 0.30 in. before fracture. Cast-iron pipe is coated by dipping in hot coal-tar pitch varnish before being laid in the ground.

Flexible Joint Pipe. The necessity for crossing streams and other waterways and of laying pipe lines into them has developed various forms of flexible joint pipe adapted to laying under water, which, when calked with lead, are capable of motion through several degrees without leakage. Figs. 2 and 3 show two styles of such joints which have an adjustment of 10 to 12 deg. in standard sizes. The **lead flexible joint,** Fig. 2, is the one generally used. Fig. 3 shows a more expensive joint intended for the larger sizes of pipe, especially when used for conveying water under considerable pressure.

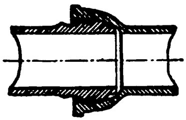

FIG. 2.

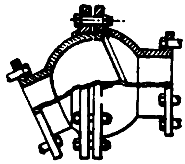

FIG. 3.

Flexible Pipe Joints.

In selecting the thickness of a pipe for a submerged line, the internal service pressure is seldom the determining factor, as ample allowance should be made to minimize the risk of breakage in laying and to withstand external shocks from floating ice or other objects. The thicknesses and weights given in Table 4 accord with good practice.

* Joints furnished with screwed, flanged, or bell-and-spigot ends, as specified.
† Class B for 200-ft. head. Class D for 400-ft. head.

"Universal" Pipe, Fig. 4, is cast-iron pipe with hub-and-spigot ends, the contact surfaces of which are machined on a taper, giving an iron-to-iron joint. By making the tapers of slightly different pitch, the joint provides for flexibility while remaining tight. Two bolts to the joint are sufficient, except for pressures above 175 lb. per sq. in. "Universal" cast-iron pipe is largely used for carrying gas and water and is suitable for all pressures

Fittings for Cast-iron Water Pipe. Flanged fittings such as those of the American 1914 Standard for steam are not used with cast-iron water pipe. The longer fittings of the American Water Works Association are generally preferred because of lower friction loss. The dimensions of the flanged fittings of this class conform very closely to the dimensions of the bell-and-spigot fittings of the American Water Works Association. The thickness of flanges equals approximately 1¼ times the thickness of the pipe plus ⅛ in., and they are drilled to American 1914 Standard templates. These fittings, both flange and bell-and-spigot type, are made in a great variety of forms known as "Standard Special Castings." For dimensions and weights, see catalog of U. S. Cast Iron Pipe & Foundry Co.

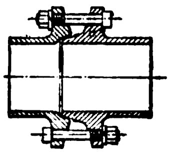

FIG. 4.—"Universal" C. I. Pipe.

WROUGHT-IRON AND STEEL PIPE

Grades. Wrought-iron and steel pipe are ordinarily adaptable for conveying steam, water, gas, oil, etc. The term wrought-iron pipe is commonly used indiscriminately to designate all butt- or lap-welded wrought-iron or steel pipe, with no special reference to either. As steel pipe has largely superseded wrought-iron pipe and is usually supplied unless otherwise specified, it must always be stated whether wrought iron or steel is required when either would not be acceptable.

Full-weight (or Standard) pipe (Table 9) is pipe of about card weight and can be obtained in random lengths of 18 to 20 ft. **Extra strong pipe** (Table 10) is heavy pipe used for high steam, gas, and hydraulic pressures when full-weight pipe will not stand the strain.

Table 8. Cast-iron Soil Pipe and Fittings

* Tapped up to 2 in.

† Weights of pipe include the hub. Laying lengths of pipe are 5 ft. From the data given for staple fittings, weights of other fittings may be calculated. For other data see "Specifications for Cast-iron Soil Pipe and Fittings," by Central Foundry Co.

Random lengths, from 12 to 20 ft. **Double extra strong pipe** (Table 11) has about twice the strength of extra strong pipe, and is suitable for very high hydraulic pressures. Random lengths, from 12 to 20 ft. **Outside diameter pipe** (Table 12): All regular sizes above 12 in., regardless of the thickness, are designated by outside diam. and thickness. Random lengths, 15 to 20 ft., depending on size. **Double-length pipe,** as made by the National Tube Co., has random lengths from 32 to 40 ft. for all kinds of pipe. The American Spiral Pipe Works furnish **large lap-welded steel pipe** in any inside or outside diameter, integral or fractional, in thicknesses from ⅛ to 1¼ in. and in lengths up to 40 ft. **Special hydraulic pipe,** for service on lines requiring the highest possible grade of material and workmanship, are bored from solid forgings and are made to order for pressures up to 10,000 lb. per sq. in.

For **physical properties** of wrought iron and steel for pipes and tubes, see p. 804.

Mill Tests on Pipe. There are no established standards for mill tests on wrought-iron and steel pipe, the various manufacturers having their own schedules of tests, of which the following (given by the National Tube Co.) is representative:

Wrought pipe	Sizes, in.	Testing pressure, lb. per sq. in.
Standard butt-welded	⅛ to 3	700 to 800
Standard lap-welded	1¼ to 15	600 to 1000
Extra strong butt-welded	⅛ to 3	700 to 1500
Extra strong lap-welded	1¼ to 15	1000 to 2500
Double extra strong butt-welded	½ to 2½	700 to 2200
Double extra strong lap-welded	1¼ to 8	2000 to 3000

Mill tests of this kind are made to ascertain possible defects in the welds or other portions of the pipe, and not the allowable working pressures.

The average ultimate strength of pipe steel is 57,000 lb. per sq. in. The relative strengths of steel pipes and tubes based on numerous tests are as follows: Butt-welded steel pipe, 73 per cent.; lap-welded steel pipe, 92 per cent.; and for seamless steel tubes approximately 100 per cent. Butt-welded wrought-iron pipe is 70 per cent. as strong as similar butt-welded steel pipe; lap-welded wrought-iron pipe is 60 per cent. as strong as similar lap-welded steel pipe. Tests on commercial tubes and pipes give the following average bursting pressures in lb. per sq. in.: Butt-welded steel, 41,000; lap-welded steel, 52,000; butt-welded wrought-iron, 29,000; lap-welded wrought-iron, 31,000; seamless steel, 62,000. The factor of safety for steam piping should not be less than six.

Pipe Threads. See p. 663.

Large Lap-welded Steel Pipe can be furnished in any inside or outside diam., integral or fractional, and in single lengths up to 40 ft. It can also be made in any thickness from 1/8 to 1 1/4 in. Forged-steel flanges and other connections are furnished in all sizes. Weights and bursting pressures are given in Table 13.

Pipe Bends of any size and shape can be obtained to suit almost any condition arising in practice. Open-hearth steel is used in sizes over 6 in., while Bessemer is employed under 6 in. The main weakness with open-hearth

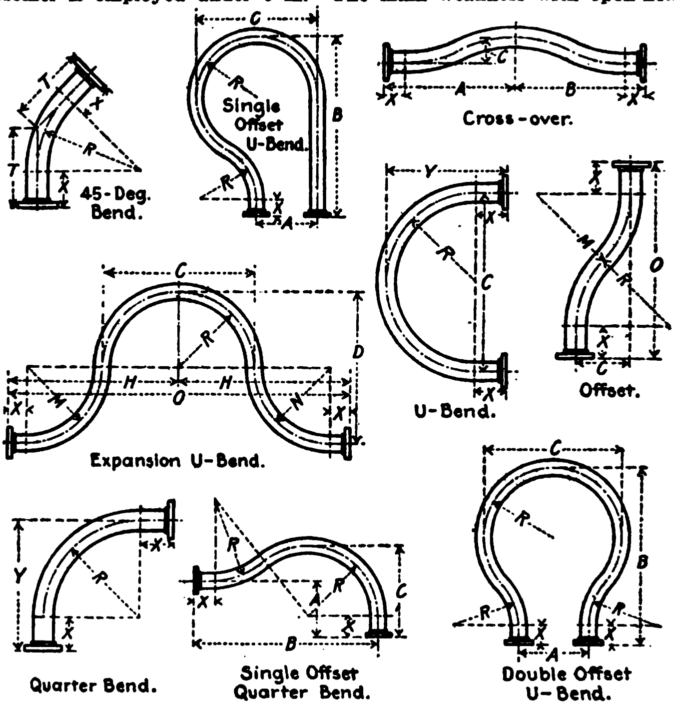

Fig. 5.—Pipe Bends.

is that the weld is not so secure. Open-hearth steel is not used on smaller-sized pipe mainly on account of difficulty in threading. Various shapes of

Table 15. Safe Expansion Values of 90-deg. or Quarters Wrought-steel Pipe Bends, in Inches

(Crane Co.)

(The values are for bends placed in line without springing. If bends are sprung to the amount of the safe expansion value, in a direction opposite to the expansion, the amount of expansion that can be taken care of will be double that shown in the table.)

pipe bends are shown in Fig. 5, the dimensions of which are given in Table 17. Their uses may be broadly classed as follows: (1) For steam lines to provide flexibility and compensate for expansion and contraction; (2) to reduce the number of joints in a pipe line; (3) to avoid obstructions such as columns, pipe foundations, which otherwise would require several pieces of pipe and fittings; (4) to reduce friction in piping; (5) for coils in heaters, refrigerating systems, etc.

Crane Co. has recently made extensive tests with various types of bends in several sizes and weights of pipe to determine their expansion values (*i.e.*, the maximum ex-

Drawings submitted should include dimensions *A*, *B*, *C*, *D*, *H* and *O* (Fig. 5) where necessary, and any other variations from dimensions as given in the above table.

Lin. ft. of pipe used in bends will vary according to dimensions differing from those in the above table.

pansion which they may be expected to take up) for steam-pipe lines. (For complete data, see *The Valve World*, Oct., 1915.) From these tests the following facts were established:

(1) Extra strong pipe bends have practically the same expansion value as the corresponding shape full-weight pipe bends.

(2) The tangents ordinarily furnished on pipe bends do not add materially to the expansion value.

(3) Bends made to a shorter radius than 5 or 6 diameters of the pipe have practically no expansion value, as they will buckle when bending.

(4) Bends are superior to the ordinary pipe-and-fitting structure because they are more flexible and do not throw all the load on the joints. Comparative tests showed that the built-up structure invariably leaked at the flanged joints, and in many cases before the fitting had been stressed near to the maximum allowable fiber stress.

(5) A U-bend has twice the expansion value of a 90-deg. or quarter bend of the same size and radius, and an expansion U-bend four times the expansion value of a quarter bend or twice that of a U-bend. A double offset expansion U-bend has two- and one-half times the expansion value of a U-bend, and one and one-fourth times that of an expansion U-bend. Safe expansion values of these bends for various radii and sizes of pipe were determined in these tests and are given in Table 15.

(6) For a given size, radius of bend and working pressure, the thicknesses of pipe for various bends as recommended by Crane Co. are shown in Table 16.

Coils and Bends of every description are made from iron, steel (preferably open-hearth), brass and copper pipe and tubing. Iron pipes, however, cannot be bent to a radius smaller than 12 in. (See catalogs of Whitlock Coil Pipe Co., Hartford Conn., and National Pipe Bending Co., New Haven, Conn.) Limiting dimensions are given in Table 14.

Table 18. Dimensions of Pipe Bends and Coils

(National Pipe Bending Co.)

NOTE.—In estimating effective steam-heating or evaporating surface of tubes, the surface in contact with air or gases of combustion, according to manner of application, as whether internal or external, is to be thus taken. For heating liquids by steam, superheating steam, or transferring heat from one liquid or one gas to another, mean surface of tubes to be computed.

Tubes. The most general applications of tubes are for oil, gas and water mains, boiler tubes, poles, conduits, ball-bearing cages and sleeves, bushings, spindles, gun barrels, axles, dies, cylinders, shrapnel cases, etc. Tubing is especially applicable to case-hardened bushings for wearing surfaces. The manufacture of tubes can be divided into two general classifications—welded and seamless. **Welded steel tubes** can be divided into two sub-classes—butt and lap. Both are made from strips of rolled iron or steel, commercially called skelp. Butt-welded tubes are made in sizes from ¼ in. to 3½ in. in diam.; lap-welded from 2 in. to 30 in.

F.h. = Finished hot; N.a. = Not annealed; F.a. = Finish annealed; M.a. = Medium annealed; S.a. = Soft annealed.

Seamless Steel Tubing, both hot-drawn and cold-drawn, is extensively used for various mechanical and engineering purposes. Owing to their smooth finish and slight variation in diameter and thickness, cold-drawn tubes can often be used to advantage and with economy in place of articles ordinarily machined from solid stock.

Seamless tubes are made by four different processes: (1) The **punching** of solid billets by hydraulic or power presses, and the subsequent rolling or hot-drawing of the hollow billet. (2) The **plate-cupping process,** which consists in taking a circular sheet or plate and cupping it while hot in a series of operations until it has been formed into a shallow cup of approximately required diam., then elongating it by hot-drawing operations on a solid mandrel through a succession of dies; this process is generally used for tubes of large diam. (3) The **cast-hollow-billet process,** where a cast-steel hollow tubular blank is used as a basis of manufacture, which is elongated by rolling over a plug or mandrel, or by hot-drawing operations. (4) The **piercing process,** which starts with a round, solid billet, which is passed through angularly-disposed rolls giving a high rotating speed and a slow advancing movement to the billet, forcing it over a pointed mandrel, increasing its length and changing it from a solid to a tubular form; this is commonly called the "Mannesmann Process."

Seamless tubes after being cold-drawn are very hard and inclined to be brittle. They are therefore furnished in three different anneals: (*a*) Hard, where great rigidity and stiffness are required and where tubes will not be bent or otherwise deformed; (*b*) medium, where strength and toughness are desired, and only slight changes of form are necessary; (*c*) soft, where a ductile and pliable material is wanted that will stand much manipulation and deformation. Outside and inside diameters vary from

* For weights of intermediate sizes (5/8, 7/8, 1 1/8, 1 3/8, 1 3/4, 2 1/4, 3 1/4, 3 3/4, 4 1/4, 4 3/4 and 5 1/4 in. diam.), take one-half of sum of weights of next larger and smaller tabulated sizes.

† Nos. 20 to 10, B. W. G. numbers; remaining sizes in fractions of an inch.

‡ For weights of intermediate sizes (6 1/2, 7 1/2, 8 1/2, 9 1/2, 10 1/2, 11 1/2, 13, 15, 17 and 19 in. diam.), take one-half of sum of weights of next larger and smaller tabulated sizes.

Square Tubing made in sizes included between heavy horizontal rules. Weight per ft. = tabular weight × 1.27.

0.005 to 0.010 in. from true diam., thicknesses from 5 to 10 per cent. Furnished in random lengths of 5 ft. and over.

Riveted Steel Pipe. Straight riveted pipe and spiral riveted pipe are furnished in lengths up to 40 ft. with pressed- or forged-steel flanges riveted to the ends. The latter are preferable, being heavier and stronger. Such pipe may be galvanized to prevent corrosion and to make the riveted joints tighter after calking. It is used extensively in non-condensing power-plant work for exhaust-steam mains, large drains, etc., but should never be used for live steam, feed water, or similar high-pressure work. **Spiral riveted pipe** (Fig. 6), because of its construction, is **stronger than straight riveted pipe** (Fig. 7) of equal size, thickness, and quality. The single seam in this pipe, being continuous and helical from end to end of pipe, stiffens it throughout its length. Weights and dimensions are given in Tables 22 and 23.

Fig. 6.—Spiral Riveted Steel Pipe.

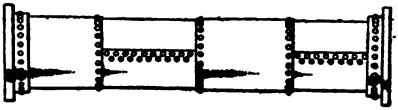

Fig. 7.—Straight Riveted Steel Pipe.

A **factor of safety** of not less than 4 should be used, and then only when the pressure is practically uniform. For pumping mains and similar piping where the pressure is apt to increase suddenly, or where shocks from water hammer are probable, a large factor should be employed; not less than 6 or 8, depending upon the conditions. The **tensile strength of the steel** plate varies from 50,000 to 70,000 lb. per sq. in., and the **efficiency of the riveted joint** in straight riveted pipe varies from 50 to 85 per cent. The friction losses in riveted pipe are greater than in smooth pipe.

Spiral riveted pipe can be furnished in lengths up to 40 ft. if asphalted or 20 ft. if galvanized. Coatings are applied by hot dipping after the pipe is made. Extra heavy and double extra heavy pipe can also be furnished for working pressures up to 400 lb. The flanges on this pipe are forged steel and of special dimensions adopted by riveted pipe manufacturers.

All diameters of pipe can be furnished with forged-steel flanges conforming to the dimensions and drilling of the A. S. M. E. Flanges are usually attached to the pipe at the factory and cannot be put on readily by the user.

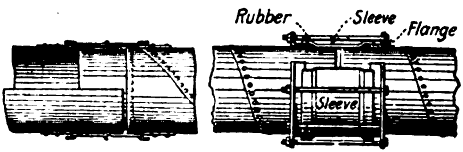
The safe working heads given above are theoretical and based on ordinary working conditions. Judgment should be used in arriving at the practical safe working heads, due allowance being made for possible water hammer, settling, and the expansion and contraction of pipe, and causes which would tend to collapse same. The working heads are based on the longitudinal seams being double-riveted and the circumferential seams single-riveted.

Pipe can be furnished, if desired, with a special forged-steel coupling which is shipped separately and which allows 5 deg. deflection at each coupling. The slip joint (Fig. 8*a*) is used largely for medium- and low-pressure work. The sleeve which is riveted in one end of the pipe may be wrapped with burlap or canvas soaked in red lead or tar, then driven into the adjoining pipe. Lugs are then connected by wire in order to hold the pipe securely. The bolted joint is shown in Fig. 8*b*.



Slip Joint (*a*). Bolted Joint (*b*).
FIG. 8.—Joints for Spiral Riveted Pipe.

A complete line of cast-iron flanged fittings, gate valves, etc., is manufactured with the flange diameters shown in Table 22.

The permissible variation in weight is ±5 per cent. Furnished with threads and couplings and in random lengths unless otherwise ordered. Taper of threads is 3/4 in. diam. per ft. of length for all sizes. The weight per ft. of pipe with threads and couplings is based on a length of 20 ft., including the coupling, but shipping lengths of small sizes will usually average less than 20 ft.

Pipe for Special Purposes. For a complete treatment of the following pipe and other pipe of special make, including dimensions, weights, test pressures, etc., see the "Book of Standards" published by the National Tube Co.

Line Pipe is a special pipe that employs recessed and taper thread couplings and usually has a greater length of thread than that given by the Briggs standard. The pipe is also subjected to a higher test. (See Table 24.)

Drive Pipe is a pipe which is driven or forced into a bored hole, to shut off water courses or to prevent caving. It has a threaded joint in which the pipe butts in the center of the coupling.

Drill Pipe is pipe fitted with special couplings, used in well boring.

Matheson Joint Pipe is wrought-iron pipe with leaded joint of the bell-and-spigot type, very similar in appearance to bell-and-spigot cast-iron pipe. This pipe is often used for water and gas under low pressures. Sizes range from 2 in. to 30 in. outside diameter; the pipe is made of different thicknesses. (See Fig. 21, p. 824.)

Converse Lock-joint Pipe is wrought-iron pipe with leaded joint used for low-pressure water or gas. Sizes range from 2 in. to 30 in. outside diameter; the pipe is made of different thicknesses. (See p. 824.)

Signal Pipe is a special pipe used on interlocking switches and the signals on railroads. It has a peculiar joint that is both threaded and connected by a plug riveted to the pipe.

Tubular Electric Line Poles made of steel pipe are used for carrying the wires for the overhead construction on electric railways, telephone, telegraph and transmission lines. Poles are made up of standard and extra strong pipe where practicable, otherwise standard tubular material is used.

Rifled Pipe is used for conveying heavy oils. The pipe is rifled with helical grooves which make a complete turn through 360 deg. in about 10 ft. of length.

Casing is a pipe used for lining oil or gas wells. It is usually characterized by light weight and fine threads. Various kinds of casing are known to the trade, differing in the range of sizes and thicknesses and the kind of joint or coupling used.

Tubing is a special grade of high-test pipe fitted with threads and couplings of special design, and is made to the same outside diameters as standard pipe. (See p. 805.) It is similar to what is known in Europe as "hydraulic pressure pipe."

* See notes at foot of Table 24.

PIPES AND TUBES OF COPPER, BRASS, LEAD, TIN AND ALUMINUM

Seamless Brass and Copper Tubes. **Brass Pipe** is made up to the same dimensions as wrought-iron and steel pipe, and threaded to the wrought-iron standard. When ordering brass pipe, iron-pipe sizes should always be specified. **Thin brass tubing** commonly used for ornamental work, brass hand railings, etc., is not of the proper size to take the standard pipe thread and is too thin for pressure work. Brass pipe is not liable to corrosion. The average ultimate strength is about 18,000 lb. per sq. in.

Copper Pipe deteriorates rapidly under high temperatures and repeated stresses. At a temperature of 360 deg. fahr. its strength is reduced 15 per cent. and on this account it should never be used for high steam pressures and temperatures.

Pipes with Special Linings. For use in lines through which are passed solutions containing more or less free acid or other corrosive agents, standard pipe, valves, and fittings may be **lead-lined** or **tin-lined** to resist corrosive action. This lining prolongs the life of the pipe and also gives it additional strength. For mine service in coal districts where the drainage water is more or less impregnated with sulphur or free sulphuric acid, **wood-lined pipe** and fittings are sometimes used. For special service, **seamless-copper-lined** pipe is also used.

VITRIFIED, WOODEN-STAVE AND CONCRETE PIPE

Vitrified Salt-glazed Pipe is used extensively for drains and sewerage systems. Burnt clay tile being rendered impervious to water by glazing, is by far the best material for sewage purposes as it is not attacked by acids.

Wooden-stave Pipe (Figs. 9 and 10) is used to a considerable extent for water supply, sewers, mining, sluicing, irrigation lines, and chemical fluids. It is durable when completely buried and kept constantly saturated. When it is used for pressures exceeding 40 lb. it should be reinforced by a banding process and the bands covered with a protective coating to prevent corrosion. **Machine-made wooden-stave pipe** is made in sizes up to 48 in. in diam. and assembled in lengths of 12 ft. for shipping. Machine-made pipe possesses the advantage of uniformity.

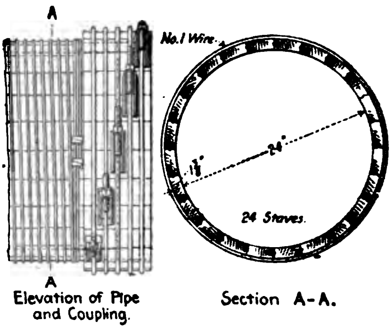

FIG. 9.—Wooden-stave Pipe.

For **continuous wooden-stave pipe,** the staves are dressed on the flat sides to circles corresponding to the diam. of the pipe to be laid, and on the edges to radial planes; and in machine-banded pipe the edges are tongued and grooved (Fig. 9). They are built into a continuous pipe by banding the staves together on the outside, so placing them as to break joints. The end of each stave is then cut off squarely and slotted for the insertion of a tight-fitting metallic tongue. The bands are spaced to conform to the pressure which the pipe is expected to withstand. Wooden-stave pipe can be made of any desired diam. and for any required pressure. Manufacturers claim that it is being used successfully for pressures as high as 200 lb. per sq. in. and for heads of over 350 ft. in extreme cases. Standard cast-iron fittings can be used for wood pipe, but special fittings may be obtained which are cheaper and better adapted to it.

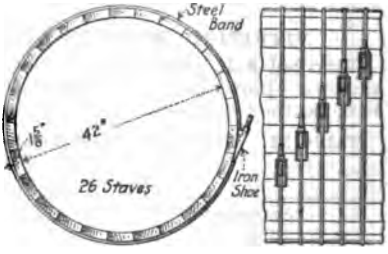

FIG. 10.—Wooden-stave Pipe.

Concrete Pipe has recently become an important factor in sewer, conduit, railroad, culvert, and water-pipe construction. The pipe, as usually made, is constructed of concrete reinforced longitudinally with bars and transversely with wire mesh or steel bands. It is made in sections of definite length, with the longitudinal reinforcement so disposed as to provide for the interlocking of one section with another, and so formed that when these are locked together and cemented they form a continuous line of pipe free from leakage or seepage. This pipe is made in diameters of 2 to 10 ft., and can be reinforced to withstand any strain. Fig. 11 shows the construction employed by the Reinforced Concrete Pipe Co., of Jackson, Mich. Pipes under 5 ft. in diam. are made in 3-ft. lengths; larger sizes in 5-ft. lengths. The wall thickness ranges from 2½ in. for a 2-ft. diam. pipe to 10 in. for a 10-ft. pipe. The flange lengths run from 3 in. for a 2-ft. pipe up to 5¼ in. for a 6-ft. pipe; above 6 ft. the flanges are all made 6 in. long.

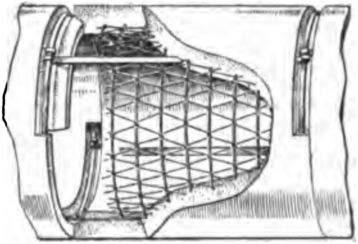

Fig. 11.—Reinforced-concrete Pipe.

FITTINGS FOR WROUGHT-IRON AND STEEL PIPE

Flanges and Flanged Fittings. Much confusion has resulted in the past, due to the various standards for flange dimensions and bolting adopted by manufacturers and engineering societies. In 1912, the American Society of Mechanical Engineers and the Master Steam and Hot Water Fitters' Association adopted what is known as "The 1912 U. S. Standard," and in the same year, at a meeting of manufacturers in New York City, the "Manufacturer's Standard" was promulgated. The disadvantages of having two standards in existence were immediately recognized, and committees of the A. S. M. E. and the manufacturers united in a compromise known as the "American Standard," to be effective after Jan. 1, 1914. The same dimensions are published by the Master Steam and Hot Water Fitters' Association under the title of "The 1915 U. S. Standard."

Notes on the American Standard. The following notes apply to the American Standard for flanges and flanged fittings:

(a) Standard and extra heavy reducing elbows carry the same dimensions center to face as regular elbows of largest straight size.

Standard and extra heavy tees, crosses and laterals, reducing on run *only*, carry same dimensions face to face as largest straight size.

Flanged fittings for lower working pressures than 125 lb. conform to this standard in all dimensions except thickness of shell.

Where long-radius fittings are specified, reference is had only to elbows made in two center-to-face dimensions and known as elbows and long-radius elbows, the latter being used only when so specified.

Standard weight fittings are guaranteed for 125 lb. working pressure and extra heavy fittings for 250 lb.

Extra heavy fittings and flanges have a raised surface 1/16 in. high inside of bolt holes for gaskets. Standard weight fittings and flanges are plain-faced. Bolt holes are ⅛ in. larger in diam. than bolts, and straddle the center line.

The size of all fittings scheduled indicates the inside diam. of ports.

The face-to-face dimension of reducers, either straight or eccentric, for all pressures, is the same as that given in table of dimensions.

Square-head bolts with hexagonal nuts are recommended. For 1⅝-in. and larger bolts, studs with a nut on each end are satisfactory. Hexagonal nuts for pipe sizes up to 46 in. on the 125-lb. standard, and up to 16 in. on the 250-lb. standard can be conveniently pulled up with open wrenches of minimum design of heads. For larger pipe sizes (up to 100 in. on 125-lb., and to 48 in. on 250-lb. standard) use box wrenches.

Twin elbows, whether straight or reducing, carry same dimensions center to face and face to face as regular straight-size ells and tees.

Side outlet elbows and side outlet tees, whether straight or reducing sizes, carry same dimensions center to face and face to face as regular tees having same reductions.

(*b*) Bull-head tees, or tees increasing on outlet, have same center-to-face and face-to-face dimensions as a straight fitting of the size of the outlet.

Tees, crosses and laterals 16 in. and smaller, reducing on the outlet, use the same dimensions as straight sizes of the larger port. Sizes 18 in. and larger, reducing on the outlet or branch, are made in two lengths, depending on size of outlet or branch as given in dimension table.

(*c*) The dimensions of reducing flanged fittings are always regulated by the reductions of the outlet or branch.

(*d*) For fittings reducing on the run only, always use the long-body pattern.

Y's are special and are made to suit conditions.

(*e*) Double-sweep tees are not made reducing on the run.

Steel flanges, fittings and valves are recommended for superheated steam.

34	22	19	25	66	44	35	45	96	64	53	64
36	24	20	26	68	44	35	46	98	64	53	65
38	24	20	28					100	66	55	67

* Long-body patterns are used when outlets are larger than given above, and therefore have the same dimensions as straight-size fittings.

See also Notes (*a*), (*b*), (*c*), (*d*), and (*e*), p. 815.

Example of Note (*b*): A 12 × 12 × 18-in. tee will be governed by dimensions of the 18-in. long-body tee; namely, 16½ in. center to face of all openings and 33 in. face to face (Table 36).

Sizes of Wrenches for Bolting Up Flanges. Tests made by Crane Co. (*Valve World*, Sept., 1913) show that a compression of about 12,000 lb. can be obtained by one man using a 16-in. wrench on ¾- to 1-in. bolts, a 36-in. wrench on 1⅛- to 1⅜-in. bolts, a 60-in. wrench on 1½- to 1¾-in. bolts, and a 72-

in. wrench on 1¾- and 2-in. bolts. Square nuts give from 20 to 25 per cent. less compression than hexagon nuts with a given effort on the wrench. Rough-cut or uneven threads reduce compression 10 to 15 per cent. Lubrication of threads and bearing surfaces increases compression about 50 per cent. over that obtained with dry threads and surfaces. It is not necessary to over-strain bolts specified in the American Standard if proper wrenches are used, and almost impossible to overstrain bolts larger than 1 in. in diam. The following overall lengths of box wrenches are recommended (interpolate for intermediate sizes):

Size of bolt, in.	½	⅝	¾	⅞	1	1¼	1½	1¾	2	2¼
Length of wrench, in.	7¾	9⅞	11½	13¼	15	19	23	27	30½	34

FIG. 14.—Standard Reducing Laterals (see Table 38).

The Bursting Pressure of Flanged Fittings. Results of hydraulic-pressure tests on flanged tees and ells made by Crane Co. (*Valve World*, Sept., 1913) are approximately expressed by the formula: Bursting point, lb. per sq. in. $= tS/D$, where t = thickness of metal in the body of the fitting in in., S = 65 per cent. of the tensile strength (T.S.) of the metal for fittings up to 12 in. diam. (60 per cent. for larger diameters), and D = inside diam. of fitting, in in. A factor of safety of from 4 to 8 should be used, depending on the size of the fitting. The formula is based on averages of tests of 52 fittings made from cast iron (T.S. = 22,000) and "ferro-steel" (T.S. = 33,000).

Flanged Pipe Joints. The flange is a most vital part of a piping system, and it is upon this that the principal cost of pipe maintenance depends. Flanges are made of cast iron, cast brass, semi-steel, and rolled steel. The important types are: the screwed, screwed and peened, shrunk and rolled, Van Stone, and welded flanges.

The **screwed joint** (Fig. 15), if properly made, compares favorably with other types of flanged joints for medium steam pressure and high water pressure in sizes up to 12 in.; above 12 in., however, it is unsatisfactory and unsafe. As an additional safeguard against leakage the inside of the pipe may be hammered or peened into the threads on the flange, making what is known as the **screwed-and-peened joint.** On account of the difficulty of properly threading sizes above 12 in., the only practical method of attaching flanges has been by riveting, or shrinking and peening. The **riveted-flange joint** (Fig. 16) and the **shrunk-and-peened joint** (Fig. 17) are mostly used for exhaust, water, and condenser service.

In the **shrunk-and-rolled joint** the flange is bored out to a shrink fit, then heated and placed on the pipe, after which the pipe is expanded by a power roller expander until it not only fits the barrel of the flange, but the metal of the pipe flows into the corrugations in the hub of the flange. Both pipe and flange are then faced off. This type of joint has been used successfully for high-pressure steam, but, having been superseded by the Van Stone joint, is used chiefly on exhaust, condenser and water lines.

The **Van Stone joint** (Fig. 18), also known by various other names, is extensively used for very-high-class work. The flange is first bored to fit over the outside of the pipe loosely. The pipe is then expanded or turned over on the end until it is at right angles to the axis of the pipe. It is then faced on the front and outer circumference. For purposes of erection this type of joint excels all others, as the flanges are loose and may be swiveled on the pipe. Rolled-steel flanges should be used, as they are practically unbreakable.

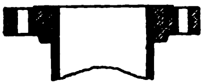

FIG. 15.—Screwed Joint.

FIG. 16.—Riveted-flange Joint.

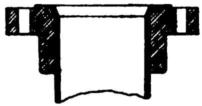

FIG. 17.—Shrunk-and-peened Joint.

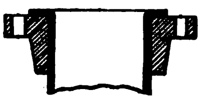

FIG. 18.—Van Stone Joint.

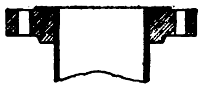

FIG. 19.—Improved Van Stone Joint.

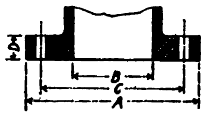

FIG. 20.—Welded Joint.

Flanged Pipe Joints.

For the **improved Van Stone joint** (Fig. 19) a distinct advantage over the ordinary joint of that name is claimed, in that the pipe is reinforced or strengthened at the turned-over portion by a band welded to the end of the pipe. It is desirable that the pipe be faced on the back surface as well as the front, as otherwise the scale formed when the pipe is heated prevents the flange from having a full and intimate bearing against the back of the pipe. After the turned-over portion is faced on the front, back, and circumference, the pipe has a thickness equal to the original thickness of the pipe and a thickness through the fillet equal to 1¼ times the original thickness of the pipe.

The **welded joint** (Fig. 20) is made by welding a rolled-steel flange to the end of a pipe, forming an integral piece of one homogeneous material. For lines subject to very high temperatures and pressures and heavy expansion strains, this joint is used very successfully. The cost of welded flanges is considerably higher than that of cast flanges, but their use makes it possible to reduce the number of joints in a run by 50 to 75 per cent., thus effecting a great saving in weight and minimizing the opportunities for leakage.

The diameters and thicknesses of the flanges shown in Figs. 15–19, as well as the diameters of bolt circles, are given in Tables 34 and 35. **Shrunk-and-peened flanges** are made in sizes 4 to 30 in. inclusive; **Van Stone flanges** in sizes 4 to 30 in. inclusive; **screwed flanges** in sizes 1 to 24 in. inclusive; and **riveted flanges** 4 to 32 in. inclusive. All but riveted flanges (cast iron) are made of either cast iron or forged steel; in the latter case somewhat smaller flange thicknesses are used. Dimensions of **welded-steel flanges** for pressures up to 250 lb. are given in Table 43.

Pipe Joints for Special Service. Various styles of pipe joints made for special service lines are shown in Fig. 21, namely, the **inserted screwed joint; flush screwed joint; Matheson joint; and Converse lock joint** for plain-end pipe. Sizes and weights of these and other joints are given in the National Tube Co.'s "Book of Standards."

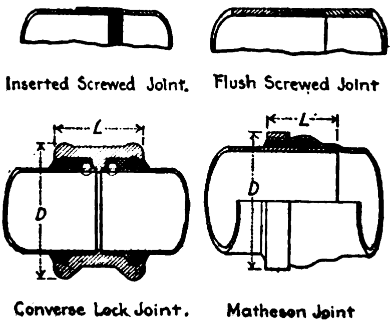

Fig. 21.—Pipe Joints for Special Service.

For water pipe which does not have to stand very high pressures, **leaded joints** are often used. The most common leaded joints are the Converse lock joint and the Matheson joint. The Converse joint is made by means of a special cast-iron coupling or hub which has a groove on each end extending around just inside of the end of the coupling, and two tee-shaped grooves on each end a short distance in from the circular groove. The pipe has two holes punched a short distance from the end on opposite sides into which rivets are driven. In making up this joint, the heads of the rivets slip into the tee-shaped slots of the hub, and the pipe is turned slightly, thus holding the pipe from pulling out of the hub endwise. This joint is then made tight by pouring lead into the circular slot and calking. The Matheson joint is another type of lead joint used for water or gas.

Gaskets. For steam and water lines where the pressure does not exceed 160 lb., wire-insertion rubber gaskets 1/16 in. thick give good service. For low-pressure lines, canvas-insertion black rubber gaskets are ordinarily used. For pressures above 160 lb. in lines carrying superheated steam, corrugated steel gaskets covering the entire annular area inside the bolt holes are highly satisfactory. Wire-inserted rubber gaskets are used for high-pressure water lines, and canvas-inserted rubber gaskets for low-pressure flanged joints.

Flange Faces for Retaining Gaskets. Flange faces are machined in various ways in order to retain the gaskets used to make fluid-tight joints. The **plain straight face** is commonly employed for pressures less than 125 lb. on steam and water lines. The best results are obtained by using a fairly thick gasket, so that the gasket will have sufficient pressure exerted on it by the bolts to make a tight joint before the outside edges of the flanges meet. The full-faced gasket is preferred by some, because it may be installed more readily and is more likely to be concentric with the bore of the flange than a ring gasket, but it has no further advantages.

In the **raised-face type** the face of the flange between the bore and inside of the bolt holes is from 3/32 to 1/16 in. above that of the remainder of the flange. It is most satisfactory on high-pressure steam lines and is very generally used. Ring gaskets are employed. The raised face prevents the touching of the outside edges of the flanges, and the entire pressure exerted by the bolts is transmitted to the gasket, which gives a maximum efficiency and resistance against leakage.

The **raised-face** type **with ground joints** has been extensively used in the past on superheated steam lines. As gaskets are now obtainable that will work successfully under temperatures as high as 800 deg. fahr., this type is becoming less frequently employed.

In the **tongue-and-groove** joint the gasket is prevented from blowing outward or squeezing inward, and its area may be considerably smaller than when unprotected. The pressure obtainable on the gasket is therefore greater than that in any other form of joint. It is especially adapted for high-pressure water, gas and air lines, and for ammonia piping.

In the **male-and-female** joint, used on high-pressure steam lines and on hydraulic lines with cup-shaped gaskets, the gasket width is greater than that in the tongue-and-groove joint. Both tongue-and-groove and male-and-female joints are expensive to install and difficult to disassemble.

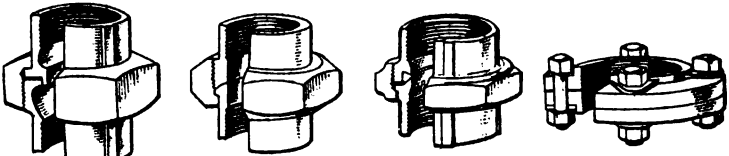
The **plain-face corrugated** joint has coarse concentric grooves upon each flange face, cut with a round-nose tool. It is used where an exceptionally thick gasket is called for, the corrugations tending to prevent the gasket from blowing out. In the **plain-face scored** joint the concentric grooves are finer and are made with a diamond-point tool. This type is used on oil or acid lines, where lead gaskets must be employed, the lead squeezing into the scores and effecting a tight joint without undue strain on the bolts and flanges.

The increasing use of **ball-shaped flanges** having inserted parts and non-corrosive rings is due to the fact that screwed unions of this type are being made to this construction.

Unions are usually classified as **nut unions** and **flange unions** (see Fig. 22). Nut unions are commonly used in sizes 2 in. and smaller, and flange unions in sizes larger than 2 in. However, many manufacturers make nut unions as large as 4 in. and flange unions smaller than 2 in.

Nut unions are made in malleable iron, brass and malleable iron, and all brass. The all-malleable-iron union (lip union) is the standard malleable union of the trade and requires a gasket. The brass and malleable-iron union (known as the "Kewanee" union) is a much better union, because no gasket is required and there is no possibility of the parts rusting together. The pipe end of the "Kewanee" union which carries an external thread, called the thread end, upon which the nut or ring screws, is made of brass, and the other pipe end (called the bottom) and nut or ring are made of malleable iron. The seat formed by the brass and iron pipe ends when brought together is truly spherical, and the harder iron is sure to make a perfect joint with the softer brass.

The brass and malleable-iron union with the inserted brass ring, known as the brass-to-iron seat, also eliminates the use of a gasket and is extensively used. The brass rings are forced into the groove under pressure and then



Lip Union. A. Kewanee Union. B Brass to Iron Seat Union. C. Flange Union. D.

FIG. 22.—Types of Pipe Unions.

ground to insure a tight joint, so that there is no possible chance for the ring to work loose. This union is also made with a brass union ring in order to provide a non-corrosive brass-and-iron thread joint that may be readily broken.

All-brass unions are made with a spherical or conical seat, no gaskets being required. Finished all-brass unions are often used where showy work is desired, such as oil piping for engines, etc.

Flange unions are made of both cast iron and malleable iron in three weights, standard, extra heavy, and hydraulic.

Expansion Joints for Steam Pipe Lines. The linear expansion of a long pipe must be taken care of by the use of some form of expansion joint or bend. The coefficients of expansion a of three metals used in pipe manufacture, within the range of temperatures common to boiler practice (32 to 392 deg. fahr.), were recently determined at the Bureau of Standards, Washington, D. C., as follows: Charcoal iron, 0.000006861; Bessemer steel, 0.000006989; seamless open-hearth steel (hot-finished), 0.000006883. The length of a tube at t deg. fahr. $= L_t = L\ (1 + at)$ in which L is the length of the tube at 0 deg. fahr. The theoretical expansion in 100 ft. of iron or steel pipe, carrying steam of various pressures and temperatures, based on an outside temperature of 32 deg. fahr., is as follows:

Gage pressure, lb. per sq. in.	30	100	125	150	175	200	Superheated steam				
Temperature of steam, deg. fahr.	274	338	353	366	377	388	420	500	550	600	650
Expansion of 100 ft. of pipe, in.	2.03	2.72	2.89	3.05	3.19	3.31	3.73	4.77	5.48	6.23	7.03

Table 44 gives the linear expansion in 100 ft. of cast-iron, wrought-iron, steel, brass or copper pipe. The expansion for a pipe of any length between any two given temperatures is found by taking the difference in length at these temperatures, dividing by 100 and multiplying by the length of the pipe in feet.

Cast-iron standard and double expansion joints are shown in Figs. 27 and 28, and the dimensions of various sizes are given in Table 46. Cast-iron double expansion joints are of the same general proportions as standard expansion joints and are more particularly designed for underground work.

Balanced expansion joints are used where the expansion of the steam line is so great as to make it impracticable to use any design of joint or bend which depends for its operation upon the elasticity of the metal. They are similar in design to the ordinary unbalanced expansion joint, with the addition of a balancing cylinder on each side. These two cylinders are of practically the same combined area as the main sleeve, and eliminate the tendency of the unbalanced expansion joint to pull itself apart.

Screwed Fittings. Malleable-iron screwed fittings are made for standard, extra heavy, and hydraulic sizes of pipe. Plain standard fittings are generally used for low-pressure gas and water, as in house plumbing and railing work, while the beaded fitting is the standard steam, air, gas, or oil fitting. **Cast-iron** screwed fittings are made in standard and extra heavy sizes 1/4 in. to 12 in. inclusive. It is not considered good practice, however, to use screwed fittings of any kind in sizes larger than 6 in. The **length of thread** on pipe that is screwed into valves or fittings, as recommended by Crane Co., is as follows:

Size of pipe, in......	1/8	1/4	3/8	1/2	3/4	1	1 1/4	1 1/2	2	2 1/2	
Length of thread, in.	1/4	3/8	3/8	1/2	1/2	9/16	5/8	5/8	11/16	15/16

Railing Fittings. Fittings of special construction and of lighter weight than standard steam, gas, and water pipe fittings are widely used for hand railings around area ways, on stairs, for office enclosures with gates, and for permanent ladders. Railing fittings are made in various styles, generally globe-shaped in body, with ends reduced to take thread and recessed to cover all threads. They are furnished in malleable iron, black and galvanized, and in brass, in sizes up to 2 in. Larger sizes are made to order.

Special railing-fitting joints are available, such as the slip-and-screwed joint, where the post connection is screwed and the rim of the fitting is so made that the rail will slip into the fitting and allow for an angular variation of

Railing acorns	0.35	0.36	0.47	0.83	1.10	1.90

Drainage Fittings, as shown in the figures accompanying Table 50, have no pockets for the lodgment of solids, and the length of the thread chamber is such that when the pipe is threaded to the Briggs standard dimensions, the end of the pipe will practically touch the shoulder when screwed in. They are especially adapted to plumbing work and vacuum cleaning pipe installations.

* Other fittings which are available are as follows: 5 5/8-deg., 11 1/4-deg., 22 1/2-deg. and 60-deg. elbows; basin crosses; double 90-deg. Y-branches; double-90 deg. long-turn Y-branches; 45-deg. double Y-branches; S-traps; half S-traps; running traps; offsets.

Ammonia Fittings are made of especially homogeneous material and usually have the mouth countersunk and both the mouth and thread tinned.

Ammonia pipe is lap-welded except under 2 in., where it is butt-welded and redrawn, as leakage occurs when butt-welded pipe is used. It should be galvanised on the outside.

Ammonia joints should be made of wrought iron or steel, as ammonia attacks and eats away copper and its alloys, brass and gun metal. On account of the penetrating nature of ammonia, all flanges should be screwed on and then soldered to the pipes. Lead washers should be used for gaskets on all flange joints. Lead or white-metal packing should be used for all valves. See also p. 1728.

The following information on ammonia fittings, valves, etc., is taken from Crane Co.'s special catalog of "Valves and Fittings for Ammonia:"

Valves and fittings for ammonia are suitable for working pressures up to 250 lb. per sq. in., and are subjected to an air-under-water test of 300 lb. Different sizes of ammonia valves have been tested to 4000 lb. per sq. in., without breaking. The material used is ferro-steel, which has an average tensile strength of 34,500 lb. Malleable iron is used for screwed ammonia fittings and has an average tensile strength of 37,000 lb. These fittings have stood tests from 3500 to 8000 lb. per sq. in. without breaking.

Valves, elbows, tees and crosses of the same type and size have the same center-to-end dimensions. A screw gland-end globe valve, for example, may therefore be substituted for a screw gland-end cross or tee, a tongue-end angle valve for a tongue-end elbow, etc.

The trimmings of valves are standardized so that the bonnet of a globe valve may be placed on an angle or a cross-valve body, and *vice versa*. The trimmings of any size valve are the same, whatever the end connections of the valve may be. Bolted bonnets for ammonia are in every way superior to screwed bonnets. Ammonia valves have the same proportions, etc., as extra heavy steam valves.

6	14	7	11	1	19	12	....	......	......	......	......	......	....

Crane Co. gives the following data relative to the quality of the **materials used for valves**: Tensile strength of brass, 30,000 lb. per sq. in.; cast iron, 22,500 lb.; ferro-steel, 33,500 lb.; hard metal (hard brass), 34,500 lb.; cast steel, 60,000 lb. Comparative destructive hydraulic tests on cast-iron and ferro-steel extra heavy gate valves showed the following results:

	Bursting pressures, lb. per sq. in.	
	Cast iron	Cast steel
Sizes 4 to 8 in.	1600 to 1900	2450 to 2600
Sizes 10 to 12 in.	1350 to 1550	1750 to 1900
Sizes 14 to 16 in.	1100	1200 to 1350

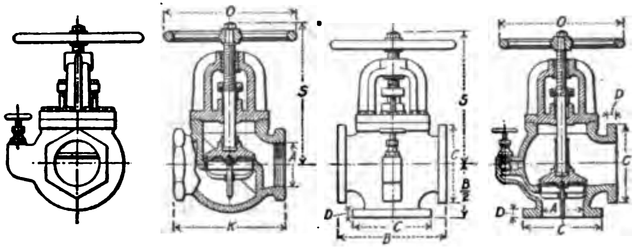
It is observed from these tests that the factor of safety is apparently very high, but in a steam line pressure is not the only consideration. Allowance must be made for the strains of expansion and contraction, settling, weight of piping, water hammer and the cutting effect of steam on the valve disk and seat.

The use of screwed valves larger than 6 in. is not recommended. On medium and extra heavy valves it is desirable to have a by-pass on sizes larger than 8 in.

For determining the water working pressures for valves and fittings based on the steam working pressures, the following rule is recommended as conservative. For sizes 12 in. and smaller add 40 per cent. to the steam working pressure; for sizes 14 in. and larger, add 20 per cent. A much greater range may be safely used for very small sizes.

Table 57. Dimensions of Medium and Extra Heavy Globe, Angle and Cross Valves

(Crane Co.)



(Medium valves: ferro-steel body with special brass seats, for steam working pressures up to 175 lb. Tested to 500 lb. hydraulic pressure per sq. in. Extra heavy valves: ferro-steel body with hard metal seats, for steam working pressures up to 250 lb. Tested to 800 lb. hydraulic pressure per sq. in. All dimensions in inches. Letters refer to dimension sketches above. For drilling templates, see Table 35.)

Cocks are generally designated under two headings, steam and gas, and are made with both brass and iron bodies. Brass-body cocks are regularly made in sizes from ¼ to 3 in., inclusive, and iron-body cocks in sizes from ¼ to 6 in., inclusive.

PIPE SUPPORTS

Pipes may be supported on rolls and chairs, anchored to brackets in various ways, and suspended from beams by hangers, or from below by floor stands. Some of the methods used are shown in Fig. 32.

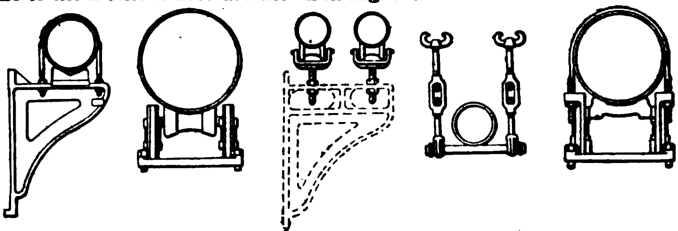

Fig. 32.—Methods of Supporting Pipes.

Tables 58 and 59 give dimensions of cast-iron rolls and chairs for pipe supports. Fig. 33 shows a heavy wall bracket adapted for any size of pipe from 5 to 20 in. in diam. Dimensions: *A*, 15 to 19 in.; *B*, 8 in.; *C*, 18¾ in.; *D*, 27 in. The universal adjustable bracket shown in Fig. 34 is made for pipe from 5 to 14 in. in diam. The inside dimension *A* ranges in six sizes from

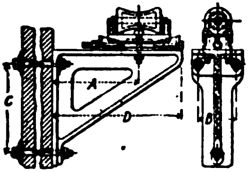

FIG. 33.

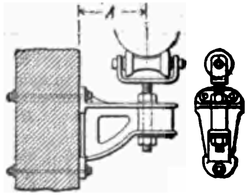

FIG. 34.

Wall Brackets for Supporting Pipes.

6 in. to 21 in.; the range of adjustment outward in each size is 3 in., and any adjustment *A* between 6 and 24 in. can be obtained from some one of the sizes made.

PIPE COVERING

(See p. 305 for heat-transmission data, and p. 633 for properties of insulating materials.)

The value of a pipe covering is measured by the percentage of saving in condensation over that which occurs in bare pipe. This percentage ranges from 65 to 85 per cent., and even higher. The **standard covering** consists of 85 per cent. of carbonate of magnesia mixed with 15 per cent. of asbestos. For first-class work the thickness for high-pressure pipes is 2 in. up to 2 in. diam., 2½ in. up to 8 in. diam., and 3 in. on larger sizes. For low-pressure lines the thickness may be less. This covering is usually applied in molded sections about 3 ft. long, the seams of which are staggered and filled with magnesia plaster. For irregular flanges or fittings magnesia (or asbestos) cement is used. The sections are bound to the pipe by means of galvanized iron wire or netting, over which is wrapped a coat of rosin-sized paper, followed by 8-oz. canvas securely sewed on.

Asbestos air-cell covering consists of several layers of corrugated asbestos sheets, making a laminated covering with air spaces between the corrugations. Another covering of the **air-space type** consists of perforated iron furred out from the pipe and wrapped with raw silk, a second jacket in a similar way being placed upon the first.

A **wood casing** is sometimes used for underground steam or hot-water pipes, for exposed steam lines in mine shafts, etc., and for cold storage and brine pipes. This covering is lined with asbestos for high-pressure steam lines, and is waterproofed for underground service. (See catalog of Wyckoff Manufacturing Co., Elmira, N. Y.)

L. B. McMillan (*Trans. A. S. M. E.*, 1915) finds, for coverings with white canvas surfaces, that the total heat flow in B.t.u. per sq. ft. of pipe surface per hour through a covering $= W_1 = at_d$, where a is taken from the accompanying table, and t_d = temperature difference (deg. fahr.) between pipe surface and air. The total B.t.u. loss per hour per sq. ft. of outside surface of covering $= W_2 = W_1r_1/(r_1 + s)$, where r_1 = outside radius of pipe, in., and s = thickness of covering, in. The temperature difference between the outer covering surface and the air corresponding to the loss W_2 is

$T_d = (328W_2 - 220)/(W_2 + 390)$, and the conductivity for a given value of T_d is $k = W_1 r_2(\log_e r_1 - \log_e r_2)/T_d$, where $r_2 = r_1 + s$. Conductivities for $t_d = 300$ deg. fahr. are given in the accompanying table.

The heat loss through any thickness of any material of which k is known for $t_d \leq 500$ deg. fahr., is $W_2 = k(t_1 - t_2 - T_d)/[r_2(\log_e r_2 - \log_e r_1)]$, where t_1 and t_2 are the temperatures of the pipe surface and room, respectively, deg. fahr. The value of W_2 for any pipe covering surfaced with white canvas may be closely approximated by use of the equation: Reading of thermometer under the canvas minus $t_2 = (328W_2 - 220)/(W_2 + 390)$.

The heat loss from *bare* pipe per deg. temperature difference per hr. per sq. ft. is as follows:

Temp. diff., deg. fahr.......	50	100	200	300	400	500
Loss in B.t.u. (= b)........	1.95	2.152	2.665	3.26	4.035	5.18

The B.t.u. *saving* due to covering per deg. temperature difference per sq. ft. per hour = $b - a$ (values of a in table), and the *efficiency* of the covering in per cent. = $100(b - a)/b$. Thus, for the first covering in the table, the saving per year per sq. ft. of covering for a temperature difference of 300 deg. fahr. (for continuous operation, or 8760 hr.) = $(3.26 - 0.455) \times 300 \times 8760$ = 7,370,000 B.t.u., and the efficiency = $100(3.26 - 0.455)/3.26 = 86$ per cent. With steam costing $0.30 per 1,000,000 B.t.u. (about 1000 lb. of steam), the gross money saving is $2.212. The first cost of the coverings mentioned ranges from 16 to 38 cents per sq. ft., installed, an average price being 24 cents. Allowing 14 per cent. of first cost for interest, depreciation, repairs, etc., makes the annual cost of covering per sq. ft. = $0.24 × 0.14 = $0.034, whence the net saving would be $2.212 − $0.034 = $2.178.

Identification of Piping by Colors. Pipe covering after being canvas-jacketed is frequently painted. The paint should be fireproof and preferably of a light color, to reduce radiation. It is well to paint pipes for different purposes of various colors. There is at present no generally accepted standard color scheme for piping. The following scheme, however, has been proposed by the A. S. M. E. Committee on Identification of Power House Piping (*Trans. A. S. M. E.*, 1911, vol. 33, p. 17).

(*a*) In the main engine room of plants which are well lighted, and where the functions of the exposed pipes are obvious, all pipes are to be painted to conform to the color scheme of the room; and if it is desirable to distinguish pipe systems, colors are to be used only on flanges and on valve-fitting flanges.

(*b*) In all other parts of the plant, such as the boiler house, basements, etc., all pipes (exclusive of valves, flanges and fittings), except the fire system, are to be painted black, or some other single, plain, durable, inexpensive color.

(*c*) All fire lines (suction and discharge), including pipe lines, valve flanges and fittings, are to be painted red throughout.

(*d*) The edges of all flanges, fittings or valve flanges on pipe lines larger than 4 in. inside diam., and the entire fittings, valves and flanges on lines 4 in. inside diam. and smaller, are to be painted the following distinguishing colors, numbered 1 to 12 inclusive:

Distinguishing Colors to be Used on Valves, Flanges and Fittings Only

Steam division	1. High pressure—white.
	2. Exhaust system—buff.
Water division	3. Fresh water, low pressure—blue.
	4. Fresh water, high-pressure boiler-feed lines—blue and white.
	5. Salt-water piping—green.
Oil division	6. Delivery and discharge—brass or bronze yellow.
Pneumatic division	7. All pipes—gray.
Gas division	8. City lighting service—aluminum.
	9. Gas-engine service—black; red flanges.
Fuel oil division	10. All piping—black.
Refrigerating system	11. White and green stripes alternately on flanges and fittings, body of pipe being black.
Electric lines and feeders	12. Black and red stripes alternately on flanges and fittings, body of pipe being black.

PRESSURE HOSE

Hose with durable rubber lining may be obtained to withstand any needed pressure. If the rubber compound is properly made the life of a hose will be from 7 to 10 years, while a cheaper hose, lined with inferior material, will probably not last more than 3 or 4 years. For fire hose, see p. 276.

National Standard Hose Couplings. There is a marked diversity in the character and dimensions of the hose couplings now in general use. Those specified below, however, have been adopted by the leading organizations supervising or controlling public utilities.

SPECIFICATIONS FOR NATIONAL STANDARD HOSE COUPLINGS

Inside diam. of hose, in.	2½	3	3½	4½
Number of threads per in.	7½	6	6	4
Male Couplings:				
Outside diam. of thread, finished, in.	3 1/16	3⅝	4¼	5¾
Diam. at root of thread, in.	2.8715	3.3763	4.0013	5.3970
Clearance between male and female thread, in.	0.03	0.03	0.03	0.05
Total length of threaded male end, in.	1	1⅛	1⅛	1⅜

Threads to be of the 60-deg. V pattern with 0.01 in. cut off the top of thread and 0.01 in. left in the bottom of the 2½-in., 3-in., and 3½-in. couplings, (0.02 in. top and bottom for 4½-in. couplings); ¼-in. blank end to be left on the male part of couplings in each case. Female ends to be cut ⅛ in. shorter for endwise clearance, and bored out 0.03 in. larger in the 2½-in., 3-in., and 3½-in. sizes, and 0.05 in. larger in the 4½-in. size in order to make up easily, without jamming or sticking. (See discussion by F. M. Griswold, *Trans. A. S. M. E.*, 1913, vol. 35, p. 423.)

Flexible Metal Hose or Tubing is made from a continuous metal ribbon or strip wound spirally. The edges are turned in during the winding so as to make an interlocked joint as shown in Fig. 35. A cord fed into a separate groove during the winding acts as a packing to keep the hose tight. The metal used for steam is bronze or copper with asbestos cord packing; for heavy pressures a braided wire jacket is added and an external spiral wire; sizes from 3/16 to 3 in. For oil, ammonia, and other non-rusting liquids steel wire is used with asbestos cord. For compressed air, cold water or suction, rubber packing is used in place of asbestos (see catalog of The American Metal Hose Co., Waterbury, Conn.).

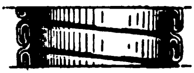

FIG 35.—Flexible Metal Hose..

WIRE ROPE, NAILS, ETC.*

Wire Rope

Wire ropes are built up of **strands** made of wires twisted together, the numbers of wires commonly used being four, seven, twelve, nineteen and thirty-seven. Ordinarily the wires are twisted into strands in the opposite direction to the twist of the strands into rope. When wires and strands are twisted in the same direction, the rope is known as **Lang lay rope. Standard wire rope** is made of six wire strands and a hemp core. Wire strands are twisted around the core, either to the right or left, and the resulting rope is thereby designated as right lay or left lay. The twist may be long or short, the shorter twist forming the more flexible rope. The **core** of a wire rope is, as a rule, hemp saturated with a lubricant. It provides little additional strength, but acts as a cushion to preserve the shape of the rope and helps to lubricate the wires. A wire strand or rope core adds from 7 to 10 per cent. to the strength of the rope, but will wear from the friction between it and the outer strands as rapidly as the outside of the rope. This does not apply to stationary ropes.

For great flexibility, the strands of a wire rope sometimes consist of wire ropes, which in turn are made of strands composed of wires, as in tiller rope. Running ropes and one construction of ship's hawsers are made with strands composed of 12 or 18 wires each, twisted about a hemp center. Ropes so made are very pliable and present good resistance to outside friction. Indi-

* Staff contribution.

vidual strands of wires are employed as smoke-stack guys, span wires for trolley roads, and wherever only moderate flexibility is needed.

Strength and Working Loads. The test **strength of wire ropes** seldom exceeds 90 per cent. of the aggregate strength of all of the wires, the average being about 82.5 per cent. The **working loads** in the following tables are calculated at one-fifth the breaking strengths, but these values are not recommended for all cases: for instance, elevator ropes seldom have a load of more than one-sixth or one-eighth of their breaking strength.

Sizes of Drums or Sheaves. (See also p. 754.) The sizes given in the tables are calculated on a basis of a working load of one-fifth the breaking strength, and provide that ropes shall not have their wires stressed beyond the elastic limit when passing around the drums or sheaves indicated. While the theoretical sizes for plow-steel ropes are smaller than for the corresponding cast-steel ropes, because the elastic limit of the former is much higher than that of the latter and the modulus of elasticity is nearly the same for both, still it is better to make drums and sheaves for the former at least as large as for the latter under ordinary conditions, since plow steel, due to its greater hardness, cracks more easily when worn. There are cases as, for example, electric cranes, where the wear is not severe, and here plow steel may be bent to more nearly its theoretical limit. Iron rope requires larger sheaves and drums than cast steel, due to its low tensile strength. When high speeds are used, much larger drums and sheaves must be employed. When working loads less than those given in the tables are used, or when the bending around sheaves and drums is very occasional, slightly smaller dimensions may be adopted. In general, the larger the drum or sheave, the longer the rope will last, while the use of diameters less than those stated in the tables will often result in a rapid deterioration of the rope. Wear increases with speed; it is therefore better to increase the load, within certain limits, than the speed.

Handling. Wire rope must not be coiled or uncoiled like hemp rope. When it is received upon a reel, the latter should be mounted upon a spindle or turn table and the rope then run off. When shipped in a coil, it should be rolled along the ground like a wheel. All untwisting and kinking must be avoided. When a wire rope is to be cut, soft iron wire should be served on each side of the place where the division is to be made to prevent the rope from untwisting.

Materials. Rope made from **Swedish iron** wire is soft, tough and pliable and has but little tendency to wear grooves in sheaves. This is of considerable advantage when wire rope is run over multiple-grooved sheaves. It is especially adapted for passenger elevators and similar service where the tendency to abrasion is comparatively slight, the speed is high, loads moderate. **Cast-steel rope** is recommended for general hoisting, such as mine hoists, derricks, coal hoists, cableways, conveyors, freight elevators, etc. It is tough and pliable, will bend over comparatively small sheaves and resist the abrasion which accompanies rapid hoisting. The wire in cast-steel rope has nearly twice the strength of that in Swedish iron rope and also has a much higher elastic limit. **Extra strong cast-steel rope** occupies an intermediate place between cast-steel and plow-steel rope. It is used in place of cast steel when it is desirable to increase the factor of safety for a given diameter. It may be used to advantage for general hoisting. **Plow-steel rope** is made of wire of great strength and toughness, capable of resisting severe abrasion. It can be used in place of cast-steel rope where it is desirable to reduce the dead weight of the rope itself, or where, by reason of increased loads, it is necessary to use a much stronger rope without increasing its diameter. Plow-steel rope is recommended especially for logging lines, scraper, dredge and wrecking ropes, heavy cranes, ballast unloader ropes, and for all rough uses requiring maximum strength and toughness. **Improved plow steel rope** is a special rope for extreme conditions. It has a maximum strength, toughness and uniformity.

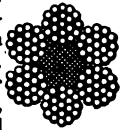

FIG. 1.

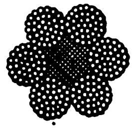

FIG. 2.

Standard Hoisting Rope (Fig. 1) is made of 6 strands, each of 19 wires, the strands being twisted around a hemp center.

Table 1. Standard Hoisting Rope

Composed of 6 strands and a hemp center, 19 wires to the strand

Extra Pliable Hoisting Rope. Made of 6 strands of 37 wires each and a hemp center (Fig. 2). The wires in this rope are much finer than those used in the standard hoisting rope and consequently not as suitable to withstand abrasion. These ropes are used on electric cranes, dredges and for similar service requiring a strong, tough rope that will operate successfully over small sheaves.

Extra Pliable Hoisting Rope of 8 strands of 19 wires and a hemp center (Fig. 3), is much more pliable than the standard construction of 6 strands of 19 wires. The metallic area of an 8-strand rope is not so great as that of a 6-strand rope, and the wires are smaller, but under severe bending stresses the decrease in strength is largely offset by the great pliability. It can be used over comparatively small sheaves and drums such as are frequently found on derricks. It is not good practice to use it where there is much overwinding, because it would flatten or lose shape more quickly than 6 × 19 rope.

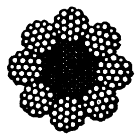

Fig. 3.

Galvanized extra pliable cast-steel hoisting rope is much more flexible than the six-strand hoisting rope, and is often used in preference to galvanized cast-steel running rope.

Standard Coarse-laid Rope (Fig. 4) is made of 6 strands and a hemp center, 7 wires to the strand. It is much stiffer than standard hoisting rope and requires larger sheaves. On account of the smaller number of wires, this rope should also be used with a higher factor of safety, as the breaking of one or two wires materially reduces the strength of the rope. The wires used are considerably larger in diameter than in hoisting rope, and consequently will stand greater wear. **Swedish iron rope** of this con-

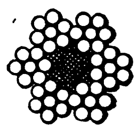

Fig. 4.

struction is recommended for power transmissions equipped with large sheaves. **Cast-steel and extra strong cast-steel rope** are recommended for mine haulages, tramways, sand lines and similar service where conditions tend to severe abrasion. **Plow-steel and improved plow-steel ropes** are recommended in place of cast steel when it is desirable to reduce the dead weight of the rope itself, or where, by reason of increased loads, it is necessary to use a stronger rope without increasing its diameter. This rope is particularly adapted for very long mine haulages.

Flat Rope is composed of a number of wire ropes called "flat rope strands," of alternate right and left lay, placed side by side, then secured or sewed together with soft Swedish iron or steel wire (Fig. 5). The sewing or filling wire is much softer than the steel wires composing the strands of the rope, acts as a cushion or soft bed for the strands, and wears out much faster than the harder wires com-

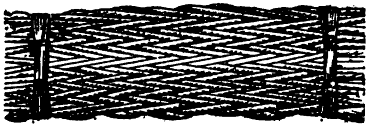

Fig. 5.—Flat Wire Hoisting Rope.

posing the latter. When the sewing wires are worn out, the flat rope can be resewed with new wire, and if any of the rope strands are also worn or damaged, these can be replaced by new portions. Flat rope is used principally for hoisting purposes. When large and long rope is used in hoisting heavy loads out of deep shafts, round rope requires large and heavy drums on which to wind, while flat rope, winding on itself, needs a reel but little wider than the width of the rope. Furthermore, flat rope does not spin or twist in the shaft. Flat rope is obtainable from 1¾ in. to 8 in. in width, and from ¼ in. to ⅞ in. in thickness, the length varying from 20 to 3000 ft. Flat rope is particularly applicable to the operating of spouts on coal and ore docks, also for raising and lowering emergency gates on canals and similar machinery. It combines flexibility and great strength, thus making possible the use of simple and compact hoisting machinery.

Table 6. Flat Rope—Crucible Steel and Plow Steel

Width and thickness, in.	Approx. weight per ft., lb.	Proper working load, tons of 2000 lb.		Width and thickness, in.	Approx. weight, per ft., lb.	Proper working load, tons of 2000 lb.

½ × 3½	2.80	12.0	14.4	⅞ × 8	10.60	45.0	51.6

The diameters of **drums and sheaves** for flat rope should be as large as possible, particularly for mine hoisting work. The desirable diameter of the drum at the bottom may be obtained from the formula $D = ct$, where D = diam. of drum at bottom, ft., t = thickness of flat rope, in., and c = 100 for drums = 160 for sheaves. For short flat ropes, drums are usually made smaller, as follows:

Thickness of flat rope, in.	¼	5/16	⅜	½	⅝	¾	⅞
Diam. at bottom of drum, in.	6	7½	9	12	15	18	21
Diam. of sheave, in.	12	15	18	24	30	36	42

Sheaves should be slightly crowned in the center and have deep flanges to guide the rope.

Flattened-strand Wire Rope is designed to give increased contact or wearing surface. The wear is consequently lessened upon any one individual wire and the necessity of the use of heavier wire diminished, which results in greater flexibility. The wearing surface is approximately 150 per cent. greater than that of a round-strand rope. Another feature of this type of rope is that the interstices between the strands being lessened, a greater number of wires are used for the same diameter. It is always made Lang lay. Flattened-strand rope has little tendency to kink, and, owing to its smooth wearing surface, saves wear on pulleys, sheaves and drums. It is made in the forms shown in Fig. 6. The working loads for types A and B are given in Tables 7 and 8, and are calculated for a factor of safety of five. They are used for elevators, hoisting, dredging, etc.

Non-spinning Hoisting Rope (Fig. 7) is constructed of 6 strands of 7 wires each, Lang lay (wires in the strands and strands themselves twisted to the left) laid around a hemp core and covered with an outer layer composed of 12 strands, 7 wires, regular lay (wires in the strands twisted to the left and strands themselves twisted to the right). The object of this combination of lays is to prevent a free load suspended on the end of a single line from rotating. This type of rope is recommended for "back-haul" or single-line derricks; also for shaft sinking and mine hoisting where the bucket or cage swings free without guides. It works best where it does not overwind on drum.

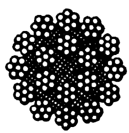

FIG. 7.

54

Either a closed or an open socket makes the best fastening on the end of non-spinning rope. These may be fastened in the same manner as any rope socket, but great care must be taken in attaching the socket to the rope to see that the strands do not untwist or allow any slack to work back into the rope. It is best to seize the end of the rope tightly for a distance of 4 or 5 in. just outside of the socket until the socketing is completed, when it may be taken off.

Steel-clad Ropes (Fig. 8) are made in three constructions for the purpose of securing different degrees of flexibility: the 6 × 19, 6 × 37 and 6 × 61 types, respectively. Flat strips of steel wound spirally around each of the six strands composing the rope, give additional wearing surface without sacrificing flexibility. When the outer flat-steel winding is worn through, a complete hoisting rope remains, with unimpaired strength. These ropes are designed to meet very severe conditions of service. The increased life obtained by the use of steel-clad rope is, in places where conditions are suitable, from 50 to 100 per cent. It is recommended particularly for such service as dredging.

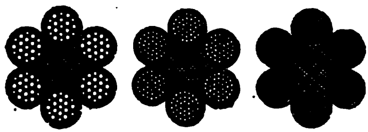

Fig. 8.—Steel-clad Ropes.

Galvanized Wire Rope has almost entirely superseded Manila rope for shrouds and stays aboard ship. It is cheaper in first cost; is not affected by the weather, and does not stretch and contract with changes in atmospheric conditions, and thus saves a great deal of labor in setting up; it is as elastic as Manila rope. There is great reduction in bulk and weight by its use, as it is only one-fifth or one-sixth as large as a Manila rope of equal strength. Consequently, it only offers half as much surface to the wind. It is much less liable to accidents by being cut or chafed, and does not rot and give way suddenly without warning. Galvanized rope is better suited for guys for derricks than hemp rope or rods linked together.

Galvanized Steel Wire Strand (Fig. 9) is used chiefly for guying poles and smokestacks, for supporting trolley wire, and for operating railroad signals. For overhead catenary construction of suspending trolley wire, the special grades of strand are preferable because they possess greater strength and toughness. The last five sizes listed in Table 13 (sometimes called "galvanized seizing strand") are used for seizing or binding the ends of wire rope and thimble splices, and for tying rope into coils.

Tramway Strand (Table 24) has usually 19, 32, 37, 61 or 91 wires, according to the diameter of the strand and the conditions of its use. It is recommended for the track or trolley cable on an aerial tramway on account of its compact construction, and is found, by reason of its comparatively smooth surface, to greatly reduce the friction on the carriage wheels. In long spans where the weight of the rope itself is a disadvantage, plow-steel quality is generally used.

Nails and Spikes

Nails are either **wire nails** of circular cross-section and constant diameter, or **cut nails** of rectangular cross-section with taper from head to point. The larger sizes are called **spikes.** The length of the nail is expressed in the "**penny**" system, the equivalents in inches being given in the following tables; the letter "d" is the accepted symbol for penny. A keg of nails weighs 100 lb. **Heavy hinge nails** or **track nails** with countersunk heads have chisel points unless diamond points are specified. **Plaster-board nails** are smooth with diamond points and ½-in. flat heads for lengths, 1, 1¼ and 1½ in.; 7/16-in. head for sizes Nos. 9, 10 and 11. **American felt roofing nails** have an extra large head and thin shank. **Spikes** are made either with flat heads and diamond points or with oval heads and chisel points.

Knots, Hitches, and Bends

No two parts of a knot which would move in the same direction if the rope were to slip, should lie alongside of and touching each other. The knots shown in Fig. 13 are known by the following names:

A, bight of a rope; B, simple or overhand knot; C, figure 8 knot; D, double knot; E, boat knot; F, bowline, first step; G, bowline, second step; H, bowline, completed; I, square or reef knot; J, sheet bend or weaver's knot; K, sheet bend with a toggle; L, carrick bend; M, "stevedore" knot completed; N, "stevedore" knot commenced; O, slip knot; P, Flemish loop; Q, chain knot with toggle; R, half hitch; S, timber hitch; T, clove hitch; U, rolling hitch; V, timber hitch and half hitch; W, blackwall hitch; X, fisherman's bend; Y, round turn and half hitch; Z, wall knot commenced; AA, wall knot completed; BB, wall knot crown commenced; CC, wall knot crown completed.

The bowline G, one of the most useful knots, will not slip, and after being strained is easily untied. Knots H, K and M are easily untied after being under strain. The knot M is useful when the rope passes through an eye and is held by the knot, as it will not slip, and is easily untied after being strained. The wall knot is made as follows: Form a bight with strand 1 and pass the strand 2 around the end of it, and the strand 3 around the end of 2, and then through the bight of 1, as shown at Z in the figure. Haul the ends taut, when the appearance is as shown at AA. The end of the strand 1 is now laid over the center of the knot, strand 2 laid over 1, and 3 over 2, when the end of 3 is passed through the bight of 1, as shown at BB. Haul all the

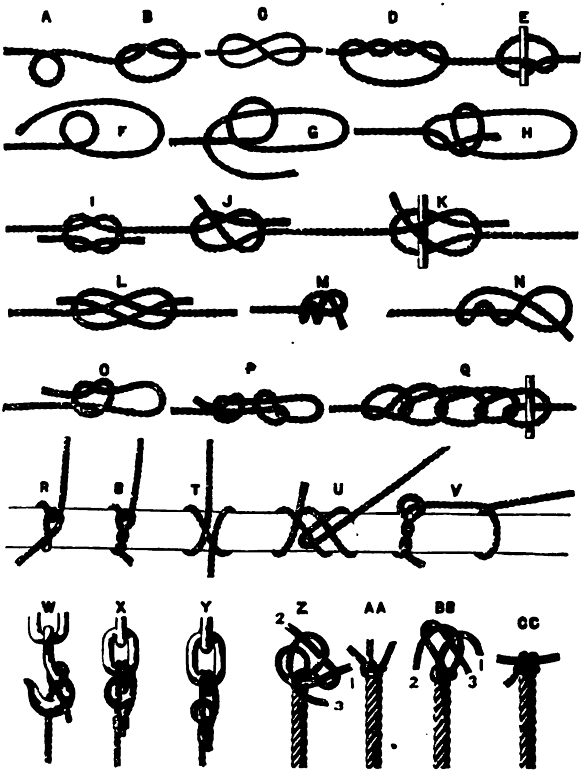

Fig. 13.—Rope Knots, Hitches and Bends.
(From C. W. Hunt Co.'s Catalog)

strands taut, as shown at CC. The "stevedore" knot (M, N) is used to hold the end of a rope from passing through a hole. When the rope is strained the knot draws up tight, but it can be easily untied when the strain is removed. If a knot or hitch of any kind is tied in a rope its failure under stress is sure to occur at that place. The shorter the bend in the standing rope the weaker is the knot. The approximate strength of knots compared with the full strength of (dry) rope (= 100), based on Miller's experiments (*Machy*, p. 198, 1900), is as follows: Eye splice over iron thimble, 90; short splice in rope, 80; S and Y (see Fig. 13), 65; H, O and T, 60; I and J, 50; B and P, 45.

Recommended Standard Cross-sections

The following cross-sections are recommended by the Cross-sections Committee of the A. S. M. E. Subdivisions of any of the materials may be

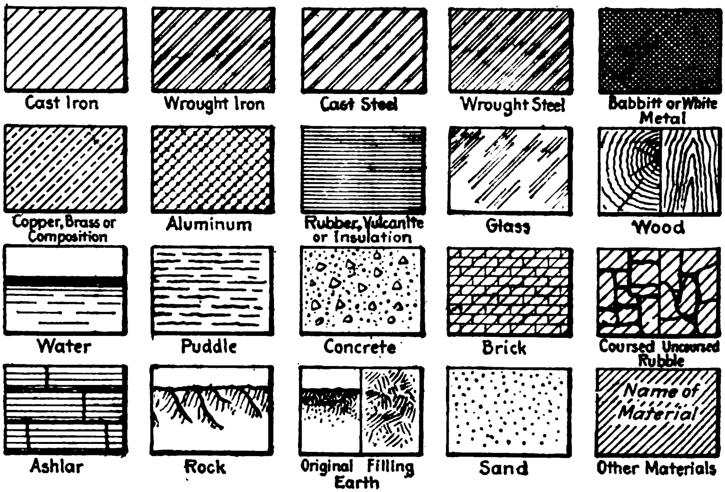

FIG. 14.—Recommended Standard Cross-sections.

made by taking one of these standard cross-sections as a basis and making minor changes or by writing on the standard cross-section the name of the material.

POWER GENERATION

MUSCULAR ENERGY OF MEN AND ANIMALS

The accompanying table gives results obtained by Poncelet, Morin, Rankine, and others. The work of Dr. F. W. Taylor shows that a maximum amount of shoveling may be accomplished by the use of a shovel taking up a load of 22 lb. Also that by the introduction of rest periods at stated intervals (determined from a study of the particular task), the amount of work done in a day by a laborer may be greatly increased above the figures given.

Nature of work	Weight moved or resistance overcome, lb. w	Velocity of movement, ft. per sec. v	Work done per sec., ft.-lb.	Time of working, hours per day	Work done per day, ft.-lb.
Raising Weights					
Man raising his own weight up a stair or ladder	143	0.5	71.5	8	2,059,200

* Dr. Taylor ("Principles of Scientific Management," p. 60) cites the instance of a laborer lifting and carrying 1156 pigs of iron (each weighing 92 lb.) up an incline into a car during a 10-hour day. Average distance of travel, 36 ft.; total lift (probably not less than) 8 ft. Ft.-lb. of work (lifting) $= 8 \times 1156 \times 92 = 850{,}816$. Prior to a study of the task and the introduction of proper rest periods, the best day's accomplishment was the transporting of 305 pigs.

* Level roads, ordinary condition.
† Weight (lb.) × distance (ft.) transported.

According to D. K. Clark a laborer can exert 0.1 h.p. for 8 hours a day on a windlass or pump, and for periods of a few minutes as much as 0.5 h.p. The maximum force which a man can exert in pushing or pulling is from 110 to 130 lb.; the greatest weight he can ordinarily carry is about 330 lb.; the weight he is capable of sustaining ranges from 450 to 650 lb.

The draft of horses is reduced by working them in teams. The draft of a horse in a 2- (4-) [8-] horse team is but 98 (80) [49] per cent. of that exerted by the horse when worked alone. A 1 : 100 grade reduces the draft 10 per cent.; a 1 : 50 grade, 20 per cent.; a 1 : 30 grade, 35 per cent.; a 1 : 20 grade, 60 per cent., and a 1 : 10 grade, 75 per cent.

WINDMILLS

REFERENCES: R. M. Dyer, *Iowa Engineer*, July, 1906, and *Machy*, Aug., 1907; Bulletin No. 82, Agl. Expt. Station, Univ. of Wis.; Water Supply and Irrigation Papers Nos. 1, 8, 14, 20, 41 and 42, U. S. Geological Survey; *Eng. Mag.* (electric lighting), Dec., 1894, p. 475.

Windmills are reversed disk or propeller fans and are built in diameters up to 30 ft., for operation with wind velocities of from 8 to 30 miles per hour. The **theoretical horse power** of the wind passing through a windmill is h.p. $= 0.075(\pi D^2/4)V^3/(2g \times 550) = 0.000001663D^2V^3 = 0.000005247D^2W^3$, where D is the maximum diam. of the wheel, ft.; V the wind velocity, ft. per sec.; and W the wind velocity, miles per hour. The rear edge of a (curved) **vane** should be nearly parallel to the plane of motion, while the forward edge should be parallel to the direction of the impinging current of air. The efficiency is materially reduced by the presence of obstacles at the back of the vanes, such as arms. The weights of wheels increase twice as rapidly as the powers developed. Smaller wheels are the more efficient.

According to U. S. Government tests of a 12 ft. Aermotor, (1) the speed of the wheel for maximum load increases slightly faster than the first power of the wind velocity; (2) the power of the mill for a constant load varies as the square root of the wind velocity; (3) the maximum power of the mill varies as the square of the wind velocity; (4) the load for maximum power does not increase quite as fast as the wind velocity; and (5) the ratio of speed for maximum load to the speed for no load increases somewhat with the wind velocity.

Brake tests of two Aermotors show that the power increases approximately as the $\frac{3}{2}$ power of the diameter (for maximum h.p.); and that the number of revolutions per min. is inversely as the diameter. Taking mean annual wind conditions as found at Dodge, Kan., a 12-ft. Aermotor will furnish on an average 1.3 h.p. 10 hours a day for 26 days a month, and a 16-ft. mill 1.9 h.p. In Table 1, the maximum power developed by a 16-ft. mill at a wind velocity of 20 miles per hour is 1.55 h.p., and the theoretical h.p. of the wind passing through the mill, from formula, is 10.75 h.p., making the efficiency = 1.55/10.75 = 14.4 per cent.

In addition to their use for driving pumps, windmills are often employed as the motive power in small electric lighting installations, where they drive direct-current dynamos for charging storage batteries. Table 2 gives data on the electrical energy generated by windmills of various sizes.

Table 1. Results of Tests of Aermotors

STEAM BOILERS

BY

ARTHUR D. PRATT

MATERIALS AND CONSTRUCTION

REFERENCES: Dept. of Commerce and Labor: General Rules and Regulations Prescribed by the Board of Supervising Inspectors, as Amended Jan., 1912. Commonwealth of Massachusetts: Rules Formulated by the Board of Boiler Rules, 1911. Report of the Boiler Code Committee, A. S. M. E., Feb., 1915.

For marine boilers, see p. 1238; for heating boilers, p. 1347.

Rules for Use in the Manufacture of Steam Boilers

The rules governing the construction of steam boilers vary with different controlling boards. There appears, however, to be a tendency toward the adoption of uniform rules in the United States. The state of Massachusetts was the first to adopt a uniform law, and this is being used as the basis for such laws in other communities. The state of Ohio, the cities of Detroit, Memphis and Manila, P. I., have all adopted laws or ordinances almost exactly similar to those adopted by Massachusetts. Boilers built for merchant vessels in the United States must be constructed in accordance with the rules and regulations prescribed by the Board of Supervising Inspectors, Department of Commerce and Labor.

The most comprehensive and probably the most rigid rules for the construction of stationary boilers are those prepared by the Boiler Code Committee of the A. S. M. E. and accepted by the Council of that Society, Feb. 13, 1915. These rules were prepared as a suggested uniform standard for adoption by all states and communities. The states of Ohio, Indiana and Wisconsin have already passed legislation under which boilers built in accordance with the A. S. M. E. Standard Code are accepted as fulfilling the requirements of their state laws. These rules, together with the Massachusetts Law and the Rules and Regulations of the U. S. Board, are quoted below as typical and, in most instances, satisfactory. For the rational design of parts of steam boilers, see pp. 392, 421, 676.

Factor of Safety (MASS. LAW). For boilers with shells or drums exposed to the products of combustion and having lap-riveted longitudinal joints, lowest factor to be five (5).

(U. S. BOARD.) No definite factor of safety (F.S.) named. Under allowable pressure for shells or drums, F.S. = 6 for single riveting, which covers actual nominal F.S. as well as loss of strength at joint. Based on reduced section at rivets, F.S. < 5.

(A. S. M. E. CODE). For new construction, 5.

Rivet Steel (MASS. LAW). Tensile strength (T.S.) of rivet steel, 45,000 to 50,000 lb. per sq. in.; yield point not less than ½ T.S.; elongation not less than 28 per cent. in an 8-in. test piece. Rivet stock of full size as rolled to endure bending 180 deg. flat upon itself, both before and after being heated to a light cherry red and quenched, without fracture on outside of bent portion.

(A. S. M. E. CODE). T.S. = 45,000 to 55,000 lb. per sq. in.; yield point, min. lb. per sq. in. = ½ T.S.; elongation in 8 in., min. per cent. = 1,500,000/T.S., but need not exceed 30 per cent. Bending tests same as Mass. Law. Certain requirements of workmanship, finish, marking and inspection.

Rivet Formulæ (Mass. Law). Maximum shearing strength of steel rivets per sq. in. of cross-sectional area: single shear, 42,000 lb.; double shear, 78,000 lb.

On longitudinal joints distance from center of rivet to edge of plate not to be less than 1½ × diam. of rivet hole. Rivet holes, except for attaching angle-bars or stay to heads, to be either drilled full size with butt straps and heads bolted up in position, or punched ¼ in. less than full size for plates over 5/16 in. thick, and ⅛ in. smaller for plates not exceeding 5/16 in. thick, and drilled or reamed to full size, with plates, butt straps and heads bolted in position. Rivets to be of sufficient length to fill rivet holes and form a head equal in strength to the body of rivet. Rivets to be machine-driven wherever possible with sufficient pressure to fill rivet holes, and allowed to cool and shrink under pressure.

(A. S. M. E. Code). In computing the ultimate strength of steel rivets in shear, the following values in lb. per sq. in. of cross-sectional area of the rivet shank shall be used: single shear, 44,000; double shear, 88,000. The cross-sectional area used in the computation shall be that of the rivet shank after driving.

On longitudinal joints distance from center of rivet to edge of plate same as Mass. Law. The distance between center lines of any two adjacent rows of rivets, or the "back pitch" measured at right angles to direction of joint, shall be at least twice diameter of the rivets and shall meet the following requirements:

(a) Where a single rivet in the inner row comes midway between two rivets in the outer row, the sum of the two diagonal sections of the plate between the inner rivet and the two outer rivets shall be at least 20 per cent. greater than the section of the plate between the two rivets in the outer row.

(b) Where two rivets in the inner row come between two rivets in the outer row, the sum of the two diagonal sections of the plate between the two inner rivets and the two rivets in the outer row shall be at least 20 per cent. greater than the difference in the section of the plate between the two rivets in the outer row and the two rivets in the inner row.

Drilling, punching and riveting as in Mass. Law.

(U. S. Board.) Appendix of rules quotes the formulæ (equivalent to those of the British Board of Trade) for determination of pitch, distance between rows, diagonal pitch and maximum pitch of steel rivets, in which p = greatest pitch of rivets, in.; n = number of rivets in one pitch; p_d = diagonal pitch, in.; d = diam. of rivets, in.; T = thickness of plate, in.

$$p = \frac{23 \times d^2 \times 0.7854 \times n}{28 \times T} + d$$

Distance between rows for double chain-riveted joints not to be less than $2d$, and preferably not less than $(4d+1)/2$.

Diagonal pitch for double-zigzag-riveted lap joints, $p_d = (6p+4d)/10$.

Maximum pitch $= 1.31T + 1\frac{5}{8}$ in. for single-riveted lap joint, and $2.62T + 1\frac{5}{8}$ in. for double-riveted lap joint.

For data on riveted joints see also p. 674.

Drum Joints (Mass. Law). Longitudinal joints of boilers with shells or drums over 36 in. in diam. to be of butt-and-double-strap construction; and for diameters ≤ 36 in., may be of lap-riveted construction. Maximum pressure allowed on such shells or drums, not over 100 lb. per sq. in. Longitudinal joints of horizontal-return tubular boilers to be located above the fire line of setting. Horizontal-return tubular, vertical tubular, or locomotive-type boilers not to have continuous longitudinal joints over 12 ft. in length. Thickness of plates in a shell or drum to be of the same gage.

(A. S. M. E. CODE). Add to Mass. Law. With butt and double-strap construction, longitudinal joints of any length may be used provided the plates are tested transversely to the direction of rolling. Tests to meet standards prescribed under specifications for boiler-plate steel.

Butt straps and ends of shell plates forming longitudinal joints shall be rolled or formed by pressure, not blows, to the proper curvature.

Material for Cylindrical Shells or Drums (MASS. LAW). All open-hearth steel classified under flange or boiler steel, fire-box steel, and extra soft steel, the physical properties of which are given in Table 1.

Table 1. Physical Properties of Steel

	Flange or boiler steel	Fire-box steel	Extra soft steel
Tensile strength (T.S.), lb. per sq. in.	55,000 to 65,000	52,000 to 62,000	45,000 to 55,000
Yield point, lb. per sq. in., not less than	½ T.S.	½ T.S.	½ T.S.
Elongation, per cent. in 8 in., not less than	25	26	28

Shells, drums and butt straps to be of fire-box steel as above.

Heads, combustion chambers, furnaces, and plates that require flanging or staying to be of open-hearth flanged, fire-box or extra soft steel.

Test specimen to be subjected to both cold and quenched bending tests, and endure bending 180 deg. flat upon itself without fracture on the outside of bent portion.

(A. S. M. E. CODE). Specifications cover two grades of steel, flange and fire-box. Steel shall be made by the open-hearth process. T.S., lb. sq. in.: flange, 55,000–65,000; fire-box, 55,000–63,000; yield point, min. lb. per sq. in., 0.5 T.S.; elongation in 8 in. min., per cent. = 1,500,000/T.S. For material over ¾ in. thick, a deduction of 0.5 from above percentages of elongation shall be made for each increase of ⅛ in. in thickness above ¾ in. to a minimum of 20 per cent. Steel plates for any part of a boiler, when exposed to the fire or products of combustion and under pressure, shall be of fire-box quality; for any part under pressure, where fire-box quality is not specified, they shall be of fire-box or flange quality. Test specimen same as Mass. Law.

(U. S. BOARD.) Test specimen (see Fig. 19, p. 386) to show an elongation of at least 25 per cent. in a length of 4 in. up to a thickness of ¼ in. inclusive, in a length of 6 in. for all thicknesses above ¼ in., to show an average reduction of sectional area of at least 50 per cent. for thicknesses up to and including ½ in., 45 per cent. for thicknesses over ½ in. and up to ¾ in. inclusive, and 40 per cent. for thicknesses over ¾ in.

Quenching and bending test pieces to be at least 12 in. long, and from 1 to 3½ in. wide. Such pieces, after being heated to a cherry red, to be quenched and endure bending to a curve whose inner radius $\leq$ 1½ $\times$ thickness of sample, without cracks or flaws.

Maximum Allowable Pressure for Shells or Drums (MASS. LAW). Maximum allowable pressure (lb. per sq. in.) on steel or wrought-iron shells or drums to be determined from the minimum thickness (t) of shell plates, the lowest T.S. (lb. per sq. in.) stamped on plate by manufacturer, the efficiency (e) of longitudinal joint or ligament between tube holes (whichever is the least), the inside diam. ($2R$) of outside course, and a factor of safety (F.S.)

of not less than five (5), the formula being $p = \text{T.S.} \times t \times e/(R \times \text{F.S.})$. R and t in in., e in per cent.

When a shell or drum is drilled for tube holes in a line parallel to the axis of the shell or drum, the **efficiency (e) of ligament between the tube holes** is to be determined as follows:

(*a*) When pitch of tube holes on every row is equal, $e = (p-d)/p$; (p = pitch of tube holes, in.; d = diam. of tube holes, in.).

(*b*) When pitch of tube holes in any row is unequal, $e = (P-nd)/P$; (P = unit length of ligament, in.; n = No. of tube holes in length P; d = diam. of tube holes, in.).

(A. S. M. E. CODE). Maximum allowable pressure on shells and drums same as Mass. Law. No boiler shall be operated at a higher pressure than the maximum allowable pressure except when the safety valve or valves are blowing, at which time the maximum allowable working pressure shall not be exceeded by more than 6 per cent.

Efficiency of ligaments between tube holes to be determined as in Mass. Law for cases (*a*) and (*b*). When a shell or drum is drilled for tube holes in a line diagonal with the axis of the shell or drum, the efficiency of the ligament between tube holes shall be determined by the following methods and the lowest value used. (*a*) $e = 0.95\,(p_1 - d)/p_1$, (*b*) $e = (p - d)/p$, where p_1 = diagonal pitch and p = longitudinal pitch.

(U. S. BOARD.) Maximum working pressure in pound per sq. in. = $(\text{T.S.} \times t)/(R \times 6)$ for single riveting, in which R = radius of shell, in. For double riveting add 20 per cent. The pressure allowed to be based on the plate whose T.S. × thickness gives a minimum product.

The U. S. rule is unsatisfactory in not taking into account the efficiency of joint or class of seam. The F.S. of 6 simply covers the actual nominal F.S., as well as the loss of strength at joint.

Efficiency of Riveted Joints. See p. 679.

(A. S. M. E. CODE). The efficiency of a riveted joint is determined by calculating the breaking strength of a unit section of the joint, considering each possible mode of failure separately, and dividing the lowest result by the breaking strength of the solid plate of a length equal to that of the section considered. The strength of circumferential joints of boilers the heads of which are not stayed by tubes or through braces shall be at least 50 per cent. that of the longitudinal joints of the same structure. When 50 per cent. or more of the load which would act on an unstayed solid head of the same diameter as the shell is relieved by the effect of tubes or through stays, in consequence of the reduction of the area acted on by pressure and the holding power of the tubes and stays, the strength of the circumferential joints in the shell shall be at least 35 per cent. that of the longitudinal joints.

Plate Thickness (MASS. LAW). Minimum thickness of plates used in boiler construction, ¼ in. Minimum thickness (t) of shell plates as follows:

For shell diam. =	36 in. or under	37 to 54 in. incl.	55 to 72 in. incl.	Over 72 in.
t =	¼ in.	5/16 in.	⅜ in.	½ in.

Butt straps to be rolled or formed to proper curvature on forms made for that purpose and to have the following minimum thicknesses:

Thickness of shell plate, in.:	¼ to 11/32	⅜ and 13/32	7/16 and 15/32	½ to 9/16	⅝ and ¾	⅞	1 and 1⅛	1¼
Minimum thickness of butt straps, in.	¼	5/16	⅜	7/16	½	⅝	¾	⅞

Minimum thickness of tube sheets (t): When diam. (d) of tube sheet $\leq$ 42 in., $t = 3/8$ in.; for d = over 42 in. to 54 in. incl., $t = 7/16$ in.; for d = over 54 in. to 72 in. incl., $t = 1/2$ in.; for d = over 72 in., $t = 9/16$ in.

Bumped Heads (Mass. Law). Minimum thickness of convex head, in. $= t = R \times$ F.S. $\times P$/T.S.; minimum thickness of concave head, in. $= t = R \times$ F.S. $\times P/(0.6 \times$ T.S.), in which $R = 1/2 \times$ radius to which head is bumped, in., F.S. = 5, P = working pressure, lb. per sq. in. for which boiler is designed, and T.S. = tensile strength (lb. per sq. in.) stamped on heads by manufacturer.

(A. S. M. E. Code). Convex Heads: The thickness required in an unstayed dished head with the pressure on the concave side, when it is a segment of a sphere, shall be calculated by the formula: $t = 1/8 + [5.5 \times P \times L/(2 \times \text{T.S.})]$, where L = radius to which the head is dished, in. Where the radius is less than 80 per cent. of the diameter of the shell or drum to which the head is attached, the thickness shall be at least that found by the formula by making L equal to 80 per cent. of the diameter of the shell or drum.

Concave Heads: Dished heads with the pressure on the convex side shall have a maximum allowable working pressure equal to 60 per cent. of that for heads of the same dimensions with the pressure on the concave side. When a dished head has a manhole opening, the thickness shall be increased by not less than 1/8 in. When dished heads are of a less thickness than called for by the formula, they shall be stayed as flat surfaces, no allowance being made in such staying for the holding power due to the spherical form. The corner radius of an unstayed dished head measured on the concave side of the head shall not be less than 1½ in. or more than 4 in. and within these limits shall be not less than 3 per cent. of L. A manhole opening in a dished head shall be flanged to a depth of not less than three times the thickness of the head measured from the outside.

Flat Stayed Surfaces (Mass. Law). Minimum thickness of plate in stayed flat-surface construction, 5/16 in.

Stay-bolt ends to be riveted over or upset by equivalent process. Pitch allowed for stay bolts on flat surfaces and on furnace sheets of internally fired boilers in which the external diameter of the furnace is over 38 in. (except a corrugated furnace or one strengthened by an Adamson ring or the equivalent), not to exceed values given in Table 2.

Table 2. Maximum Allowable Pitch of Stay Bolts

Pressure, lb. per sq. in.	Thickness of plate, in.							Pressure, lb. per sq. in.	Thickness of plate, in.						
	5/16	3/8	7/16	1/2	9/16	5/8	11/16		5/16	3/8	7/16	1/2	9/16	5/8	11/16
	Maximum pitch of stay bolts in in.								Maximum pitch of stay bolts in in.						
100	5½	6¼	7	7¾	8½	....	....	170	4½	5	5⅝	6⅛	6¾	7¼	7⅜
110	5¼	6	6¾	7⅜	8⅛	....	....	180	4⅜	4⅞	5½	6	6½	7⅛	7¾
120	5⅛	5¾	6½	7⅛	7⅞	8½	....	190	4⅜	4⅞	5⅜	5⅞	6⅜	7	7½
125	5	5⅝	6⅜	7	7¾	8⅜	....	200	4¼	4¾	5¼	5¾	6¼	6¾	7⅜
130	5	5⅝	6¼	6⅞	7⅝	8¼	....	225	4⅛	4½	5	5½	6	6½	7
140	4¾	5½	6	6⅝	7⅜	8	....	250	4	4⅜	4¾	5¼	5¾	6¼	6⅝
150	4¾	5¼	5⅞	6½	7⅛	7¾	8⅜	300	3¾	4⅛	4½	4⅞	5⅜	5¾	6⅛
160	4⅝	5⅛	5¾	6¼	6⅞	7½	8..	....	....	....	....	....	....	....	..

For a pitch not exceeding 8½ in. that is not given in Table 2, use formula $P = C(t+1)^2/(S^2-6)$, in which S = max. pitch of stay bolts, in.; C = 66; t = thickness of plate in sixteenths of an inch, and P = working pressure, lb. per sq. in.

For hollow stay bolts with holes ¼ in. in diam. or over, maximum allowable pitch may be increased by the mean diam. of stay bolt. Mean diam. = (least outside diam. of stay bolt + diam. of hole)/2.

(A. S. M. E. Code). The ends of screwed stay bolts shall be riveted over or upset by equivalent process. The outside ends of such stay bolts shall be drilled with a hole at least 3/16 in. diameter to a depth extending ½ in. beyond the inside of the plates, except on boilers having a grate area not exceeding 15 sq. ft. where the drilling of the stay bolts is optional. The maximum allowable pitch in inches of screwed stay bolts, ends riveted over, shall not exceed values given in Table 2*a*.

Table 2a. Maximum Allowable Pitch of Screwed Stay Bolts, Ends Riveted Over

Pressure, lb. per sq. in.	Thickness of plate, in.					Pressure, lb. per sq. in.	Thickness of plate, in.					
	5/16	3/8	7/16	1/2	9/16		3/8	7/16	1/2	9/16	5/8	11/16
	Maximum pitch of staybolts, in.						Maximum pitch of staybolts, in.					
100	5¼	6⅜	7⅜	......	....	170	4⅞	5⅝	6¾	7½	8⅜	....
110	5	6	7	8⅜	....	180	4¾	5½	6½	7⅜	8⅛	....
120	4¾	5¾	6¾	8	....	190	4⅝	5⅜	6⅜	7⅛	7⅞	....
125	4¾	5⅝	6⅝	7¾	....	200	4½	5¼	6⅛	7	7¾	8½
130	4⅝	5½	6½	7⅝	....	225	4¼	4⅞	5⅞	6½	7¼	8
140	4½	5⅜	6¼	7⅜	8⅜	250	4	4⅝	5½	6¼	6⅞	7⅝
150	4¼	5⅛	6	7⅛	8	300	....	4¼	5	5⅝	6¼	7
160	4⅛	5	5⅞	6⅞	7¾	....	....	....	.....	.....	......	....

For a pitch not exceeding 8½ in. not given in the table, the maximum allowable working pressure may be calculated by the formula of the U. S. Board given below. The values of C are as follows: $C = 112$ for stays screwed through plates not over 7/16 in. thick, with ends riveted over; = 120 for stays screwed through plates over 7/16 in. thick, with ends riveted over; = 135 for stays screwed through plates and fitted with single nuts outside of plate; = 175 for stays fitted with inside and outside nuts and outside washers where the diameter of washers is not less than $0.4p$ and thickness not less than t.

In water-leg boilers the stay bolts may be spaced at greater distances between the rows than indicated in Table 2*a*, provided the portions of the sheet which come between the rows of stay bolts have the proper transverse strength to give a factor of safety of at least 5 at the maximum allowable working pressure. The diameter of a screw stay shall be taken at the bottom of the thread, provided this is the least diameter. Holes for screw stays shall be drilled full size or punched not to exceed ¼ in. less than full diameter of the hole for plates over 5/16 in. in thickness. and ⅛ in. less than the full diameter of the hole for plates not exceeding 5/16 in. in thickness, and then drilled or reamed to the full diameter. The holes shall be tapped fair and true, with a full thread. An internal cylindrical furnace which requires staying shall be stayed as a flat surface as in Table 2*a*.

(U. S. Board.) The maximum stress allowable on flat plates supported or stayed, to be determined by the following formulæ (all stayed surfaces formed to a curve, the radius of which is over 21 in., excepting surfaces otherwise provided for, shall be deemed flat surfaces):

$$\text{Working pressure (lb. per sq. in.)} = C \times T^2/P^2$$

in which T = thickness of plate in sixteenths of an inch, P = greatest pitch of stays, in., and C = a constant, varying for various types of stay bolts as follows:

C = 112 for screw stays with riveted heads, T = 7/16 in. and under.
C = 120 for screw stays with riveted heads, T = above 7/16 in.
C = 120 for screw stays with nuts, T = 7/16 in. and under.
C = 125 for screw stays with nuts, T = over 7/16 in. and under 9/16 in.
C = 135 for screw stays with nuts, T = 9/16 in. and over.
C = 175 for stays with double nuts, having one nut on the inside and one nut on the outside of plate, without washers or doubling plates.
C = 160 for stays fitted with washers or doubling strips having a thickness of at least ½P, riveted to outside of plates, and stays having one nut inside of plate and one nut outside of washer or doubling strip. For T take 72 per cent. of the combined thickness of plate and washer or plate and doubling strip.
C = 200 for stays fitted with doubling plates having a thickness equal to at least ½ the thickness of the plate reinforced, and covering the full area braced (up to curvature of flange, if any), riveted to either the inside or outside of plate, and stays having one nut outside and one inside of plate. Washers or doubling plates to be substantially riveted. For T take 72 per cent. of combined thickness of the two plates.
C = 200 for stays with plates stiffened with tees or angle bars having a thickness of at least ⅔T and depth of webs at least ¼P, and substantially riveted on the inside of plates, and stays having one nut inside bearing on washers fitted to the edges of webs, that are at right angles to plate. For T take 72 per cent. of combined thickness of web and plate.

No such flat plates or surfaces to be unsupported at a greater distance than 18 in.

British Board of Trade Rule (see notation for Mass. Law):

$$P = C(t+1)^2/(S-6)$$

In which

C = 125 for plates not exposed to heat or flame, the stays fitted with nuts and washers, the latter at least 3 × stay diam. and ⅔ × thickness of plate.
C = 187.5 for the same condition, but with washers = ⅔S in diam. and thickness not less than plate.
C = 200 for the same condition, but with doubling plates in place of washers, the width of which is ⅔S and thickness the same as the plate.
C = 112.5 for the same condition, but the stays with nuts only.
C = 75 when exposed to impact of heat or flame and steam in contact with plates, and stays fitted with nuts and washers 3 × stay diam. and ⅔ the plate's thickness.
C = 67.5 for the same condition, but stays fitted with nuts only.
C = 100 when exposed to heat or flame, and water in contact with the plates, and stays screwed into plates and fitted with nuts.
C = 66 for the same condition, but stays with riveted heads.

The Board of Trade rules are based on actual experiments and are satisfactory.

Tube Sheets—Internally Fired Boilers (U. S. Board). Maximum working pressure of a tube sheet supporting a crown sheet braced by crown bars to be

$$P = (D-d)T \times 27{,}000/(W \times D)$$

in which P = working pressure, lb. per sq. in.; D = least horizontal distance between tube centers, in.; d = inside diam. of tubes, in.; T = thickness of tube plates, in.; and W = extreme width of combustion chamber, in.

The compressive stress on tube plates, as determined by the following formula, shall not exceed 13,500 lb. per sq. in., when pressure on top of combustion chamber is supported by vertical plates of such chamber.

$$C = P \times D \times W/[2T \times (D - d)]$$

Where C = stress on tube sheet, lb. per sq. in.; P = working pressure, lb. per sq. in.; D = least hor. dis. between tube centers, in.; d = inside diam. of tubes, in.; W = extreme width of combustion chamber, in., and T = thickness of tube sheet, in.

(A. S. M. E. Code). Maximum allowable working pressure on a tube sheet of a combustion chamber where the crown sheet is *not* suspended from the shell of the boiler, same as in rule of U. S. Board, above.

Furnace Formulæ (Mass. Law):

$$L = \left(\frac{Ct^2}{Pd}\right)^2, \quad t = \sqrt{\frac{Pd\sqrt{L}}{C}}, \quad P = \frac{Ct^2}{d\sqrt{L}}, \quad d = \frac{Ct^2}{P\sqrt{L}}$$

in which P = working pressure, lb. per sq. in.; C = a constant = 110; t = thickness of furnace sheet in thirty-seconds of an inch, d = external diam. of furnaces, in., and L = longitudinal pitch of stay bolts, in in., or ½ × height of furnace if only one row of circumferential stay bolts is required.

(A. S. M. E. Code). Plain Circular Furnaces. The maximum allowable working pressure for unstayed, riveted, seamless or lap-welded furnaces, where the length does not exceed 6 times the diameter and where the thickness is at least 5/16 in., shall be determined by one or the other of the following formulæ:

(*a*) Where the length does not exceed 120 times the thickness of the plate, $P = 51.5\ (18.75T - 1.03L)/D$.

(*b*) Where the length exceeds 120 times the thickness of the plate, $P = 4250T^2/LD$, where P = maximum allowable working pressure, lb. per sq. in.; D = outside diameter of furnace, in.; L = length of furnace, in.; T = thickness of furnace walls, in sixteenths of an inch.

Where the furnaces have riveted longitudinal joints, no deduction need be made for the joint provided the per cent. efficiency of the joint is greater than $PD/1250T$.

A plain cylindrical furnace exceeding 38 in. in diameter shall be stayed in accordance with the rules governing flat surfaces.

(U. S. Board.) Tensile strength of steel used in construction of corrugated or ribbed furnaces not to exceed 67,000 lb. and not to be less than 54,000 lb.; for all other furnaces minimum T.S. not less than 58,000 lb. and maximum not more than 67,000 lb. Minimum elongation in 8 in. to be 20 per cent.

All corrugated furnaces having plain parts at the ends not exceeding 9 in. in length and made to practically true circles, shall be allowed a steam pressure in accordance with the formula $P = C \times T/D$, in which P = pressure lb. per sq. in.; T = thickness, in.; D = mean diam. in., and C = a constant, with the following values with various types of furnaces: Leeds, C = 17,300, $T \geq$ 5/16 in.; Morison, C = 15,600, $T \geq$ 5/16 in.; Fox, C = 14,000, $T \geq$ 5/16 in.; Purves, C = 14,000, $T \geq$ 7/16 in.; Brown, C = 14,000, T = 5/16 in.; type having sections 18 in. long, C = 10,000, T = not less than 7/16 in.

Material for Stays (Mass. Law). For maximum allowable stress per sq. in. on net cross-sectional area of stays and stay bolts for various materials.

see Table 3. When a stress greater than given in Table 3 is required, material should have a T.S. not over 62,000 lb. per sq. in., a yield point not less than ½ × T.S., and an elongation not less than 28 per cent. in an 8-in. test piece. Maximum allowable stress to be based on a factor of safety of not less than 6.5.

Table 3. Maximum Allowable Stress on Net Cross-sectional Area of Stays and Stay Bolts (lb. per sq. in.)

Material and type	Size up to and including 1¼ in. diam. or equivalent area	Size over 1¼ in. diam. or equivalent area
Weldless mild steel head to head or through stays....	8000	9000
Weldless mild steel diagonal or crowfoot stays.......	7500	8000
Weldless wrought-iron head to head or through stays..	7000	7500
Weldless wrought-iron diagonal or crowfoot stays....	6500	7000
Welded mild steel or wrought-iron stays............	6000	6000
Mild steel or wrought-iron stay bolts...............	6500	7000

(A. S. M. E. Code). The maximum allowable stress in lb. per sq. in. net cross-sectional area of stays and stay bolts shall be as follows:

(*a*) Unwelded stays less than twenty diameters long screwed through plates with ends riveted over, 7500.

(*b*) Unwelded stays and unwelded portions of welded stays, except as specified in (*a*), 9500 for lengths between supports not exceeding 120 diameters; 8500 for lengths exceeding 120 diameters.

(*c*) Welded portions of stays, 6000 for lengths between supports not exceeding 120 diameters; 6000 for lengths exceeding 120 diameters.

The length of the stays between supports shall be measured from the inner faces of the stayed plates. The stresses are based on tension only.

(U. S. Board.) Use of welded steel stay bolts prohibited. The maximum allowable working stress in lb. per sq. in. of cross-sectional area for stays accurately fitted and properly secured, is 9000 for tested steel stays 1¼ in. in diam. and above (stays thoroughly annealed); 8000 for tested Huston or similar type of brace, the cross-sectional area of which exceeds 5 sq. in.; 7000 for such tested braces when the cross-sectional area is not less than 1.227 and not more than 5 sq. in.; 7500 for wrought-iron through stays 1¼ in. and upward; 6800 for welded crowfoot stays of best quality refined wrought iron, and for all stays not provided for above when made of the best quality refined iron and steel without weld.

Tubes and Tube Tests (U. S. Board). All lap-welded tubes to be of charcoal iron, or mild steel, made by any process, and to undergo the following tests before shipment by the manufacturer:

(*a*) Test piece 2 in. in length cut from a tube to stand being flattened by hammering until sides are brought parallel with the curves on inside of ends not greater than 3 × thickness of metal without showing cracks or flaws, with bend at one side being in the weld.

(*b*) A second tube to have a flange turned over at right angles to body of tube and have a width of ⅜ in. Tests (*a*) and (*b*) to be done cold.

Each tube to be subjected to an internal hydrostatic pressure of 500 lb. per sq. in. without showing signs of weakness or defects. All steel tubes to have ends properly annealed by manufacturer before shipment, and stand expanding, flanging over on tube plate and beading without flaw, crack, or opening at weld.

Seamless Steel Boiler Tubes

Material. Tube steel, to be made by the open-hearth process.

Surface Inspection. Tubes to be free from all surface defects, particularly tears, snakes, checks, slivers, scratches, laps, pits, rings, and sinks. All seamless steel cold-drawn tubes to be annealed as a final process. One or more tubes to be selected at random from each charge of annealing furnace, and coupons cut from same for testing.

(a) A piece 3 in. long cut from the first tube to stand being flattened by hammering until its sides are brought parallel with a curve on inside of ends not greater than 3 × thickness of metal, without showing cracks or flaws.

(b) A flange to be turned all around the end of tube to a width equal to ⅜ in. beyond outside body of tube. Tests (a) and (b) to be done cold.

Hot-finished tubes to pass the same manipulating tests as cold-drawn tubes and be subject to the same conditions as to gage; annealing not required.

Each tube to be subject to an internal hydrostatic pressure of 1000 lb. per sq. in. without showing signs of weakness or defects.

All tubes to stand expanding, flanging over on the tube plate and beading without flaw or crack.

All individual tubes to be carefully gaged with a Birmingham wire gage, and come within the limits of one gage under or one gage over the specified thickness.

(A. S. M. E. Code). Lap-welded tubes shall be made of open-hearth steel or knobbled hammered charcoal iron. Seamless tubes shall be made of open-hearth steel.

A test specimen not less than 4 in. in length shall have a flange turned over at right angles to the body of the tube without showing cracks or flaws. This flange as measured from the outside of the tube shall be ⅜ in. wide.

A test specimen 3 in. in length shall stand test (a) of the U. S. Board.

Tubes under 5 in. in diameter shall stand an internal hydrostatic pressure of 1000 lb. per sq. in., and tubes 5 in. in diameter or over an internal hydrostatic pressure of 800 lb. per sq. in. Lap-welded tubes shall be struck near both ends, while under pressure, with a 2-lb. hand hammer or the equivalent.

All test specimens shall be taken from tubes before being cut to finished lengths and shall be smooth on the ends and free from burrs. All tests shall be made cold.

The finished tubes shall be circular within 0.02 in., and the mean outside diameter shall not vary more than 0.015 in. from the size ordered. All tubes shall be carefully gaged with a B. W. G. gage and shall not be less than the gage specified; but tubes on which the standard slot gage (specified) will go on tightly at the thinnest point, will be accepted. The length shall not be less, but may be 0.125 in. more, than that ordered.

The finished tubes shall be free from injurious defects and shall have a workmanlike finish and shall be practically free from kinks, bends and buckles.

Tube Holes and Ends. Tube holes shall be drilled full size from the solid plate, or they may be punched at least ⅛ in. smaller in diameter than full size and then drilled, reamed or finished full size with a rotating cutter. A fire-tube boiler shall have the ends of the tubes substantially rolled and beaded, or welded at the fire-box or combustion-chamber end. The ends of all tubes, suspension tubes and nipples shall be flared not less than ⅛ in. over the diameter of the tube hole on all water-tube boilers and superheaters, or they may be beaded. The ends of all tubes, suspension tubes and nipples of water-tube boilers and superheaters shall project through the tube sheets or headers not less than ¼ in. nor more than ½ in. before flaring.

Tubes for Water-tube Boilers. The minimum thicknesses of tubes used in water-tube boilers measured by Birmingham wire gage, for maximum allowable working pressures not exceeding 165 lb. per sq. in., shall be as follows: Diameters less than 3 in., No. 12 B. W. G.; 3 in. or over, but less than 4 in., No. 11 B. W. G.; 4 in. or over, but less than 5 in., No. 10 B. W. G.; 5 in., No. 9 B. W. G.

The above gages shall be increased for maximum allowable working pressures higher than 165 lb. per sq. in. as follows: Over 165 lb. but not exceeding 235 lb., 1 gage; over 235 lb. but not exceeding 285 lb., 2 gages; over

285 lb. but not exceeding 400 lb., 3 gages. Tubes over 4 in. diameter shall not be used for maximum allowable working pressures above 285 lb. per sq. in.

Tubes for Fire-tube Boilers. The minimum thicknesses of tubes used in fire-tube boilers measured by Birmingham wire gage, for maximum allowable working pressures not exceeding 175 lb. per sq. in., shall be as follows: Diameters less than 2½ in., No. 13 B. W. G.; 2½ in. or over, but less than 3¼ in., No. 12 B. W. G.; 3¼ in. or over, but less than 4 in., No. 11 B. W. G.; 4 in. or over, but less than 5 in., No. 11 B. W. G.; 5 in., No. 9 B. W. G.

For higher maximum allowable working pressures than given above the thicknesses shall be increased one gage.

Hydrostatic Pressure (Mass. Law). Maximum hydrostatic pressure applied to boiler not to exceed 1½ × maximum allowable working pressure. Boiler to be examined both internally and externally after test.

(A. S. M. E. Code). Same pressure as U. S. Board. The pressure shall be under proper control, so that in no case shall the required test pressure be exceeded by more than 6 per cent. During the test the safety valve or valves shall be removed, or each valve disk shall be held to its seat by means of a testing clamp and not by screwing down the compression screw upon the spring.

(U. S. Board.) Hydrostatic pressure applied = 1½ × steam pressure allowed in lb. per sq. in.; after applying hydrostatic test, inspector to thoroughly examine every part of boiler. All coil and pipe boilers when complete and ready for inspection to be subjected at the first inspection to a hydrostatic pressure double that of the steam pressure allowed in the certificate of inspection.

Recommendations Made by the Massachusetts Board of Boiler Rules

1. The installation of more than one safety valve on a boiler permitted to carry over 25 lb. pressure per sq. in.
2. Externally fired boilers over 84 in. in diam. not to be used.
3. Use of steam domes not recommended. Advise use of a reflecting plate, or a dry pipe located at the highest point of the steam space, and having closed ends and small slotted or drilled openings on its upper part, a total area of openings not less than twice the area of the outlet, and an ample drain opening at the lowest point.
4. Diagonal stays not to be attached to shell plates directly over the fire.
5. Cast-iron or copper steam pipe not to be used.
6. Elliptical handholes of the following sizes to be used: 2¼ × 3¼ in.; 2¾ × 3¾ in.; 3 × 4½ in.; 3½ × 5 in.; 4 × 6 in.
7. Boiler on which a longitudinal lap crack is discovered to be discontinued from service and not repaired.
8. O. G. form of construction at the lower end of furnace sheets not recommended.
9. Lead manhole gaskets below the water line are not to be used.

Miscellaneous (A. S. M. E. Code). Cross pipes connecting the steam and water drums of water-tube boilers, headers and cross boxes, and all pressure parts of the boiler proper over 2-in. pipe size or equivalent cross-sectional area for boilers in which the maximum allowable working pressure exceeds 160 lb. per sq. in.; mud drums of boilers used for other than heating purposes, and pressure parts of superheaters, separately fired or attached to stationary boilers, unless of the locomotive type, shall be of wrought steel or cast steel of Class B grade, see p. 463.

Cast iron shall not be used for boiler and superheater mountings such as nozzles, connecting pipes, fittings, valves and their bonnets, for steam temperatures of over 450 deg. fahr.

WELDED JOINTS. The ultimate tensile strength of a longitudinal joint which has been properly welded by the forging process, shall be taken as 28,500 lb. per sq. in. with steel plates having a range in tensile strength of 47,000 to 55,000 lb. per sq. in.

CALKING. The calking edges of plates, butt straps and heads shall be beveled. Every portion of the calking edges of plates, butt straps and heads shall be planed, milled or chipped to a depth of not less than 1/8 in. Calking shall be done with a round-nosed tool.

STOP VALVES. Each steam discharge outlet over 2 in. in diameter, except safety-valve and superheater connections, shall be fitted with a stop valve or valves of the outside screw and yoke type, located as near the boiler as practicable. The main stop valves of boilers shall be extra heavy when the maximum allowable working pressure exceeds 125 lb. per sq. in. When two or more boilers are connected to a common steam main, two stop valves, with an ample free blow drain between them, shall be placed in the steam connection between each boiler and the steam main. The discharge of this drain valve must be visible to the operator while manipulating the valve. The stop valves shall consist preferably of one automatic non-return valve (set next the boiler) and a second valve of the outside screw and yoke type; or, two valves of the outside screw and yoke type may be used.

When the maximum allowable working pressure exceeds 125 lb. per sq. in., the bottom blow-off pipe shall have two valves, or a valve and a cock, and such valves, or valve and cock, shall be extra heavy, except that on a boiler having multiple blow-off pipes, a single master valve may be placed on the common blow-off pipe from the boiler, in which case only one valve on each individual blow-off is required.

Every superheater shall have one or more safety valves near the outlet. The discharge capacity of the safety valve or valves on an attached superheater may be included in determining the number and sizes of the safety valves for the boiler, provided there are no intervening valves between the superheater safety valve and the boiler. Every safety valve used on a superheater, discharging superheated steam, shall have a steel body with a flanged inlet connection, and shall have the seat and disk of nickel composition or equivalent material, and the spring fully exposed outside of the valve casing so that it shall be protected from contact with the escaping steam.

Boiler Tubes

Holding Power of Expanded Tubes. C. B. Richards has investigated the holding power of expanded tubes (*The Locomotive*, 1881). The tubes tested were 3 in. diam. by 0.109 in. thick, and were expanded into plates 5/8 and 15/32 in. thick. The stresses at which the tubes yielded ranged from 5000 to 7500 lb. when the tubes were expanded, but neither flared nor beaded. When expanded and the ends were flared, the holding power was much greater, ranging from 19,000 to 20,500 lb.

Slipping Point of Expanded Joints. The slipping point is defined as that at which a leak will show. The working load, therefore, must be kept below the slipping load. O. P. Hood and G. L. Christensen (*Trans. A. S. M. E.*, vol. 30, p. 1193), after experiments with 3-in. No. 12 gage cold-drawn tubes expanded into 1-in. sheets, arrived at the following conclusions: (1) The slipping point of such tubes rolled into straight, smooth, machined holes in a 1-in. plate occurs with a pull of about 7000 lb.; (2) various degrees of rolling above the practice ordinarily followed do not affect particularly the point of initial slip; (3) the frictional resistance of such holes is about 750 lb. per sq. in. of tube-bearing area in sheets 5/8 and 1 in. thick; (4) for a higher resistance to initial slip, resistance other than friction must be depended upon; (5) the slipping point may be raised to three or four times that where a smooth hole is used, by serrating the tube seat by cutting or rolling grooves 0.01 in. deep into the machined hole; (6) a rolled joint may be made that will offer a resistance beyond the elastic limit of tubes and remain tight. As tubes increase in diameter and thickness, the normal pressure developed when rolled will be higher than that in the case just cited; the area of the tube seat will also be greater, and the resistance to slipping will, therefore, be increased.

Bursting Pressure of Boiler Tubes. Table 4 gives data on the bursting pressure of boiler tubes, derived from experiments conducted by I. Harter, Jr., in 1906, agreeing with other published data. The test pieces used were 2 ft. long. They were held at the ends from expanding, but were free to shorten, and this actually occurred before bursting. The figures are the results of six breaks in each instance.

Table 4. Physical Tests and Bursting Pressures of Boiler Tubes

Tube (4-in. No. 10 gage)	Lap-welded steel	Cold-drawn seamless	Charcoal iron	Charcoal iron
Original area of piece tested, sq. in.	0.1153	0.1045	0.1072	0.1132
Area after fracture, sq. in.	0.0628	0.0509	0.0718	0.0524
Elastic limit as tested, lb.	4,007	3,140	2,982	3,643
Maximum load, lb.	6,627	5,372	5,062	5,690
Elastic limit, lb. per sq. in.	34,850	29,928	27,800	32,180
Elongation, per cent. in 8 in.	16.7	21.5	15.65	22.21
Reduction of area, per cent.	45.6	51.3	33.1	53.6
Tensile strength, lb. per sq. in.	57,495	51,385	47,163	50,357
Bursting pressure, lb. per sq. in.	4,733	4,183	3,333	3,970

Collapsing Pressures of Tubes. See "Strength of Materials," p. 393, for results of tests by Stewart and Carman.

Working Pressures for Steel Flues (U. S. BOARD). The working pressure and corresponding minimum thickness of wall for long, plain, lap-welded and seamless steel flues, 7 to 18 in. in diam. and subjected to external pressure only, may be determined from the formula $t = [(F.S. \times P) + 1386] \times D/86{,}670$, in which t = thickness of wall, in.; P = collapsing pressure, lb. per sq. in.; D = outside diam. of tube, in.; and the factor of safety (F.S.) is not less than 5.

Standard Tubular Boiler Specifications

The following dimensions and specifications for fire-tube boilers, issued by the National Association of Tubular Boiler Manufacturers, have been generally adopted. For specifications of the American Boiler Manufacturers' Association, see p. 881.

Materials. The shell, heads and covering strips of the standard boiler shall be of flange steel as described in the standard specifications of the Association of American Steel Manufacturers. All such plates shall be marked 60,000 lb. tensile strength and in building the boiler the plates shall be so placed that these stamps are plainly visible on the outside. These plates shall have the full specified thickness at the edges and shall meet the tensile, quenching and bend tests described.

The tubes shall be standard quality lap-welded mild steel of standard manufacture. The thickness of the metal shall be 12 B. W. G. for 3-in. tubes, 11 B. W. G. for 3½-in. tubes and 10 B. W. G. for 4-in. tubes.

The rivets shall be of boiler-rivet steel as described in the standard specifications of the Association of American Steel Manufacturers and of proper size to suit the size of the hole and the thickness of the plates and to form up heads equal in strength to the pressed heads of same.

The diagonal braces shall be weldless, of the same quality as the flange steel previously described and pressed from the solid plate, or else forged from steel bars. The number of braces to be used shall be computed on an allowance of not more than 7500 lb. of load per sq. in. of section of brace neglecting, in this, the inherent strength of the heads and the slight angularity of the braces.

Suitable through rods and braces shall be installed below the tubes when necessary to sustain the pressure. These shall be of steel and shall be computed with the same allowance as diagonal braces.

Table 5. Dimensions for Standard Return Tubular Boilers

Working pressure	Seams	Horse-power of boiler as rated	Diam. of boiler, in.	Length of tubes, ft.	Number of 3½-in. tubes	Number of 4-in. tubes	Tube heating surface with 3½-in. tubes, sq. ft. Other standardised dimensions of fittings are as follows: Size of water gage glass, ¾ in. Size of water column connections, 1¼ in. Size of gage cocks, ¾ in. Size of blow-off, 2 in. up to 125 boiler h.p.; 2½ in. from 125 to 200 b.h.p. Size of feed and check valves, 1½ in. up to 180 b.h.p., and 2 in. from 180 to 200 b.h.p. Size of steam gage dial, 5 in.

Braces as above described shall be carefully placed so that the pressure on the flat surfaces, both above and below the tubes, shall be as nearly equally distributed as possible.

For any boiler head the area to be supported by braces shall be the surface included within lines drawn 2 in. from the outside of the tubes and 3 in. from the inside of the shell.

Design. The longitudinal seam of the shell shall be of the butt-joint type having inside and outside covering strips and either double, triple or quadruple riveted as indicated in Table 5.

The circumferential seams shall be of the lap type of joint and single-riveted.

In all joints the size, number and spacing of the rivets shall be such as to provide the strength necessary to maintain the factor of safety of 5.

The tubes shall be placed in vertical and horizontal rows with ample space between the adjacent tubes and also between tubes and shell for the circulation of water and also with a large steam space above the water line.

Boilers 44 in. or less in diam. shall have a manhole above the tubes and a handhole below the tubes. These may both be in the front head, or the handhole may be in the front head and the manhole in the back head. Boilers 48 in. in diam. shall have two manholes, both in the heads, one above the tubes and one below the tubes. They may both be in the front head or one manhole may be in the front head below the tubes and the other in the back head above the tubes. Boilers larger than 48 in. shall have two manholes, one of which shall be in the front end below the tubes, the other shall be above the tubes in either head or preferably may be placed in the shell.

The opening in the manhole shall not be less than 10×15 in. Each manhole shall be equipped with a heavy plate, bale, bolt, nut and gasket.

Manholes placed in the shell shall be properly reinforced with a suitable steel saddle.

All openings 2 in. in diam. or larger shall have suitable steel reinforcing flanges riveted on. Cast-iron flanges or nozzles shall not be used.

Boilers for 125 to 150 lb. working pressure shall have the feed opening in the front head over the tubes and same shall be provided with a brass bushing and an internal feed pipe extending from the front end of the boiler to within about 3 ft. of the rear head, thence across to the side of the shell terminating in an elbow for discharge below the top row of tubes.

Boilers for 100 lb. working pressure shall be arranged to feed through the blow-off connection and the internal feed pipe be omitted.

Each boiler shall be provided with four steel lugs or brackets, two on each side for supporting the boiler, except that boilers 78 in. in diam. or boilers 20 ft. long shall be provided with eight such lugs, four on each side of the boiler and all of them arranged in pairs.

Workmanship. All rivet holes and all tube holes shall be either drilled from the solid or punched small and reamed to size. After drilling or reaming the plates shall be taken apart and all burrs removed and the tube holes chamfered with a rose reamer.

The edges of the plates shall be beveled to an accurate calking edge and after being riveted shall be calked tight with a round-nose tool.

The tubes shall be carefully placed, expanded tight in the heads with a roller expander and the ends carefully beaded over against the head at both ends.

Water Column. The water column shall be provided with three gage cocks and shall be so placed that the lowest gage cock shall be 2 in. above the tops of the uppermost row of tubes. The middle gage cock shall be 3 in. and the uppermost gage cock 6 in. above the lowest gage cock, measured vertically.

Tests. The completed boiler shall be subjected to a steady water pressure 50 per cent. above its proposed working pressure and made tight.

Equipment. A complete standard boiler equipment includes: The bare boiler with lugs; cast-iron front with anchors; grate bars with bearers; rear arch bars; rear ash-pit door and frame; safety valve with nipple to connect it to boiler; steam gage with siphon; water column with gage glass, three gage cocks and pipe connections to boiler; blow-off valve; check valve; stop valve for water feed line; smoke stack and guys; stacks less than 60 ft. long shall have four guy eyes, and guys six times as long as the stacks. Stacks 60 ft. long or longer shall have six guy eyes, two sets of three, and guys ten times as long as the stack. A stack plate or nozzle shall be included with each full-front boiler.

The boiler specifications adopted by the American Boiler Manufacturer's Association (1898) differ from those preceding in the following particulars:

Steel for shells heads and covering strips to be as specified in Table 1 *ante* (max. sulphur, 0.03 per cent.; max. phosphorus, 0.04 per cent.). Thickness of charcoal iron or mild steel tubes, B. W. G.: 1 to 1¾-in. tubes, No. 13; 2 to 2½-in., No. 12; 2¾ to 3½-in., No. 11; 3¾ and 4-in., No. 10; 4½ and 5-in., No. 9. Rivets to be of charcoal iron or of mild steel having the properties of fire-box steel in Table 1. Rivets to have height of head at periphery of shank = ½ shank diam.; shank to join head with a slight fillet. Pressures used in machine riveting: 1⅛ and 1¼-in. rivets, 80 tons; 1-in., 65 tons; 15/16-in., 57 tons; ¾-in., 35 tons. Make resistance to shear of aggregate rivet section at least 10 per cent. greater than tensile strength of the net or standing plate metal. Copper ferrules (Nos. 18 to 14 B. W. G.) to be used on ends of tubes of fire-tube boilers subject to direct heat. Iron stay bolts: T.S., $>$ 46,000 lb.; E.L., $>$ 26,000 lb.; elongation $>$ 22(20) per cent. for bolts $<$ ($>$) 1 sq. in. in cross-section. Steel stay bolts: T.S. $>$ 55,000 lb.; E.L., $>$ 33,000 lb.; elongation $>$ 25 (22) per cent. for bolts $<$ ($>$) 1 sq. in. in cross-section. Braces and stays: Allowable actual pull per sq. in. of net section of good stock, 6500 lb. for wrought iron and 8000 lb. for mild steel. Hydrostatic test pressure not to exceed 1½ $\times$ working pressure; water temperature $\geqq$ 125 deg. fahr. In flanging, bending and forming no work is to be done on any point which does not show red by daylight and at least 4 in. around it.

THE BURNING OF FUEL

Hand-firing with Coal

Anthracite. See p. 595. This fuel is marketed under the names given in Table 6 to designate sizes. The larger sizes are not generally employed for commercial steam generation, the grades now used in power-plant work being Nos. 1, 2 and 3 buckwheat.

Table 6. Anthracite Coal Sizes

Trade name	Round mesh, in.		Testing segments, standard square mesh, in.	
	Through	Over	Through	Over
Broken	4½	3¼	4	2¾
Egg	3¼	2⅜	2¾	2
Stove	2⅜	1⅝	2	1⅜
Chestnut	1⅝	⅞	1⅜	¾
Pea	⅞	⅝	¾	½
No. 1 buckwheat	⅝	⅜	½	¼
No. 2 buckwheat or rice	⅜	3/16	¼	⅛
No. 3 buckwheat or barley	3/16	3/32	⅛	1/16

This class of fuel is usually hand-fired. It should be spread evenly in small charges at frequent intervals and left alone after it strikes the fire bed, the fire tools being used as little as possible. The thickness of the fires is not over 2 or 3 in., but the fuel bed builds up between cleaning intervals and the total thickness may be from 14 to 16 in. just before such an interval. Cleaning periods should depend upon the combustion rate and the class of fuel. The fuel ignites with difficulty, and in cleaning fires this fact must always be taken into consideration. Combustion arches sprung over the grates assist in the ignition of freshly fired fuel and in keeping the furnace temperature high. A forced blast is usually employed.

The rated capacity of a boiler can be obtained with the ratio of grate to heating surface of 1 to from 35 to 40. With the finer sizes of anthracite and where overloads are desired, however, this ratio should preferably be 1 to 25. Grates 10 ft. deep, with a slope of 1½ in. to the foot, may be conveniently handled, and grates 12 ft. deep with the same slope, successfully handled. Wherever grates over 8 ft. deep are installed, the rear portion at least should

56

be of the overlapping dumping type. Air openings in the grate bars should be from 3/16 in. for No. 3 buckwheat to 5/16 in. for No. 1 buckwheat. These openings should be equally distributed over the whole surface to prevent blowing holes in the fire.

For burning the smaller sizes of anthracite a blast up to 3 in. should be available. Stacks should be of such sizes as to insure a suction at all times within all parts of the boiler setting. Ashes may be economically disposed of when circumstances permit, by flushing with water. A forced blast with anthracite fuel causes rapid fouling of the heating surfaces, the dust carried over amounting often to as much as 10 per cent. of the total coal fired.

Bituminous Coal. See p. 595. The sizes and grades of bituminous and semi-bituminous coals vary so much according to kind and locality, that there are no standards of size for these coals which are generally recognized. The following classification is sometimes used:

EASTERN BITUMINOUS COALS

(*a*) Run of mine coal; the unscreened coal taken from the mine.

(*b*) Lump coal; that which passes over a bar screen with openings 1¼ in. wide.

(*c*) Nut coal; that which passes through a bar screen with 1¼-in. openings and over one with ¾-in. openings.

(*d*) Slack coal; that which passes through a bar screen with ¾-in. openings.

WESTERN BITUMINOUS COALS

(*e*) Run of mine coal; the unscreened coal taken from the mine.

(*f*) Lump coal; divided into 6-in., 3-in., and 1¼-in. "lump," according to the diam. of the circular openings over which the respective grades pass; also 6×3-in. "lump" and 3×1¼-in. "lump" according as the coal passes through a circular opening having the diam. of the larger figures and over that of the smaller diam.

(*g*) Nut coal; divided into 3-in. "steam nut," which passes through an opening 3 in. in diam.; 1¼-in. "nut," which passes through a 1¼-in. diam. opening and over a ¾-in. diam. opening; ¾-in. "nut," which passes through a ¾-in. diam. opening and over a ⅝-in. diam. opening.

(*h*) Slack coal; that which passes through a ⅝-in. diam. opening.

(*i*) Washed sizes; those passing through or over circular openings of the following diameters, in inches:

Number	1	2	3	4	5
Through	3	1¾	1⅛	¾	¼
Over	1¾	1⅛	¾	¼	0

In burning bituminous coals the volatile gases distilled from the coal should be brought into intimate contact with air sufficiently heated to cause them to ignite; sufficient space should be allowed for their thorough mixture with the air; and sufficient time should be allowed for their combustion before the gases strike the comparatively cool heating surfaces.

As the volatile content of the coal increases, the difficulty of burning it successfully will increase. Highly volatile coals need an added combustion space, which can only be obtained by the use of an extension furnace. The percentage of volatile matter will govern the thickness of fuel bed to be carried for the best results. The following suggestions for general conditions may be of service: Semi-bituminous coals, such as Pocahontas, New River, Clearfield, etc., require fires from 12 to 14 in. thick; bituminous coals from the Pittsburg District, from 4 to 6 in. thick; Kentucky, Tennessee, Ohio, and Illinois bituminous coals, from 4 to 6 in.; free-burning Wyoming coal from the Rock Spring District, from 6 to 8 in.; poorer grades of western coals, from Montana, Utah and Washington, about 4 in.

Firing Methods. (*a*) In the spreading method but little fuel is fired at one time, and is spread evenly from front to rear of the fuel bed. Where there is more than one firing door, the doors should be fired alternately, so that the whole surface of the fire will not be blanketed with green coal.

(b) In the coking method, fresh coal is fired to a considerable depth at the front of the grate and, after it is partly coked, is pushed back into the furnace. This preserves a bed of burning carbon at the rear of the grate, which burns the volatile matter driven off from the green coal. This method is not applicable where the gases pass directly upward from the fire. Modern practice for hand-fired boilers favors the spread-firing method. As a rule, the less a bituminous coal fire is worked, the better the results.

Table 7 gives the **ratios of grate surface to heating surface** for conditions of economy and capacity and the width of grate-bar openings which, under ordinary conditions, will give satisfactory results with various bituminous coals. In general, the ratio for capacity should be selected, as grates can always be cut down.

Table 7. Grate Dimensions and Ratios of Grate Surface to Heating Surface with Various Bituminous Coals

Coal	Grate-bar openings, in.		Ratio for economy		Ratio for capacity	
	Mine run	Slack	Mine run	Slack	Mine run	Slack
Virginia, West Virginia, Maryland and Pennsylvania	1/2	3/8	1:60	1:55	1:55	1:50
Ohio, Kentucky, Tennessee and Alabama	3/8 to 1/2	1/4	1:55	1:50	1:50	1:45
Illinois, Indiana, Kansas and Oklahoma	3/8 to 1/2	1/4	1:50	1:45	1:45	1:40
Colorado and Wyoming*	3/8	1/4	1:50	1:45	1:45	1:40

* Some of the latter classes can be best handled with ratios as given for Ohio coals, but in general the larger ratios should be used.

Lignites. See p. 603. The volatile content of this class of fuel is higher than in bituminous coal and the difficulties of burning it greater. A large combustion space is necessary and the best results are obtained with furnaces of the reverberatory type. A fuel bed of from 4 to 6 in. should be maintained, and firing should be in small quantities at frequent intervals by the spreading method. Clinker forms rapidly on exceeding certain combustion rates, and a steam jet in the ash pit for softening such clinker is often desirable. Shaking grates aid in cleaning fires, but must be handled carefully to prevent good fuel being lost in the ash pit. Lignites usually produce much smoke when hand-fired. For western lignites, air spaces in grate bars should be 1.2 in.; for Texas lignites, 7/16 in.

For **briquetted fuel** and **pulverized coal**, see p. 604.

Automatic Stokers

Stoker-fired furnaces have the advantage over hand-fired furnaces of minimizing smoke. In general, a stoker installation is not practicable unless both the coal and ashes are automatically handled. In large plants the labor saving made possible by the installation of stokers in connection with modern methods of coal storage and coal and ash handling, is considerable. In small plants, however, the labor saving may be negligible. Stokers are therefore advisable in small plants only where the fuel saving will be large, or where the smoke question is important.

The upkeep cost of stoker-fired furnaces will in general be higher than that of hand-fired furnaces. The use of stokers makes it possible to burn cheaper fuels with as high or higher efficiencies than those obtainable with better grades of fuel in hand-fired furnaces. This better efficiency is due to even and continuous firing as against intermittent firing, and a constant air supply as against a variation in such supply with varying furnace conditions in hand-fired practice. When properly proportioned and designed, the boiler capacity can be increased over hand-firing without loss of efficiency.

There is a tendency in all stokers to cause loss of unburned fuel in the ash pit. Other conditions being equal, there will be no appreciable difference in the efficiency or capacity of various types of stokers, provided care is taken to select the proper type for the fuel to be burned and the operating conditions to be fulfilled. No stoker will satisfactorily handle all classes of fuel.

Types of Stokers. Stokers can be classified under three general types: (1) traveling-grate, (2) overfeed, and (3) underfeed.

Traveling-grate Stokers. This type is illustrated by the Babcock & Wilcox Co.'s chain-grate stoker which consists of an endless grate composed of small bars passing over sprockets at the front and rear of the furnace. Coal is fed from a hopper by gravity on to the forward end of the grate, is ignited as it passes under an ignition arch and is carried by the grate to the rear as the combustion progresses. When properly operated, combustion is completed when the fire reaches the end of the grate and the refuse is carried over the rear end. Generally a bridge-wall water box or similar device at the rear serves as a seal to prevent the admission of excess air at that point, and in some cases closes up the rear portion of the fire by partly obstructing its passage over the rear of the grate. Some types are equipped with automatic dumping grates at the rear.

Advantages: Especial adaptability for burning low grades of coal running high in volatile matter—burned only with difficulty on other stokers; comparatively low upkeep cost; ease of withdrawal from furnace for inspection and repairs without in any way disturbing the boiler setting; continuous and automatic cleaning.

Overfeed Stokers may be divided into two general classes, the distinction being in the direction in which the coal is fed relatively to the furnace. In one class (illustrated by the Roney stoker) the coal is fed into hoppers at the front end of the furnace to the upper part of grates inclined downward toward the rear at about 45 deg. The grates are reciprocated, taking alternately straight and inclined positions, and this motion gradually carries the fuel as it is burned toward the rear and bottom of the furnace. At the bottom of the inclined grates flat dumping grates are supplied for completing the combustion and for cleaning. The fuel is coked on the upper portion of the grates, and the volatile gases driven off in this process are ignited and burned in their passage over the bed of burning carbon lower on the grates.

In the other class (represented by the Murphy stoker) the fuel is fed from the sides of the furnace for its full length on to the upper part of grates inclined downward toward the center. The inclined grates are moved by rocking bars and the fuel is gradually carried on to the bottom and center of the furnace as combustion proceeds, where a clinker breaker grinds out and removes the refuse.

Overfeed stokers are advantageous in the burning of coals of the caking class. The fires ordinarily carried are comparatively thin, and the movement of the grate bars keeps them broken up and open, thus preventing caking.

Underfeed Stokers. These are of two classes, either horizontal or inclined. In the Taylor inclined underfeed stoker the fuel is fed from beneath by plungers. The green fuel is fed under the coked and burning coal, the volatile gases from this fresh fuel being heated and partially burned in their passage through the hottest fire on the top. As in the overfeed stokers, the refuse is carried downward to the rear where there are dumping grates.

The American underfeed stoker is an example of the horizontal class of underfeed stoker. The principle of operation of this stoker is the same as that of the Taylor stoker. The fuel is fed continuously from beneath by a screw, which carries it as it is consumed upward and backward, depositing the ash on dead plates on either side of the retorts, from which it is removed either by dumping or by hand through doors at the front of the furnace.

Advantages: Underfeed stokers, as a class, have the ability to carry heavier fires. As they are practically all operated with a forced blast (driven in some cases by the same mechanism as the stoker drive), but a small amount of draft suction is necessary in the furnace, and, due to the thickness of the fuel bed, the air supply is kept at a minimum, with a resulting high CO_2 reading. As the plunger and screw feeds both tend to break up the fire, caking coals can be burned with satisfactory results.

Very high temperatures are ordinarily developed in the furnaces of underfeed stokers, which may result in brickwork troubles if the draft is not properly regulated.

Smoke

Many plants burning a wide variety of fuels in hand-fired furnaces operate under ordinary conditions without smoke. When, however, a load is suddenly thrown on and the fires have to be brought up quickly, the steam pressure can only be maintained by the free use of the slice bar. This working of the fire will cause smoke.

In hand-fired furnaces the spreading method with alternate firing should be used, the coal being fired evenly, quickly, lightly and often, and the fire worked as little as possible. Smoke can be diminished by giving the gases a long travel under the action of heated brickwork (in an extension furnace or otherwise) before striking the boiler heating surfaces. Air introduced over the fires and the use of heated piers, arches, etc., for mingling the air with the gases distilled from the coal, will diminish smoke.

Under ordinary operating conditions, stoker-fired furnaces are much more nearly smokeless than hand-fired, and may be to all intents and purposes smokeless. In stoker installations, the volatile gases as they are distilled should be acted upon by ignition or other arches before they strike the heating surfaces.

So-called "smoke consumers" are for the most part, impracticable and diminish smoke only at a loss of efficiency and capacity through the addition of excess air, or through using a considerable amount of steam.

Smoke Determinations. No wholly satisfactory methods for either quantitative or qualitative smoke determinations have come into use, or any reliable method for fixing even the relative density of smoke issuing from a chimney at different times. The character of the sky or the background has a bearing on the color and density, and the personal equation of the observer enters very largely. Density charts and smoked-glass apparatus in general have proven unsatisfactory. A method sometimes employed is that of making 1-min. observations and recording these according to the degree of blackness, giving the various degrees an arbitrary percentage value, rated about as follows: Dense black, 100; medium black, 80; dense gray, 60; medium gray, 40 light gray, 20; very light, 5; trace, 1; clear chimney, 0.

The most generally used basis of qualitative smoke determination is the chart known as **Ringlemann's chart.** This consists of four cards ruled with vertical and horizontal lines forming squares. No. 1 is ruled with lines 1 mm. thick, the spaces being 9 mm. wide. No. 2 is ruled with 2.3-mm. lines, the spaces being 7.7 mm. No. 3 is ruled with 3.7-mm. lines, the spaces being 6.3 mm. No. 4 is ruled with 5.5-mm. lines, the spaces being 4.5 mm. Cards thus ruled are placed about 50 ft. from the observer, in line with the chimney emitting smoke, together with a white card and one that is solid black. The observer glances rapidly from the chimney to the cards and judges which one corresponds with the color and density of the smoke.

Smoke Ordinances. Numerous city and town smoke ordinances have been passed recently, but many of these are defective or ineffective. Some of the features included in the Chicago ordinance, which is one of the most comprehensive in use, are:

(*a*) A department of smoke inspection, at the head of which there is a mechanical engineer, with necessary assistants, deputies, etc.

(*b*) No new power plant to be constructed or old plant reconstructed until plans and specifications are approved by inspector and a permit issued.

(*c*) No new or reconstructed plant to be put in operation until approved by board and certificate issued.

(*d*) The emission of dense smoke from any stack, except for a period of 6 min. in any one hour during which a fire box is being cleaned or a new fire is being built therein, is a nuisance and may be summarily abated. (Penalty for violation of this provision.)

(*e*) The smoke inspector shall keep a complete record of all plans submitted, of all plants examined and of all certificates issued.

The principal objection to this ordinance is the lack of a statement as to what constitutes dense smoke or the fixing of a standard to be used as a basis of comparison.

The Bureau of Mines, Department of Interior, in its Bulletin 49, 1912, offers a suggested form of smoke ordinance for large and medium-sized cities. This ordinance differs from that of Chicago, above quoted, mainly in that a standard of grading smoke is given. The paragraphs relative to the allowable emission of smoke read as follows:

The emission of dense smoke within the city from the smoke stack of any locomotive, steamboat, or steam tug for a period of more than 1 min., except for a period or periods aggregating not to exceed 10 min. in any one hour during which period or periods the fire box is being cleaned or a new fire is being built therein, is hereby declared a nuisance: *Provided*, that the fire engines or the fire boats of the city fire department, or both of them, shall be exempt from these restrictions.

The emission of dense smoke within the city from the smoke stack of any steam roller, steam derrick, steam pile-driver, tar kettle, or other similar machine or contrivance, or from the smoke stack or chimney of any building or premise, except for a period or periods aggregating not to exceed 6 min. in any hour during which period or periods the fire box is being cleaned or a new fire is being built therein, is hereby declared a nuisance.

For the purpose of grading the density of smoke, the Ringlemann smoke chart shall be the standard of comparison. Smoke shall be considered "dense" when it is of greater density than No. 3 of the chart.

Wood Burning

Wood, as used commercially for steam-generating purposes, is usually a waste product from some industrial process, refuse from lumber mills forming the greater portion of this class of fuel. In some refuse the moisture content may run as high as 60 per cent. of the total weight, and the composition may vary widely during different portions of the mills' operations. Such fuel consists of sawdust, hogged wood and slabs, the percentage of each varying widely.

Wet Wood. It is essential that a large combustion space be provided and, where there is a high moisture content, heated brickwork to radiate heat to the fuel bed and evaporate the moisture is necessary. Extension furnaces are usually necessary to give good results. Where this fuel alone is burned, added combustion space can be obtained by dropping the grates to the floor line. A comparatively thick fuel bed is necessary to reduce the excess air to a minimum. Where hogged fuel and sawdust alone are used, they are best fed to the furnace through chutes on the top, the fuel from such chutes being allowed to pile up to a height of 3 ft. or 3 ft. 6 in. In properly designed furnaces, one chute can take care of approximately 30 sq. ft. of grate surface with this fuel. With proper draft conditions, 150 lb. of wet fuel can be burned per sq. ft. of grate surface per hour, and in well-designed wood-burning furnaces 1 sq. ft. of grate surface can readily develop from 5 to 6 boiler h.p. A strong natural draft is to be preferred to a forced blast with this fuel.

Unconsumed particles of wood fuel may be carried over into the heating surfaces and lodged in the setting out of the path of the gases. Such particles may ignite if air leaks to them, with harmful results. This is especially true where particles are carried into the base of a stack and settle at a point below the flue entrance. Collecting chambers should be provided in the setting and should be kept clean where wood fuel is used.

Dry Wood. Dry sawdust, chips and blocks from wood-working industries are sometimes used as fuel. Here, too, ample combustion space is required. The action of heated brickwork is not as necessary as where the moisture content is high. Where the fuel is largely sawdust, and an extension furnace is not used, the sawdust can be fed through chutes in the boiler front over the grates. The fire doors should be large for the introduction of such fuel as cannot be fed through the chutes.

Bagasse. See p. 609. In practically all cases where bagasse is burned, some auxiliary fuel will be required, the amount depending largely upon the proportion of fiber in the cane. Much better results are secured where large quantities are burned; that is, a given quantity burned in one furnace between two boiler units will give better results than the same quantity burned in two separate furnaces with separate boilers. (See Geerlig's "Cane Sugar and Its Manufacture.")

The best combustion is secured by burning the fuel on a hearth rather than on grates, air for combustion being admitted through several rows of tuyères placed above and symmetrically around the hearth. High combustion rates give the best results. With a natural draft in the furnace of, say, 0.3 in. water column, a combustion rate of from 250 to 300 lb. per hour per sq. ft. of grate surface may be secured. With a blast of 0.5 in. available, this rate may be increased to 450 lb. per hour per sq. ft. These rates are for bagasse containing approximately 50 per cent. of moisture. The most economical combustion rate is approximately 300 lb.

Considerable dirt is deposited from this class of fuel, and the gas ducts and furnace should be thoroughly cleaned out once in 24 hr. If this cleaning is not properly taken care of, the dirt will fuse into a glass-like clinker which is particularly difficult to remove.

Oil Fuel

Petroleum (see p. 610) is the only liquid fuel sufficiently abundant and cheap to be used for the generation of steam. It possesses many advantages over coal and is extensively used in some localities where its cost as compared with coal makes it the cheaper fuel. The petroleum most generally used for fuel purposes in the United States is that which upon distillation yields asphalt, the other classes yielding upon distillation such a variety of lighter oils that their use as fuel is prohibitive because of price. To the asphalt petroleums belong the oils found in Texas and California.

Oil vs. Coal. Advantages of the use of oil over coal may be summarised as follows:

1. The handling cost is low, oil being fed by simple mechanical means.
2. A general labor saving throughout the plant in the elimination of stokers, coal passers, ash handlers, etc.
3. For equal heat value, oil occupies very much less space than coal, and the storage space can be at a distance from the boiler without detriment.
4. Combustion with oil is more perfect than with coal, the excess air being more readily reduced to a minimum, and there being no ash which in the burning of coal

usually contains considerable combustible matter. The furnace temperature may be kept practically constant and smoke may be eliminated with the resulting increased cleanliness of heating surfaces. The more perfect combustion results in higher efficiencies than are attainable with coal.

5. The intensity of the fire can be almost instantaneously regulated to meet fluctuations in load.
6. There is no loss in calorific value or difficulties arising from disintegration and slow oxidation where oil is stored such as are possible in coal storage.
7. Oil is cleanly and free from dust, with a consequent saving in wear on machinery.

The disadvantages of oil are as follows:

1. The necessity that the oil have a high flash point to minimise the danger of explosions.
2. Ordinances relative to location and isolation of oil storage tanks may in certain cases make the use of oil fuel prohibitive.
3. Unless boilers and furnaces are especially adapted for oil fuel, the upkeep cost will be higher than if coal were used.

Table 8, comparing oil and coal, calculated by C. C. Moore & Co., Engineers, of San Francisco, takes into consideration the variation in boiler efficiency, and is a good basis for rough approximations.

Table 8. Relative Values of Coal and Oil Fuel

Gross boiler efficiency with oil fuel	Net boiler efficiency* with oil fuel	Net evaporation, lb. from and at 212 deg. fahr. per lb. of oil	Water Evaporated from and at 212 Deg. Fahr. per Pound of Coal

* Net efficiency = gross efficiency less 2 per cent. for steam used in atomizing oil. Heat value of oil = 18,500 B.t.u.

Burning Oil Fuel. The requirements for burning petroleum with the highest economy are as follows:

1. Its atomization must be thorough.
2. When atomised it must be brought into contact with the requisite quantity of air for its combustion, and this quantity kept at a minimum.
3. The mixture must be burned in the presence of refractory material, which radiates heat to assist in the combustion. A high grade of fire brick must be used for the furnace to stand up under the high temperatures developed.
4. Combustion must be complete before the gases are cooled by coming into contact with the boiler heating surfaces.
5. There must be no localisation of the heat on certain portions of the heating surfaces such as may be produced by a blow-pipe action in the burners, or trouble will result from overheating and blistering of the boiler tubes.

See "Developments in Oil Burning," E. H. Peabody, *Trans. Soc. Nav. Arch. and Mar. Eng.*, 1912. B. R. T. Collins, *Trans. A. S. M. E.*, vol. 22, 1911; *Jour. Am. Soc. Nav. Eng.*, vol. 23, 1911.

Oil Furnaces. The best results are secured where a furnace is used in which the oil is introduced in the direction in which it increases in volume, insuring free expansion and a thorough mixture of the oil with the air, and complete combustion of the gases before they come into contact with the heating surfaces. In such a furnace a flat-flame burner gives the best results. Burners should be so located that the flames from individual burners will not interfere or impinge to any extent on the side walls or lanes of smoke and an uneven distribution of heat will result.

Burners

Spray Burners are almost universally used and the simplicity and excellent economy of the steam atomizing burners make them the most satisfactory where the loss of steam and the consequent requirement of an equal added amount of fresh make-up water is not of great consequence. Air atomizing burners have practically gone out of use in this country.

Steam atomizing burners are of the inside or outside mixing type. In the former, steam and oil come into contact inside of the burner and the mixture is atomized in passing through the burner nozzle. In the latter type the steam passes through a narrow slot or row of small holes below a similar slot through which the oil flows. The oil is picked up by the steam outside of the burner and is atomized by it.

Heating the oil is advantageous in causing it to be atomized more readily and in securing economical combustion. Such heating should be done as close to the burners as is practicable. If the temperature of the oil is raised too near its flash point and any material vaporization occurs, the oil will flow irregularly and the flame will splutter. By-passes should be provided between the oil and steam ducts of a burner for blowing out the oil piping and burner to clean out any deposits. Strainers should be installed in duplicate in the oil lines for removing the silt carried by the oil, and should be so located as to allow for rapid removal, cleaning and replacing without interfering with the operation of the boilers.

Mechanical Atomizing Burners are usually of the round-flame type. The oil is fed to the burner under pressure varying with the rates at which it is to burn. It is given a rotary motion before issuing from the burner nozzle. Heating the oil is an aid to atomization. Heating and the pressure affect the capacity of individual burners, and provide a means of regulation of individual burners. Large variation in demand for steam is taken care of by changing the number of burners in service.

Steam Consumption of Burners. With a good type of steam atomizing burner, the steam required for atomization is less than 2 per cent. of the total steam generated with the boiler running at its rated capacity. This figure will decrease as the boiler rating increases.

The steam required by mechanical burners in heating and pumping is in the neighborhood of 0.25 per cent. of the total generated, and this steam can be returned to the system. It is this fact that makes a mechanical atomizing burner more satisfactory for marine work than a spray burner, or for any work where the question of make-up feed water is important.

Gaseous Fuel

Natural Gas (see p. 614) is best burned by the use of a large number of small burners, each being capable of handling approximately 30 rated h.p. This obviates the danger of any laning or blow-pipe action of the gases which might be present where large burners are used. Where natural gas is the only fuel, the burners should be evenly distributed over the lower portion of the boiler front. If this fuel is used as an auxiliary to coal, these burners may be placed through the fire doors. A large combustion space gives the best results, say, 2 cu. ft. per rated h.p. A checkerwork wall is sometimes placed in the furnace about 3 ft. from the burners to break up the flame, but with a good type of burner and furnace this wall is not necessary. Good results are secured with the burners inclined slightly downward toward the rear of the furnace where the gas is burned alone and there are no coal-firing grates.

Blast-furnace Gas. See p. 614. For good efficiency a long flame travel and ample furnace volume are necessary. The combustion space should be from 1½ to 2 cu. ft. per rated boiler h.p. The most satisfactory type of burner is that in which both the amount of gas and air can be regulated. The question of handling dust when burning this fuel is important. If auxiliary grates are used for igniting the fires, these may be placed immediately under the burners; much of the dust is then precipitated on the fire and will be cleaned out when the fires are cleaned. Dust precipitated in the furnace, if allowed to accumulate, becomes fused and is difficult to remove.

With gas passages of 0.8 sq. in. per rated boiler h.p. a boiler can be run at its rated capacity with a gas pressure of 2 in. of water. The pressure in the main is usually from 6 to 8 in., which allows for overloads and throttling of the gases to equalise the flow to the various boilers in a plant. The air passage should be from 0.75 to 0.85 sq. in. per rated h.p.

Stack Sizes with Blast-furnace Gas. Stacks 130 ft. high are sufficient for this class of work. Such stacks will give sufficient draft to obtain 175 per cent. of the boiler's rated capacity. The capacity beyond a certain point will not increase proportionately with the draft. With too much draft the mixture of gas and air is not good, sometimes resulting in a pulsating action of the flame—if not actual explosion, danger of burning out dampers, and increase in wear and tear on settings. Pulsations within the setting may also be occasioned through a lack of air for combustion.

The brickwork must be well laid. The pulsating action of the flame shakes the setting, and the possibility of explosions makes it necessary that the whole should be properly tied and buckstayed. Extension furnaces, where used, should be particularly well buckstayed.

Flue-gas Analysis

The quantities determined in the ordinary gas analysis are the relative proportions by volume of carbon dioxide, oxygen and carbon monoxide, the determinations being made in the order named. In boiler practice the nitrogen content of the flue gases is obtained by deducting the sum of the other constituents from 100. See also pp. 369 and 1695.

Incomplete combustion is indicated by the presence of carbon monoxide in the analysis. It is the result either of a deficient air supply or an imperfect mixture of the combustible gases with the air supplied. The loss due to incomplete combustion of the carbon in the fuel, in B.t.u. per lb. of fuel, is

$$L = 10{,}150\,C \times CO/(CO + CO_2),$$

where 10,150 = difference in heat evolved in burning 1 lb. of carbon to CO_2 and to CO; CO and CO_2 = percentages by volume of carbon monoxide and carbon dioxide as found by analysis; and C = fraction by weight of carbon in the fuel which is burned and passes up the stack. The presence of 1 per cent. of CO in the flue gases will represent a decrease in the boiler efficiency of 4.5 per cent.

C is to be distinguished from the per cent. of carbon by ultimate analysis of the fuel, and is that quantity, less the per cent. of unconsumed carbon in the ash. Where an ultimate analysis of the ash is not available, the percentage of carbon in the ash is determined by the difference in the ash percentage by proximate analysis of the fuel and as found at the time of the boiler test by actual weight.

It is generally assumed that high CO_2 readings are indicative of good combustion, and hence of high efficiencies. Such readings are not satisfactory when considered apart from the CO determination. The best percentage of CO_2 to maintain varies with different fuels, and is lower for those with a high hydrogen component than for fuel mainly composed of carbon.

For the air supply, combustion products, etc., with complete combustion, both with and without excess of air, see p. 362. If part of the carbon is burned to CO (**incomplete combustion**), the equations are as follows:

The air supply per pound of fuel is: $W^1 = 3.036(C \times N/(CO_2 + CO))$, where W^1 = pounds of air supplied per lb. of fuel and N = percentage by volume of nitrogen in the flue gases. The error in using this formula does not exceed 0.2 per cent.

Hydrogen in the volatile content of fuel increases the nitrogen content of the flue gases. This is due to the fact that the water vapor formed by the combustion of hydrogen will condense at the temperature at which the analysis is made, while the nitrogen which accompanied the oxygen maintains its gaseous form and passes in such form into the sampling apparatus. For this reason, where highly volatile coals, producing a large quantity of water vapor, are used, the apparent nitrogen content is increased.

The weight of flue gases per pound of fuel,* including moisture formed by the hydrogen component $= 3.036\,[N/(CO_2 + CO)]C + (1 - A)$, where A = per cent. of ash as found in test.

The weight of dry flue gases per pound of fuel* may be determined from the formula: $W^1 = C[11\ CO_2 + 8O + 7\ (CO + N)]/3\ (CO_2 + CO)$.

The ratio of air supplied per pound of fuel to the air theoretically required is: $W^1/W = 3.036C \left(\frac{N}{CO_2 + CO}\right) / 34.56 \left(\frac{C}{3} + H - \frac{O}{8}\right)$.

The ratio of air supplied per pound of combustible to that theoretically required is: $N/[N - 3.782\ (O - \frac{1}{2}\ CO)]$, on the assumption that all the nitrogen in the flue gas comes from the air supplied. Fig. 1 gives the value of this ratio for varying flue-gas analyses where there is no CO present.

Effects of Excess Air. The heat loss in the dry stack gases is: $L = 0.24 \times (T - t) \times W$, where L = B.t.u. lost per lb. of fuel; W = weight of flue gases in lb.; T = temperature of flue gases, deg. fahr.; t = temperature of atmosphere, deg. fahr.; and 0.24 = specific heat of flue gases.

The heat lost in dry chimney gases is shown in Fig. 2, which is calculated on the assumption that the gas contains (in addition to the percentage of carbon dioxide marked on the curves) 80 per cent. of nitrogen, and that the rest of the gas is oxygen. In those cases where some CO is present, the correction is quite negligible if the CO is reckoned as CO_2. In using Fig. 2 the heat contained in the gases at boiler-room temperature must be subtracted from the heat at chimney temperature in order to find the heat carried away by the dry gases. For loss per lb. of coal, multiply by per cent. of carbon in coal as shown by ultimate analysis. The heat going up the chimney with the superheated steam resulting from evaporation of moisture in the coal and from the combustion of H should be added to that in the dry gases when finding the total heat escaping up the chimney. See p. 896.

* In this formula, the weight of gas is per lb. of dry or moist fuel as the percentage of C is referred to a dry or moist basis.

The **minimum quantity of air** varies widely with the fuel. In a boiler test where the highest authentic efficiency ever secured with oil was obtained, the ratio of the air supplied to that theoretically required was 1.18 : 1. In tests with low volatile bituminous coals where similar efficiencies (the highest ever secured with such fuels) were obtained, these ratios were respectively

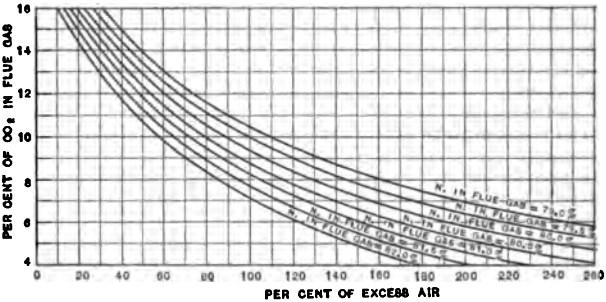

FIG. 1.—Ratio of Air Supplied per Pound of Combustible to That Theoretically Required.

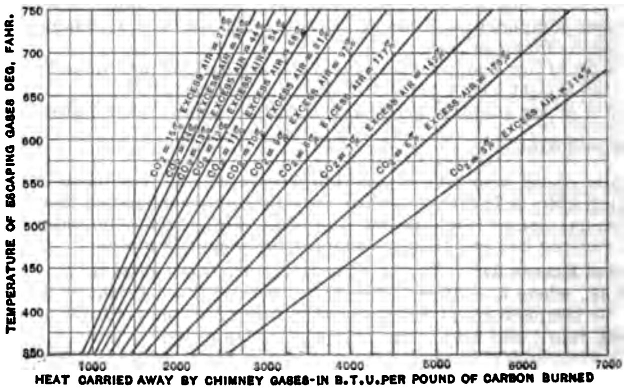

FIG. 2.

1.20 and 1.26 to 1. In a test with a highly volatile coal in which an efficiency was obtained at least as high as any that has been authentically secured for such coal, the ratio of air supplied to that required was approximately 2 : 1. The difference in efficiencies between the last case cited and the first two was from 5 to 7 per cent. The fact that the efficiencies taken are the highest on record indicates that a considerable excess of air is necessary even where combustion is as nearly perfect as practicable. The ratios of air supplied to that theoretically required, as given above, are under test conditions and in ordinary practice will be much larger. Table 9 gives the average losses as indicated by a heat balance for test conditions and for ordinary operating conditions.

THE CAPACITY AND EFFICIENCY OF STEAM BOILERS

The capacity of a boiler should be stated in terms of its evaporative power. As temperatures of feed water and steam pressures are different in various boilers, it is necessary, in order to secure a means for comparing the operation of different boilers, to reduce all results to some common basis. The method adopted is to transform the evaporation to an equivalent evaporation under a set of standard assumed conditions.

The Committee of Judges in charge of the boiler trials at the Centennial Exposition at Philadelphia in 1876, recommended that an evaporation of 30 lb. of water from an initial temperature of 100 deg. fahr. to steam at 70 lb. gage pressure be considered **1 boiler h.p.** A boiler h.p. so defined is really a measure of the amount of heat transmitted. The standard conditions now accepted are a feed temperature of 212 deg. fahr. and evaporation at the same temperature. These conditions are described by the term "evaporation from and at 212 deg." The weight of water which would be evaporated (under the assumed standard conditions), by the amount of heat actually absorbed by the boiler, is called the **equivalent evaporation from and at 212 deg.** The committee on boiler tests of the A. S. M. E. defines the **boiler h.p. as the equivalent evaporation of 34.5 lb. of water from and at 212 deg. per hour.** This is the same as 33,479 B.t.u. per hour.

The **factor of evaporation** is the ratio of the heat required to generate 1 lb. of steam under actual conditions to that required to generate 1 lb. of steam "from and at 212 deg." This ratio may be expressed for either saturated or superheated steam, as follows:

$$\text{Factor of evaporation} = (H - h)/970.4,$$

where H = total heat in 1 lb. of steam at boiler pressure and steam temperature; h = heat of the liquid at feed temperature, and 970.4 = latent heat of evaporation of 1 lb. of steam at 212 deg.

A method of determining the factor of evaporation for any set of conditions from a chart is indicated in Fig. 3. This chart, prepared by Professor Marks and based on the Marks and Davis Steam Tables, give factors for the usual range of steam pressures, steam qualities, superheat and feed-water temperatures. The main vertical scales give the factor of evaporation for a feed-water temperature of 32 deg. fahr. To correct for the actual feed-water temperature, go vertically from the feed-water temperature as given on the top horizontal scale to the diagonal line; the correction is shown on the extreme vertical scales. This quantity must in all cases be subtracted.

Unit of Boiler Capacity. In view of the very arbitrary unit adopted as a basis for boiler work, many attempts have been made to devise a unit of greater utility. H. G. Stott has suggested the **myriawatt** as a means of connecting mechanical units directly with electrical units. It has its basis in the fact that the present boiler h.p. (33,479 B.t.u.) and the kilowatt-hour (3412 B.t.u.) bear such a close relation. The "myriawatt," or 10 kw.-hr., would be equivalent to 34,120 B.t.u., or within 1.91 per cent. of the value of a boiler h.p.

Rating. As sold to-day, boilers are rated at a stated or nominal h.p. In stationary practice it is customary to rate a boiler on the basis of 10 sq. ft. of heating surface per h.p., *i.e.*, 10 sq. ft. of heating surface under normal operating conditions are considered capable of evaporating 34.5 lb. of water per hour from and at 212 deg. This method of rating a boiler is arbitrary, and has been adopted simply as a matter of convenience.

The capacity of a boiler usually designates its maximum capacity for

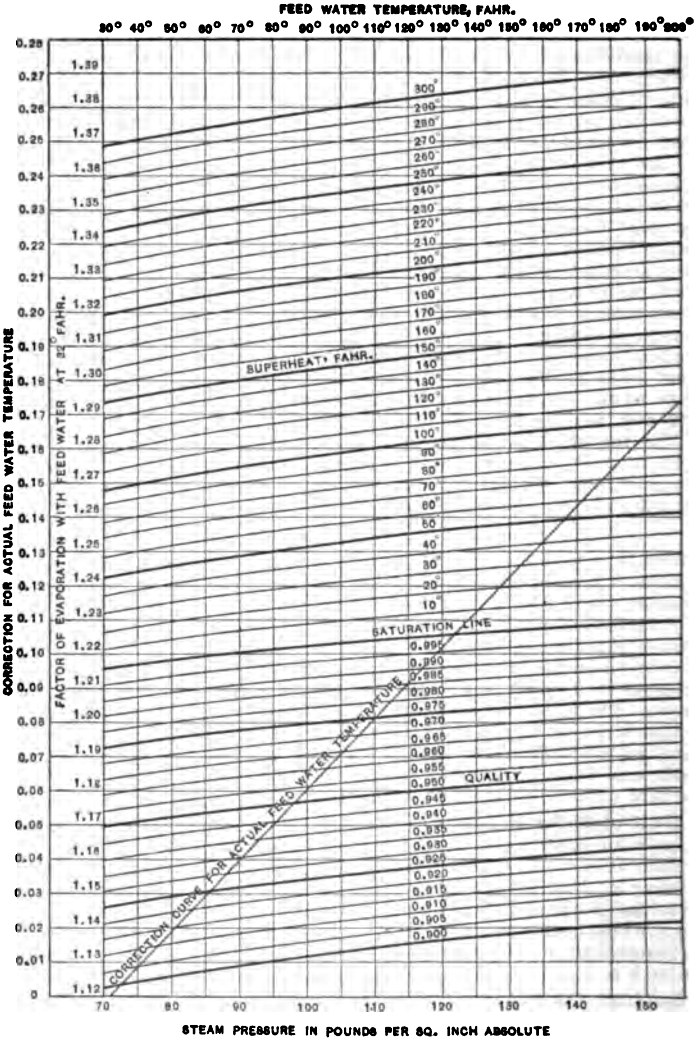

FIG. 3.—Chart for Determining

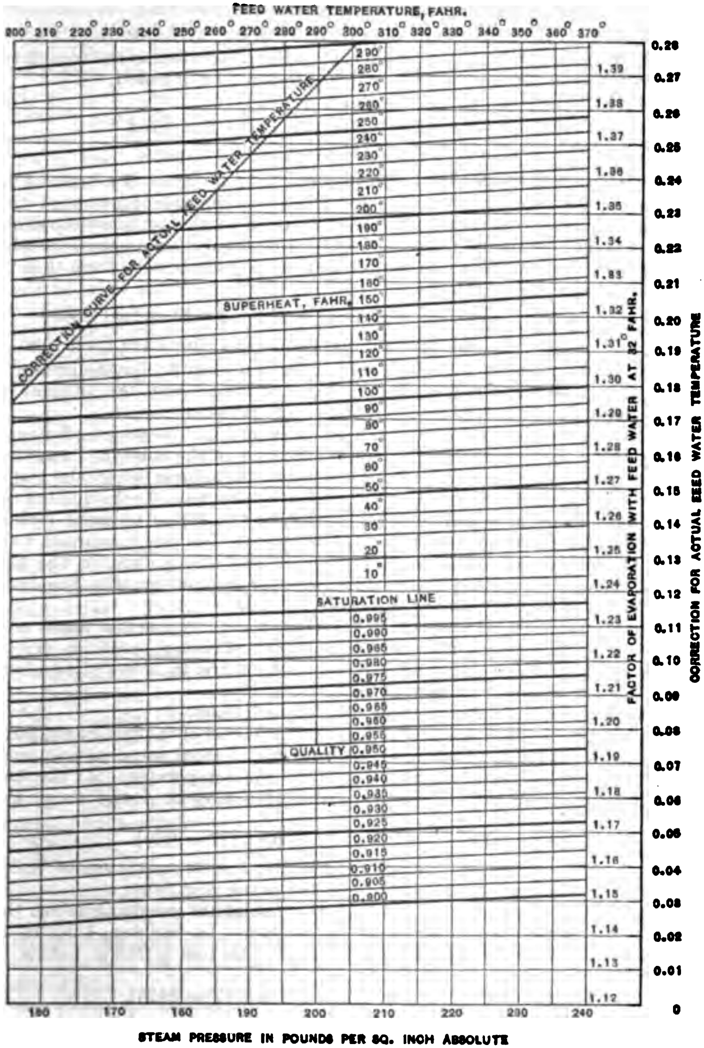

Factors of Evaporation.

evaporation. This maximum capacity, expressed in boiler h.p., is ordinarily given in terms of per cent. of the builder's nominal rated h.p.

Efficiency. The efficiency of a boiler, as ordinarily stated, is the combined efficiency of boiler, furnace and grate. Expressed as a formula,

Efficiency of boiler, furnace and grate =

$$\frac{\text{Heat absorbed by boiler per lb. of fuel fired}}{\text{Heat of perfect combustion per lb. of fuel}}$$

This efficiency will be the same whether based on moist or dry fuel. The heat absorbed by the boiler comes from the combustible portion of the fuel actually burned, irrespective of what fraction of the total combustible fired this may be. This has led to a second efficiency, based on combustible, which is called the **efficiency of boiler alone**, as distinguished from that of boiler and grate. As a formula,

$$\text{Efficiency of boiler} = \frac{\text{Heat absorbed by boiler per lb. of fuel fired}}{\text{Heat actually developed in furnace per lb. of fuel}}$$

The furnace is not entirely eliminated from the last formula, for the presence of excess air in the gases lowers the efficiency obtained, and the amount of excess air depends upon the furnace design and operation.

It is extremely difficult, if not impossible, to determine the actual efficiency of a boiler alone, as distinguished from the efficiency of the combined apparatus. When guarantees are to be met by a boiler manufacturer, where the boiler and stoker or grate are different installations, the only way of establishing an efficiency that has a practical value is to require the stoker or grate manufacturer to make certain guarantees as to minimum CO_2 and maximum CO, and that the amount of combustible in the ash and blown away in the flue gases shall not exceed certain limits. In usual commercial practice the combined efficiency of boiler, furnace and grate is used.

For approximate results a chart such as Fig. 4 may be used in place of a computation of efficiency. This may be used for efficiency based on dry or moist coal, and, where evaporation and heat values are in terms of combustible, for efficiency based on combustible.

The **heat losses** in a boiler may be divided as follows:

(1) Loss due to the utilization of a portion of the heat of the fuel in **evaporating** the **moisture** contained in it, after raising it from atmospheric temperature to 212 deg. and superheating it to the temperature of the flue gases. This loss in B.t.u. per lb. of combustible may be found from the formula:

$$\text{Loss} = W[(212 - t) + 970.4 + 0.47\ (T - 212)]$$

where W = moisture per lb. of combustible, lb.; t = temperature of boiler room, deg. fahr., and T = temperature of flue gases, deg. fahr.

(2) Loss due to heat carried away by the **moisture** resulting **from** the burning of the **hydrogen** component of the fuel. In burning, 1 lb. of H unites with 8 lb. of O to form 9 lb. of steam. This loss in B.t.u. per lb. of combustible is:

$$\text{Loss} = 9H[(212 - t) + 970.4 + 0.47(T - 212)],$$

where H = weight of hydrogen in the fuel per lb. of combustible.

Where an ultimate analysis of the fuel is not available, the hydrogen content may be determined approximately, for American fuels, from the proximate analysis of the fuel, according to a method devised by Professor L. S. Marks from a study of proximate and ultimate analyses carried out in 1904–1908 by the U. S. Government on about 240 different coals, from 28 states and territories, representing every kind of fuel from anthracite to peat, and a range of volatile matter in the combustible of from 6 to 70 per cent. Prof. Marks has shown (*Power*, Dec. 1, 1908) that the hydrogen in coal, not contained in moisture, can be found from the results of the proximate analysis, and further, that the computation of the chemical analysis of a coal can be made from its proximate analysis with sufficient accuracy for all usual heat-engine-investigation purposes.

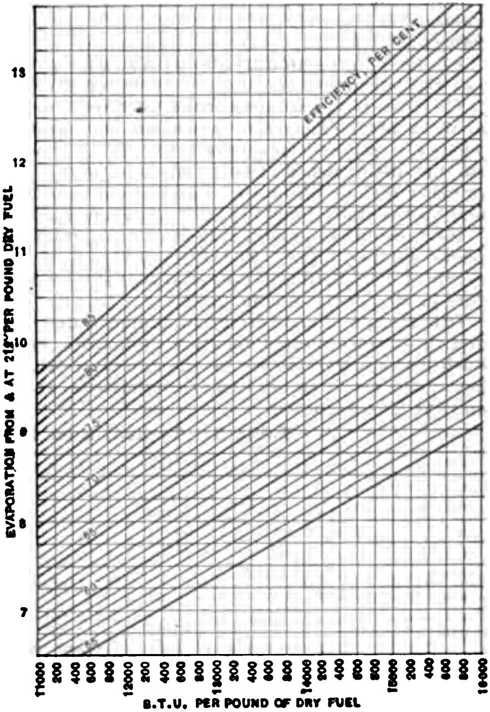

Fig. 4.—Chart for Determining Efficiency of Steam Boilers.

In proximate analysis the combustible = volatile matter + fixed carbon = coal as received − moisture and ash. Let V, H, C and N be respectively the percentage by weight of volatile matter, hydrogen, volatile carbon and nitrogen in the combustible. Then $H = V[7.35/(V + 10) - 0.013]$, which is accurate for American coals to about ±0.2 per cent.

The volatile carbon may be calculated from the content of volatile matter with an accuracy of ± 2 per cent., approx., by the following formulæ:

$C = 0.9 (V - 10)$ for anthracite and semi-anthracite.
$C = 0.9 (V - 14)$ for bituminous and semi-bituminous.
$C = 0.9 (V - 18)$ for lignites.

Sulphur in coal directly increases the value of V; values of C calculated as above will be too high practically by the sulphur content of the combustible.

The nitrogen (coming off in the volatile matter) may be calculated with an accuracy of ± 0.5 per cent. by the formulæ,

$N = 0.07 V$, for anthracite and semi-anthracite.
$N = 2.10 - 0.012 V$, for bituminous and lignite.

The formulæ given above are taken from Carpenter and Diederichs' "Experimental Engineering" (p. 507, 1911 edition).

(3) Loss due to heat carried away by **dry chimney gases.** This loss has been discussed on p. 891. In cases where the total carbon content of the fuel has not been determined by an ultimate analysis, it is possible to get its value from the proximate analysis, adding the fixed carbon content to the value of C obtained by the method given above.

(4) Loss due to **incomplete combustion** of the carbon content of the fuel, *i.e.*, the burning of carbon to CO instead of CO_2. See p. 890.

(5) Loss due to **unconsumed carbon** in the ash. This item requires an analysis of the ash and is, per lb. of combustible, Loss $= C \times A \times Q$, where C = per cent. of carbon in the ash; A = per cent. of ash as found in test (to be distinguished from that determined by an analysis, and should properly include unconsumed particles of fuel carried into the boiler setting and up the stack); and Q = heat value per lb. of combustible in the ash.

(6) Loss due to superheating **moisture in** the **air** supplied, from the atmospheric temperature, t, to the temperature of the flue gases, T. This loss per lb. of combustible is, Loss $= M \times 0.47(T - t)$, where M = weight of moisture in air per lb. of combustible.

Other losses—due to radiation, to unconsumed hydrogen and hydrocarbons, and those unaccounted for—are ordinarily grouped together in one item. Such losses will obviously be the difference between 100 per cent., the total heat value per lb. of dry fuel or combustible, and the sum of the above items and the heat absorbed by the boiler.

Table 9. Typical Heat Balances

TEST DATA AND ANALYSES

		Test conditions	Operating conditions

Relation Between Boiler Efficiency and Capacity

Efficiency. Thermal efficiencies of boilers, under various test conditions of operation are given in Table 10.

Capacity. The evaporation from a definite amount of heating surface in a well-designed boiler is limited only by the amount of fuel that can be burned under that heating surface. The factors limiting the production of high power from small heating surfaces are:

1. **Efficiency.** As capacity increases there will be in general a decrease in efficiency (see below).

2. **Possible or Practicable Grate Ratio.** Since all fuels have a combustion rate above which satisfactory results cannot be obtained, regardless of draft available, the only method of increasing capacity beyond such rates will be to increase grate surface. There is a point beyond which the grate surface for a given boiler cannot be increased, due to impracticability of handling or of features of construction.

3. **Gas Friction.** The frictional resistances to the passage of the gases increase very rapidly at high capacities, and may require excessive draft to overcome them.

4. **Feed Water.** The quality of feed water used is frequently the limiting factor in the capacity to be obtained from a definite amount of heating surface. With increased capacities comes an added concentration of such ingredients in feed as will cause priming, foaming or rapid scale formation. Certain waters, giving no difficulty with boilers operating at ordinary ratings, will cause difficulties at higher ratings out of all proportion to any advantage secured by an increase in capacity from the heating surface available.

Relation of Efficiency and Capacity. The increase in furnace efficiency at moderate capacities is usually at a greater rate than is the decrease in boiler efficiency, with the result that the combined efficiency of a boiler and furnace increases at first with an increase in capacity. This makes the ordinary point of maximum combined efficiency somewhat above the boiler's rated capacity, and in many instances the combined efficiency is approximately the same for a considerable range of ratings.

The usual variation of efficiency with capacity in modern boilers and furnaces is as follows:

Per cent. of boiler's rated capacity developed	80–100	120	140	160	180	200	220	240	260	280
Combined efficiency of boiler and furnace, per cent.	75	74.9	74.8	74.5	73.9	73.2	72.2	70.8	69.1	66.9

These values are derived from a number of tests, the results of which have, as far as possible, been modified to place them on a comparable basis. They are based on a combination of boiler and furnace which will give a maximum efficiency at or about the boiler's nominal rated capacity. If the arrangement is such as to give the maximum efficiency at a point considerably above the rated capacity of the boiler, the values for combined efficiency will drop off at the lower ratings. While the efficiencies represent those secured under test conditions, they nevertheless may be assumed to be an approximate representation of the variation in efficiency with capacity under any conditions of operation.

Performance of Steam Boilers

The highest authentic efficiencies that have been obtained with coal fuel are those secured by Dr. D. S. Jacobus in a series of tests at the Delray plant of the Detroit (Mich.) Edison Co. These tests were run on Stirling boilers containing approximately 23,650 sq. ft. of heating surface, the principal results of some of the tests being given in Table 11. The boilers tested were large-sized units, and the furnace was specially designed for the securing of the highest possible efficiency.

With oil fuel a gross efficiency of somewhat over 83 per cent. has been obtained as a maximum, and this figure is frequently approached.

The highest authentic capacity obtained with a standard stationary type of steam boiler, over a period of time of any duration, is 294 per cent. of the boiler's rated capacity, or at a rate of evaporation of 10.14 lb. of water from and at 212 deg. per sq. ft. of heating surface per hour. The test in which this capacity was secured was of 5 hours' duration, and was run at the plant of the Edison Electric Illuminating Co. of Boston. There are undoubtedly plants in which boilers are operated during short intervals of peak load at ratings considerably in excess of this figure, but the intervals are short and the exact capacity hard to determine.

In a series of tests on a Babcock & Wilcox marine boiler at the company's shops, Bayonne, N. J., with coal fuel, an equivalent evaporation of 14.76 lb. per sq. ft. of heating surface per hour was obtained. This rate is equivalent to approximately 428 per cent. of the boiler's rated capacity. In a test on the same boiler with oil fuel, an equivalent evaporation of 15:83 lb. per sq. ft. of heating surface per hour was obtained, or, on the ordinary stationary boiler basis of rating, 458 per cent. of the boiler's rated capacity. In these two cases a boiler h.p. was developed with 2.34 and 2.18 sq. ft. of heating surface, respectively.

Combustion Rates. Table 12 gives the draft required in the furnace for various combustion rates of different coals, and covers the ordinary range of such rates as found in modern practice.

Table 12. Pounds of Coal Burned per Sq. Ft. of Grate per Hour

(*A*) Md., Pa., Va., and W. Va. semi-bituminous coals.
(*B*) Ill., Ind., and Kan. bituminous coals.
(*C*) Ala., Ky., Pa., and Tenn. bituminous coals.

It may be of interest to note the following high combustion rates actually obtained in boiler-testing work:

(1) Burning low-grade Illinois slack coal on Babcock & Wilcox chain-grate stokers with a natural draft of 0.69 in. in the furnace, a rate of 45.2 lb. of dry coal per sq. ft. of grate surface per hour was secured. With the same class of fuel on a similar stoker with a draft of 0.75 in. in the furnace, 53.2 lb. of dry coal per sq. ft. of grate were burned per hour. This coal averaged approximately 15 per cent. of moisture, which would make the combustion rates, based on coal as fired, respectively 53.2 and 62.6 lb.

(2) Burning New River coal in a Murphy furnace, a rate of 39.2 lb. per sq. ft. of projected grate area per hour was obtained with a natural draft of 0.44 in. in the furnace. With a blast of 1.03 in. and a draft in the furnace of 0.03 in., with the same stoker and coal, 58.3 lb. were burned per sq. ft. of projected grate area per hour.

(3) In a test of a Babcock & Wilcox marine-type boiler burning Pocahontas hand-picked coal, with an ash-pit blast of 3 in., a combustion rate of 69.72 lb. of dry coal, or 70.24 lb. of coal as fired, per sq. ft. of grate surface per hour was obtained.

GENERAL DESIGN

Heat Transfer in Steam Boilers

Experimental determinations have been made in recent years of the heat transfer rate in cylindrical tubes at comparatively low temperatures and small temperature differences, and Nusselt (*Z. V. D. I.*, 1908, p. 1750), from a study of his own work as well as that of others, has derived the empirical formula:

$$a = 0.0255 \frac{L_w}{d^{0.214}}\left(\frac{Wc_p}{AL}\right)^{0.786}$$

in which a = transfer rate in B.t.u. per hour per sq. ft. of surface per deg. fahr. difference in temperature; W = lb. of gas flowing through tube per hour; A = cross-sectional area of tube, sq. ft.; d = diam. of tube, ft.; c_p = specific heat of the gas at constant pressure; L = conductivity of the gas at the mean temperature and pressure in B.t.u. per hour per sq. ft. of surface per deg. fahr. drop in temperature per ft., and L_w = conductivity of the steam at the temperature of the wall of the tube. Values of L are: for air, 0.0122 (1 + 0.00132 T); CO_2, 0.0076 (1 + 0.00229 T); superheated steam, 0.0119 (1 + 0.00261 T), where T = temperature in deg. fahr. See also p. 301.

When a fluid is flowing through a pipe at low velocities the loss of head is directly proportional to the velocity and the fluid flows in straight stream lines. When, however, the velocity exceeds a value which is determinable for any size of tube, the direct or stream-line motion is replaced by an eddy or mixing flow, in which the loss of head by friction is approximately proportional to the square of the velocity. Croker and Clement (*Proc. Roy. Soc.*, vol. 71) have shown that the heat transferred during the mixing flow is at a much higher rate than with direct or stream-line flow. Nusselt's formula applies only to mixing flow, *i.e.*, above the critical velocity. Below the critical velocity the transfer rate seems to be little affected by change in velocity, and he concludes that, while it is approximately constant as regards the velocity in a straight cylindrical tube, it will vary from point to point of the tube, growing less as the surface passed over increases.

A large proportion of the heat absorbed by a boiler is received direct as radiation from the furnace. The lower row of tubes of a Babcock & Wilcox boiler absorb heat at an average rate per sq. ft. of surface between the first baffle and the front headers equivalent to the evaporation of from 50 to 75 lb. of water from and at 212 deg. fahr. per hour. Part of this heat is absorbed through actual contact between the hot gases and the tubes, but a large portion of it must have been received through radiation.

The average heat transfer rate, R (B.t.u. per sq. ft. per hour), in Babcock & Wilcox boilers with ordinary clean surfaces can be determined to a fairly close approximation from the formula $R = 2 + 0.0014\ (W/A)$, in which A is the average area in sq. ft. between all the passes of the boiler, and W is the total weight of gases passing per hour.

The relation between the boiler heating surface, the capacity being developed and the flue-gas temperatures for normal conditions of boiler operation is shown in the following table, which represents the average result of a large number of tests:

Boiler surface per boiler horse power developed, sq. ft....	4.0	6.0	8.0	10.0	12.0	14.0	16.0	18.0	20.0
Flue gas temp., deg. fahr.....	660	570	510	470	440	420	405	395	390

Proportioning of Gas Passages in Steam Boilers

Experience has shown that an area of 10 sq. in. per nominal rated h.p. at the point where the gases leave the boiler furnace to enter the heating surface will give satisfactory results. In water-tube boilers this applies not only to the throat of the furnace, but also to the net area between tubes at the point where the gases enter the heating surfaces. This area has been found sufficient to allow for present-day overloads, without undue throttling action at this point. Assuming that for any given set of furnace conditions the best results are to be secured with a constant resistance to the gases throughout the heating surface, the cross-sectional area of passage per h.p. for varying amounts of heating surface passed over will be approximately as follows:

Heating surface passed over, in per cent	0	20	40	60	80	100
Gas-passage area per h.p., in sq. in	10	8.4	6.8	6.2	5.8	5.7

From the nature of their design, it is impossible to get with cylindrical or return-tubular boilers a variation in gas-passage areas that will at all correspond to these figures. Water-tube boilers lend themselves more readily to such a variation in gas-passage areas, and in the modern designs will be found to approximate these figures closely.

Superheaters

Superheaters are of two general classes, those integral with the boiler and those separately fired. The first type is the more common and is more efficient. The efficiency of a boiler and furnace containing a properly designed integral superheater will be slightly higher than of a boiler in which there is no superheater installed.

In the design of integral superheaters, the following features are to be observed:

The superheater should be so located that it will be in the direct path of the products of combustion and that no by-passing of any portion of these gases is necessary to divert them from their regular path over the boiler heating surface in order to give the required superheat. At the same time it should be so placed that the frictional resistance of the gases through the boiler is not unduly increased. Superheaters should be so designed that they are free to expand without affecting the boiler parts or the setting. The location should be such that there is no possibility of the superheater tubes burning when the boiler is started up, and that there will be no excessive or sudden fluctuation of temperature with fluctuating loads. All superheaters should be equipped with independent safety valves of the outside spring type, set slightly lower than the boiler safety valves. This is essential to provide a flow of steam through the superheater and thus prevent burning in case the load should suddenly be thrown off the boiler or plant. The superheater should be equipped with a drain for drawing off, before starting up, any water that may have collected in the superheater headers or manifolds. The area for steam passage and steam connections should be such that there will be no possibility of the steam by-passing any of the tubes; that is, the cross-sectional area of the tubes must be such, in relation to the area of the manifolds or headers, and the steam connection must be such, that approximately the same quantity of steam will pass through all the tubes. Any tubes that may be by-passed are in danger of burning. The velocity of steam through superheaters may be figured slightly higher than is good practice in designing boiler-room piping, provided this does not result in too great a drop of pressure through friction.

In properly designed and located integral superheaters, while the heat transfer rate will vary widely with the ratings at which a boiler is run and operating conditions in general, under ordinarily good conditions, with a boiler delivering approximately its rated capacity, a transfer rate of about 1500 B.t.u. per sq. ft. of heating surface per hour may be expected.

Separately Fired Superheaters. In some instances where it is desired to use superheated steam in a plant already in operation, or where the prime movers are a long distance from the steam generators, the best solution of the problem may be the installation of a separately fired superheater on the main steam line. In certain special processes temperatures are required that it is not feasible to attempt with the integral type, and here only separately fired superheaters can fill the requirements.

There is danger in the separately fired type that too high superheat may be obtained by reason of the temporary checking of the demand for steam, and the fires must be watched carefully to avoid such danger. These superheaters should also be equipped with safety valves set below the boiler safety valves. The best economy is obtained where the counterflow principle of steam and gas flow is used, having the gas make three or four passes over the superheating surfaces. In some designs the steam is first brought to the hottest section of the setting, as a measure to guard against burning of tubes, and from this section is passed to the coldest part of the setting and thence forward toward the hottest part. In a properly designed, separately fired superheater an efficiency of from 55 to 60 per cent. may be secured, and in figuring surface a heat transfer rate of 2500 B.t.u. per sq. ft. of superheating surface per hour may be safely assumed.

The velocity of the steam in passing through a superheater should be from 30 to 50 ft. per sec. The temperature loss of superheated steam in steam mains varies from 30 to 60 deg. fahr. per 100-ft. length, according to the kind of lagging used.

Waste Heat

The power that can be obtained by utilizing the waste heat from certain commercial processes depends upon the temperature, specific heat and weight of the gases. The temperatures vary over a wide range in the different commercial operations. Table 13 gives a list of certain of these operations yielding waste heat available for the generation of steam and the approximate temperatures of the waste gases.

Table 13. Temperatures of Waste Gases from Various Industries

Waste heat from	Temperatures, deg. fahr.*
Brick kilns	2000–2300
Zinc furnaces	2000–2300
Copper matte reverberatory furnaces	2000–2200
Bee-hive coke ovens	1800–2000
Cement kilns	1200–1600†
Nickel refining furnaces	1500–1750
Open-hearth steel furnaces	1100–1400

* Temperatures are average over one cycle or operation, and may vary widely as to maximum and minimum. † Dependent upon length of kiln.

Where the temperatures of the waste gases are high, approaching those found in direct-firing boiler practice, boilers modified but little from standard may be used. As the temperatures are lower the velocity of the gases must be increased in order to secure a heat-transfer rate at all comparable with those found in direct-firing practice. Sufficient draft must be provided to overcome the frictional loss in drawing the waste gases through the boiler.

Table 14, of tests on waste-heat boilers, gives the relations between the temperatures, draft resistance, and horse power developed.

Table 14. Results Obtained with Waste Heat from Commercial Processes

	Bee-hive coke ovens	Reverberatory copper furnaces	Nickel refining furnaces
Type of boiler	Stirling	Stirling	Rust
Heating surface, sq. ft	8416*	3560	3927
Temperature of entering gases, deg. fahr	1804	1728	1700
Temperature of exit gases, deg. fahr	490	733	612
Draft at boiler entrance, in	0.36	0.35	0.33
Draft at boiler exit, in	0.56	0.60	0.50
H.p. developed	824	241.3	263
Sq. ft. of heating surface per h.p	10.2	14.8	14.9

* Two boilers.

The following table shows the relation between gas temperatures, heating surface passed over, and the amount of work done by such surfaces in generating steam for a boiler in which the velocity of gases is that usual in direct-fired boilers and the entering gas temperature is assumed to be 2500 deg., the exit gas temperature 500 deg., and the unit of heating surface per h.p. assumed to be 10 sq. ft.

Evaporation in Waste-heat Boilers

Temperature of hot gases, deg. fahr....	2000	1500	1200	1000	900	800	700	650	600	550
Water heating surface passed over by the gases, per cent......	8	18.5	27.5	37	43	50.5	60	66	73.2	82.5
Per cent. of the total steam generated in the boiler..........	25	49	64	75	80	83	90	92	94	96

This table has been shown by experiment to be very nearly correct for boilers not absorbing heat by direct radiation from a fire, and for this reason is applicable in waste-heat work. From this table it is possible to determine the approximate heating surface required per h.p. for any other entering and exit gas temperatures, provided the boilers are baffled about as they would be for direct-fired practice. Decreasing or increasing the velocity of the gases over the heating surfaces, *i.e.*, decreasing or increasing the frictional resistance through the boiler, will increase or decrease the heating surface necessary. This method is best illustrated by example.

Assume the entering gas temperatures to be 1470 deg. and that the gases are cooled to 570 deg. From the table, under what are assumed to be standard conditions, the gases have passed over 19 per cent. of the heating surface by the time they have been cooled 1470 deg. When cooled to 570 deg., 78 per cent. of the heating surface has been passed over. The work done in relation to the standard of the table is represented by $(1470-570)/(2500-500) = 45$ per cent. (These figures may also be read from the table in terms of the per cent. of the work done by different parts of the heating surfaces.) That is, 78 per cent. $-$ 19 per cent. $=$ 59 per cent. of the standard heating surface has done 45 per cent. of the standard amount of work. $59/45 = 1.31$, which is the ratio of surface of the assumed case to the standard case of the table. Expressed differently, there will be required 13.1 sq. ft. of heating surface in the assumed case to develop 1 h.p., as against 10 sq. ft. in the standard case.

Practically all waste gases contain much dust, and provision should be made for removing deposits from the heating surfaces. In some instances, as in the case of waste-heat boilers set in connection with cement kilns, dust-precipitating chambers should be provided between the kilns and the boiler proper.

When the operation of the furnace is intermittent, or the gas supply varies in quantity and temperature at different stages of the process, auxiliary coal grates may be supplied to insure a constant steam output from the boiler. No deleterious action on the heating surfaces of the boilers installed has been observed to result from sulphur fumes or other constituents of certain waste gases.

BOILER FEED WATERS AND ECONOMIZERS

REFERENCES: W. H. Booth, "Water Softening and Treatment." W. W. Christie, "Water, Its Purification and Use."

Where water of sufficient purity is not available for the purposes of feed, it is usually found necessary to render suitable the supply which must be used by some method of treatment. Against the cost of any such treatment there is to be placed the interest and depreciation on the increased number of boilers necessary where there is a tendency for the boilers to become scaled; the losses due to the cost of taking off boilers for cleaning; and the decrease in efficiency and capacity accompanying an increased incrustation of the boilers in use.

Troubles arising from the use of poor feed water may be classified as foaming, priming, formation of scale and corrosion.

Impurities in Feed Water. The following table gives an approximate classification of the impurities found in boiler-feed water, the difficulties arising from their presence, and the means ordinarily adopted for the treatment of the water to overcome such effects.

Approximate Classification of Impurities Found in Feed Waters, Their Effect and Ordinary Methods of Relief

Impurity	Nature of Difficulty	Ordinary Method of Overcoming or Relieving
Sediment, mud, etc.	Incrustation	Settling tanks, filtration, blowing down.
Readily soluble salts	Incrustation	Blowing down.
Bicarbonates of lime, magnesia, etc.	Incrustation	Heating feed. Treatment by addition of lime or of lime and soda. Barium carbonate.
Sulphate of lime	Incrustation	Treatment by addition of soda. Barium carbonate.
Chloride and sulphate of magnesium.	Corrosion	Treatment by addition of carbonate of soda.
Acid	Corrosion	Alkali.
Dissolved carbonic acid and oxygen.	Corrosion	Heating feed. Keeping air from feed. Addition of caustic soda or slacked lime.
Grease	Corrosion	Filter. Iron alum as coagulant. Neutralization by carbonate of soda. Use of best hydrocarbon oils.
Organic matter	Corrosion	Filter. Use of coagulant.
Organic matter (sewage)	Priming	Settling tanks. Filter in connection with coagulant.
Carbonate of soda in large quantities.	Priming	Barium carbonate. New feed supply. If from treatment, change.

Foaming is likely to occur in waters contaminated with sewage or organic growths, due to the fact that the suspended particles collect on the surface of the water in the boiler and render difficult the liberation of the steam bubbles arising to that surface. It is sometimes due to the light, flocculent precipitates from carbonates in solution, and in certain cases where any animal or vegetable oil is present to the fact that there is an excess of sodium carbonate added to the water during treatment.

Priming is the passing off of steam in belches which carry over water; it is caused by the concentration of sodium carbonate, sodium sulphate, or sodium chloride in solution. Sodium sulphate occurs in many southern waters and is also found where calcium or magnesium sulphate is precipitated with soda ash. The degree of concentration that may occur before priming will commence varies widely with conditions of operation and may be definitely determined only by experience with individual cases.

Scale is formed on boiler heating surfaces by the depositing of impurities in the feed water in the form of a more or less hard, adherent crust. Such deposits are due to the fact that the water loses its soluble power at high temperatures, or, through evaporation, the concentration becomes so high that the impurities crystallize and adhere to the surfaces. The salts usually responsible for this incrustation are the carbonates and sulphates of lime and magnesia.

The most widely known evidence of the presence of scale-forming ingredients in feed water is what is known as hardness. **Temporary hardness** is due to the presence of the carbonates of lime and magnesium which may be precipitated by boiling at 212 deg. fahr., and water containing no other scale-forming elements than these becomes "soft" under such treatment. **Permanent hardness** is due mainly to the presence of sulphate of lime, which is precipitated only at temperatures above 300 deg. fahr. Boiler-feed treatment consists in the main of getting rid of these salts more or less completely.

Scale is also formed by the settling of sediment and mud carried in suspension, which may bake or be cemented to a hard scale when mixed with other scale-forming ingredients.

Scale may have various characteristics. The sulphates of lime form the hardest, most flint-like scale. The scale formed from the carbonates of lime is somewhat softer. Sulphate of magnesia, when present alone, does not form a hard scale, but when carbonate of lime is present a chemical reaction takes place, forming hydrate of magnesia and calcium sulphate, which forms a particularly hard and stony scale. Carbonate of magnesia when present often separates out as a floury precipitate which floats for a time on the surface of the water or may be carried off in priming water. Its presence is particularly dangerous if the water contains grease, as it will combine with such grease to form a peculiar spongy scale that is less conductive of heat than a solid, stone-like scale. Such a spongy scale forming on heating surface directly exposed to the fire may lead to disastrous results.

Treatment of Water

Foaming. Where this is caused by organic matter in suspension, it may be largely overcome by filtration. Such matter as is not left in the filter may usually be taken care of by surface blowing. In some instances settling tanks are used to overcome this difficulty, but where large quantities of water must be provided, filtration is used as a substitute for the time and area necessary in settling tanks. When caused by overtreatment of feed water, such treatment should, of course, be changed.

Priming. Where this is caused by excessive concentration, it may be overcome largely by frequent blowing down of the boilers. Where the salts in the boiler feed exist in such quantities that to blow down sufficiently to keep the concentration below the priming point is not feasible because of the resultant losses, it may be overcome by some process of feed treatment.

Scale Prevention. The treatment of waters carrying scale-forming ingredients is along two main lines: (1) By chemical means, and (2) by means of heat.

Chemical Methods. (1) Lime Process. This process is used where waters contain bicarbonates of lime and magnesia. Slaked lime in solution (as lime water) is used, combining with the carbonic acid which is present either free or as carbonates, to form an insoluble monocarbonate of lime, the soluble bicarbonates of lime and magnesia losing their carbonic acid but thereby becoming insoluble and precipitating.

(2) Soda Process. This process is used for waters containing sulphate of lime and magnesia. Carbonate of soda and hydrate of soda (caustic soda) are used either alone or together as reagents. Carbonate of soda added to water containing a little (or no) carbonic acid or bicarbonates, decomposes the sulphates to form insoluble carbonates of lime and magnesia, which precipitate, the neutral soda remaining in solution. If free carbonic acid or

bicarbonates are present, bicarbonate of lime is formed and remains in solution, though under the action of heat the carbon dioxide will be driven off and insoluble monocarbonates will be formed. Caustic soda used in this process causes a more energetic action.

(3) Lime and Soda Process. This method, which is a combination of (1) and (2), is by far the most general in water purification, and is used where water contains sulphates of lime and magnesia and carbonic acid or bicarbonates in such quantities as to impair the action of soda. Sufficient soda is added to decompose the sulphates of lime and magnesia, with as much lime as is required to absorb all the carbonic acid not taken up by the soda reaction.

All apparatus for effecting this treatment is approximately the same in its chemical action, the different systems varying in the mechanical methods of introducing and handling the reagents. In an apparatus of this description water is ordinarily tested for hardness, alkalinity and causticity. The **scale of hardness** usually accepted (grains of dissolved salts per gal.) is as follows: Soft water, 1 to 10; moderately hard water, 10 to 20; very hard water, above 25. (One grain per U. S. gal. = 1.714 parts per 100,000.)

Alkalinity is a general term used for the presence of compounds having the power to neutralize acids. **Causticity**, as used in water treatment, is a term to indicate the presence of an excess of lime added during treatment. Though such presence would also indicate alkalinity, the term is arbitrarily used to apply to those hydrates whose presence is indicated by phenolphthalein.

When properly treated, the alkalinity, hardness and causticity should be in the approximate relation of 6, 5 and 4. When too much lime is used in the treatment, the causticity will be high in the purified water, nearly equaling the alkalinity. If too little lime is used, the causticity falls to approximately half the alkalinity. The hardness should not be in excess of two points less than the alkalinity. Where too much soda is used, the hardness is lowered and the alkalinity raised. If too little, the hardness is raised and the alkalinity lowered.

Other Reagents. Barium carbonate is sometimes used in removing calcium sulphate, the products of the reaction being barium sulphate and lime carbonate, both of which are insoluble. It is in itself an insoluble salt and cannot be added as a solution. It is a most satisfactory reagent for use in settling tanks, though until recently its price has made its use prohibitive. Barium hydrate is also used to reduce permanent hardness or the calcium sulphate component. It sets free any lime hydrate, which will reduce any lime carbonate present to insolubility. Where both carbonate and sulphate of lime are present, both barium hydrate and carbonate must be used. Silicate of soda will precipitate lime carbonate with the formation of a gelatinous silicate of lime and carbonate of soda. If sulphate of lime is present, carbonate of soda is formed in the above reaction, which will decompose the sulphate as well. Oxalate of soda is an expensive, but efficient, reagent which forms a precipitate of calcium oxalate of a particularly insoluble nature. Alum and iron alum will act as coagulants in waters where there is organic matter present. Iron alum has not only this property, but also that of reducing oil from water discharged from surface condensers to a condition in which it can be removed by filtration.

Testing Water as Treated by the Lime and Soda Process

A standard solution of sulphuric acid is used in testing for alkalinity and causticity. A soap solution is used in testing for hardness. A silver nitrate solution may also be used to determine whether an excess of lime has been used in the treatment.

Alkalinity. To 50 cu. cm. of treated water, to which sufficient methylorange has been added to color it, add the acid solution drop by drop until the mixture is just on the point of showing red. This point can be determined by shaking the mixture. As the acid solution is first added the red color quickly disappears, and more slowly as the critical point is reached. One-tenth cu. cm. of the standard acid solution corresponds to 1 deg. of alkalinity.

Causticity. To 50 cu. cm. of treated water to which one drop of phenol, dissolved in alcohol, has been added (resulting in a pinkish color), add the acid solution drop by drop, shaking until all color disappears. One-tenth cu. cm. of acid solution corresponds to one unit of causticity.

The alkalinity may be determined from the same sample after the causticity by coloring with methylorange and adding the acid to the point where the solution turns red. The *total* acid added (in determining both causticity and alkalinity) is the indication of the alkalinity.

Hardness. 100 cu. cm. of water are used for this test 1 cu. cm. of soap solution corresponds to 1 deg. of hardness. The soap solution is added a small quantity at a time to the sample, and the whole violently shaken. Enough must be added to make a permanent lather or foam, that is, when the shaking is stopped the soap bubbles should not disappear.

Nitrate of Silver Test for Excess of Lime. If there is an excess of lime in the water, the addition of silver nitrate will cause the sample to become dark brown. Otherwise a milky white solution will be formed.

Effects of Scale on Efficiency. Many tests have been made to indicate the loss in boiler efficiency due to the presence of scale. Some such tests would indicate that a scale ⅛ in. in thickness will decrease efficiency as much as 20 per cent., but, unfortunately, the figures that have been published are not to be implicitly relied upon. This is due largely to difference in conditions between tests with clean boilers and those in which scale has been allowed to accumulate, but to a greater extent to the impossibility of knowing the thickness of scale that has formed over *all* the heating surfaces.

The rate of such a falling off of efficiency as the thickness of scale increases will depend upon the nature of the scale formed. The effect of a very thin coat of scale on the heating surfaces of a boiler would probably be imperceptible in the efficiency of a boiler.

Allowable Degree of Concentration. The allowable concentration of salts in the water in a boiler depends on the operating conditions; in some instances trouble will be experienced with a concentration as low as 30 gr. per gal., while in others 300 gr. can be handled without priming. A trace of oil or the presence of a small amount of organic matter will cause priming with waters which would otherwise give no trouble.

Where the soluble salts are mainly sodium chloride, if the degree of concentration is kept below 150 to 175 gr. per gal., no priming difficulty should be experienced. In a test for the amount of sodium chloride concentration possible before priming would start, 330 gr. per gal. were handled with no priming, the steam showing 0.5 per cent. of moisture. With the concentration increased to 400 gr. per gal., priming was practically continuous.

Where the soluble salts are mainly sodium carbonate, the permissible degree of concentration may be increased. With a boiler properly operated at moderate loads, this concentration, if kept below 300 gr. per gal., should cause no difficulties from priming. In a test with a particularly bad water, containing salts which were mainly sodium carbonate, there was no priming with a concentration of 440 gr. per gal., the steam showing 1 25 per cent. of moisture. With a concentration of 560 gr. per gal., there was no priming, but the moisture content was increased to 2 per cent. With the idea of indicating the maximum concentration possible, special arrangements were made in the manner of drawing off steam and the concentration increased to over 1500 gr. per gal. without any priming action. Any such degree of concentration, however, is decidedly inadvisable.

The limiting factor in deciding whether a water carrying a large amount of soluble salts may be used for boiler feed purposes, is the amount of blowing down necessary to keep the degree of concentration within the limits shown by experience to be necessary.

Allowable Degree of Concentration in Treated Water. Where boiler feed water is treated with soda ash, experience has shown that there are certain limits of concentration of this chemical, above or below which difficulties will be encountered. Ordinarily, these limits are between 25 and 70 gr. of soda per gal., with the best results secured where they are between 30 and 40 gr.

The usual method employed in keeping between such limits of concentration, when the treated water is fed to all boilers of a plant, is to titrate the water from each boiler once a week to determine the amount of soda contained. Where this falls below the lower limit an additional amount of the saturated solution of soda is introduced by a hand pump. If the amount of soda is above the upper limit, the boiler is blown down sufficiently to reduce the soda to the proper amount.

Purification Plants. The approximate cost of a water purification plant will be between $500 and $750 per 1000 gal. treated per hour, the smaller plants costing more per unit of capacity than the larger. The space occupied by some typical apparatus of this nature is given in Table 15.

Table 15. Floor Space Required by Water Purification Apparatus

System	Capacity, Gal. per Hour			
	2,000	5,000	10,000	20,000
L. M. Booth Co.	7′ 9″ diam.	12′ 3″×19′10′	17′ 6″×26′ 2″	24′ 6″×35′ 7″
The Kennicott Co.	9′ diam.	13′ 6″ diam.	18′ diam.	24′ diam.
Wm. B. Scaife Co. (Intermittent.)	24′×15′	42′×18′	57′×23′	80′×30′
Wm. B. Scaife Co. (Continuous.)	25′×15′ 6″	25′×15′ 6″	30′ 6″×20′	48′× 25′

Heights of Apparatus, Ft.: 2000 gal.—Booth, 26½; Kennicott, 16½. 5,000 gal.—Booth, 26⅙; Kennicott, 20. 10,000–20,000 gal.—Booth, 27⅙; Kennicott, 23.

Time for reaction is approximate and variable, depending upon the water treated. With the Booth system it is claimed that the time (3½ to 4 hr.) is shortened through mechanical agitation. The Kennicott Co. states that the time will vary with the temperature of water treated, from 4 hr. at 50 deg. fahr. to as low as 1 hr. at 200 deg. fahr.

Table 16 gives a means of computing the cost of treatment of feed water by a typical "lime and soda" apparatus. It is based on using lime containing 90 per cent. of calcium oxide and soda ash containing 58 per cent. of sodium oxide, the amounts of these reagents required for each grain per gal. of various impurities found being given in lb. per 1000 gal. From local prices of the reagents the costs of purification may be readily computed. Lime ordinarily costs about $0.50 per 100 lb., while soda ash costs about $1 per 100 lb.

When treated by the lime and soda process, water containing less than 20 gr. of scale-forming matter will ordinarily, after treatment, contain less than 3 gr. Water containing 20 to 30 gr. will be reduced to 4 gr.; 30 to 40 gr. reduced to 5 gr., and 40 to 50 gr. reduced to approximately 6 gr. In general, only waters containing over 5½ gr. per gal. will deposit scale.

Boiler Compounds are almost invariably based on soda, with certain tannic substances, and in some instances a gelatinous substance which is presumed to encircle the scale particles and prevent their adhering to the boiler surfaces. The action of such compounds is usually to reduce the lime sulphate by means of carbonate of soda and to precipitate it as a muddy form of carbonate of lime, which may be blown off. The object of using the tannic compounds with soda is to introduce organic matter into scale already formed, so that when it has penetrated to the surface of the metal, below the scale, decomposition will set up, causing a disruptive effect which uplifts scale, sometimes in large slabs. The latter effect should be guarded against in the use of compounds, or trouble will arise due to the presence of loose scale and the consequent danger of burning the boiler tubes. See p. 557 for effects of compounds or corrosion.

Table 16. Reagents Required in Lime and Soda Process for Treating 1000 U. S. Gal. of Water per Grain of Contained Impurities per Gal.*

	Lime†	Soda‡		Lime	Soda
Calcium carbonate	0.098 lb.	....	Ferrous carbonate	0.169 lb.	....
Calcium sulphate	....	0.124 lb.	Ferrous sulphate	0.070	0.101 lb.
Calcium chloride	....	0.151	Ferric sulphate	0.074	0.126
Calcium nitrate	....	0.104	Aluminum sulphate	0.087	0.147
Magnesium carbonate	0.234	....	Free sulphuric acid	0.100	0.171
Magnesium sulphate	0.079	0.141	Sodium carbonate	0.093	....
Magnesium chloride	0.103	0.177	Free carbon dioxide	0.223	....
Magnesium nitrate	0.067	0.115	Hydrogen sulphide	0.288	....

* L. M. Booth Co. † Based on lime containing 90 per cent. calcium oxide.
‡ Based on soda containing 58 per cent. sodium oxide.

When proper care is taken to suit the compound to the water used, it may be fairly effective. Compounds should be used, however, to prevent the formation of scale rather than to remove scale already formed. The cost of compounds is usually high as compared with the actual amount of active material they contain.

Oil as a Scale Preventive. The introduction of crude oil or kerosene into a boiler has from time to time been used as a means of preventing scale formation on the heating surfaces, but this use of kerosene or of crude oil is not to be recommended. While cases may arise in which boiler waters can be effectively treated within the boiler itself, oil is not the reagent to be used. The distilling off of the lighter oils finally leaves a heavy, gum-like carbonaceous deposit on the heating surfaces, which will tend to cause a burning out of the affected parts. Further, such oils may contain materials which will saponify where the feed is sufficiently alkaline, and severe foaming will result.

Economizer Practice

The **efficiency due to an economizer installation** will increase as the temperature of the gases entering the economizer increases, as the velocity of the gases through the economizer for a given weight of gas handled per hour increases, as the temperature of the water entering the economizer decreases, and as more heating surface is supplied in the economizer. The heating surface that can best be installed is limited by the expense warranted and the added draft resistance of the larger economizer.

The **heat transfer rate** to be expected **through economizers** will vary somewhat with the difference between the mean temperatures of the gases and the water. Under ordinary conditions, with a gas velocity through the economizer of approximately 1000 ft. per min., a heat transfer of from 2.25 to 3 B.t.u. per hour per sq. ft. of surface per deg. fahr. of difference in temperature may be expected. With the velocity of gas increased to about 1800 ft., this transfer rate will be approximately 3 B.t.u.

Where boilers are run at slightly above their rated capacity, the efficiency with an economizer having approximately 60 per cent. of the boiler heating surface will be increased approximately 6 per cent. With boilers run at about their rated capacity, with exit gas temperatures of approximately 500 deg. and gas velocities such as the present design of economizer ordinarily gives, the added efficiency will be in the neighborhood of 5 per cent. With economical boilers run at 200 per cent. of their rated capacity, with exit gas temperatures somewhat above 600 deg. and a gas velocity of about 1800 to 2000 ft. per min., with economizers containing approximately 70 per cent. of the boiler heating surface this increase will approach 10 per cent. and with uneconomical boilers may be still greater.

The saving in B.t.u. per year of continuous operation for various amounts of economizer surface per boiler h.p. and for each 100 deg. difference in temperature between the entering flue-gas temperatures and the entering boiler-feed temperature is shown in the following table which represents the average of results obtained in 200 plants. For shorter periods of operation the saving is decreased proportionately; the saving varies also as the temperature difference.

Economizer surface, sq. ft. per 100 deg. fahr. difference per boiler h.p.	0.5	1.0	1.5	2.0	2.5	3.0	3.5	4.0
Millions of B.t.u. saved per sq. ft. per year	11.1	6.7	4.6	3.6	2.9	2.5	2.2	1.9

The installation of economizers generally necessitates the use of an induced-draft fan. For the ordinary arrangement of sections, the draft loss may be considered as about 0.15 to 0.2 in. of water with boilers operated at 200 per cent. of their rated capacity.

Materials of Economizer Construction. Cast iron is ordinarily used in economizer construction to obviate danger of corrosion. Wrought-iron and steel tubes have been used and are being used in European practice, and while some economizers with wrought-iron tubes appear to have stood up well, others have failed through corrosion in a comparatively short time. Much depends upon the nature of the feed water, and, in certain instances, economizers with wrought-iron tubes which have stood up for a time have afterward failed rapidly when the amount of make-up water at the plant was so reduced that the water fed through the economizer was purer than before. Air in the water appears to have important influence. Corrosion occurring in such apparatus may be external or internal, though the former, which comes through condensing vapor from the gases on the colder economizer surfaces, is unlikely where the water fed to the economizer is at a higher temperature than 120 deg. fahr.

Practice in this country in removing dust from the outside of economizer tubes has been largely limited to the use of scrapers. European practice has shown that such removal can be done in a satisfactory manner through the use of compressed air.

The average cost of economizers installed is about $1.20 per sq. ft. of surface.

BOILER-SETTING BRICKWORK, GASKETS, ETC.

Red Brick should be used in boiler settings only where it is protected from heat, and should be of the best grade, sound, hard, well-burned and uniform. For properties of bricks, see p. 622.

Fire Brick. The quality of fire brick is ordinarily judged by the following features:

Plasticity: The tendency of a brick to become plastic, at a temperature much below the melting point, and to a degree that may cause the brick to become deformed under the stress to which it is subjected. This is now considered the determining factor in considering the suitability of fire brick. To enable a brick to be used with any degree of satisfaction, the plastic point should be above 2400 deg. fahr. under a unit stress of 100 lb. per sq. in.

Fusing Point: The temperature at which the brick will fuse. Important only in that a high fusing point ordinarily indicates a high critical temperature of plasticity.

Expansion. The lineal expansion will vary from 0.009 in. to 0.08 in. in 9 in. Within these limits, the expansion of the brick is not an important factor in a properly designed furnace.

Compression. The strength necessary to cause crushing at the center of the 4½-in. face by a steel block 1 in. square.

Hardness: Relative, usually figured on an arbitrary scale of 10.

Size of Nodules: The average size of flint grains when a brick is carefully crushed. The scale of nodules is: Small, or the size of anthracite rice; large, or the size of anthracite pea.

Ratio of Nodules: Percentage of a given volume occupied by flint grains. This scale is ordinarily: High, 90 to 100 per cent.; medium, 50 to 90 per cent.; low, 10 to 50 per cent.

See Technologic Papers Nos. 7 and 10 of the U. S. Bureau of Standards, entitled "The Testing of Fire-Clay Refractories," and "Melting Points of Fire Bricks."

The values of fire brick are necessarily relative, but, generally **speaking**, what are known as **first-grade fire brick** may be divided into **three classes** suitable for various operating conditions as follows:

Class A: For stoker-fired furnaces where high overloads are to be expected, or where other extreme conditions of service are liable to occur.

Class B: For ordinary stoker settings where there will be no excessive overloading of the boiler, or in hand-fired settings where the rates of driving will be high.

Class C: For ordinary hand-fired settings where the presumption is that the boilers will not be overloaded, except at rare intervals and for short periods only.

The characteristics of these three classes are given in Table 17.

Table 17. Characteristics of First-grade Fire Brick

Characteristics	Class A	Class B	Class C
Fuse point, deg. fahr.	Safe at 3,200 to 3,300 deg.	Safe at 2,900 to 3,200 deg.	Safe at 2,900 to 3,000 deg.
Compression, lb.....	6,500 to 7,500	7,500 to 11,000	8,500 to 15,000
Hardness, relative...	1 to 2	2 to 4	4 to 6
Size of nodules......	Medium	Medium to medium-large	Medium to large
Ratio of nodules.....	High	Medium to high	Medium low to medium

Many fire brick are sold for No. 1 grade that are in reality No. 2. The characteristics of such fire brick are: Fuse point, 2400 to 2700 deg. fahr.; hardness, 6 to 10; compression, 14,200 to 32,000 lb.; size of nodules, small to very small: ratio of nodules, low to very low. It will be seen that as the brick is poorer it is harder, but it is recognized that if a brick be of sufficient hardness to withstand its load, any additional hardness is a detriment rather than an advantage.

A rough indication of the **quality of a fire brick** is afforded by the appearance of a **fracture**. A fine, uniform texture, like bread, shows a poor brick. If the fracture is open, clean. white and flinty, the brick is probably good. The best fire brick are manufactured from Pennsylvania fire clays. South and west from Pennsylvania the quality of fire clay in general becomes poorer as the distance increases. Some of the southern fire clays contain a considerable amount of metallic iron.

Red brick should be laid in a thoroughly mixed mortar, composed of 1 volume of Portland cement, 3 volumes of unslaked lime, and 16 volumes of clean sharp sand. Not less than 2¼ bushels of lime should be used in laying 1000 brick. Every brick should be thoroughly imbedded and each joint filled.

All fire brick should be protected from moisture, and should be dry when used. Each brick should be dipped in a thin clay wash, "rubbed and shoved" into place, and tapped with a wooden mallet until it touches the brick next below it. Fire clay is not a cement, and has little or no holding power. Its action is not that of a binder, but of a filler, and a consistency in fire-clay wash sufficient to permit the use of a trowel should not be allowed.

Walls of red and fire brick should be carried up together. Furnace linings should be laid with four courses of headers and one stretcher. Furnace center walls should be entirely of fire brick.

Fire-brick arches should be constructed of selected brick that are smooth, straight and uniform. Arch centers or frames should be built of batten strips not more than 2 in. in width. Brick should be dipped on one side and two edges only, and tapped into place with a mallet. They should be laid in courses along the arch center and not in rings, and each joint should be broken with a bond equal to half a brick. Each course should be tried in place dry, and checked with a straight edge to insure a uniform thickness of joint between courses. A course of wedge brick should be used only where necessary to keep the bottom of the straight brick in even contact with the arch center, and where it is impossible to obtain such contact by the use of wedges, the straight brick should lean away from the center line of the furnace, rather than toward it. When an arch is about two-thirds completed, a trial ring should be laid to determine if the key course will fit. Where cutting is necessary to fit the keying course, it should be done on the two adjacent courses on the side of the brick away from the key. The keying course should be a true fit from top to bottom, and after being dipped and driven it should not extend below the surface of the arch; preferably, it should extend about ¼ in. above the surface. After fitting, the keys should be dipped, replaced loosely, and then driven uniformly into place by a heavy hammer and a piece of wood extended along the full width of the keying course. Arch centers should be so constructed that they can be dropped down free of the arch after it is keyed, and removed from the setting without being burned out.

Care of Boiler Brickwork. To avoid cracking it is essential that the setting be dried out thoroughly before a boiler is placed in service. As a preliminary drying process, the boiler damper and ash pit doors should be blocked open and a circulation of air maintained through the setting for two or three days. When it is desired to place the boiler in service, a light wood fire should be started and this fire built up very gradually until the walls are thoroughly warm, at which time coal may be fired and steam raised.

Cracks in the setting cause deterioration in addition to a decrease in efficiency. Soot will fill up such crevices, become packed tight and will have a tendency to loosen the brickwork. Cracks about cleaning-door frames should be at once filled and the whole setting kept pointed up. Any leakage of steam or water within a setting will cause the latter to disintegrate rapidly. The draft suction available has also a direct bearing upon the life of a setting. In installations where furnace temperatures are high, if there is not sufficient draft, the hot gases will tend to percolate outward through the brickwork, and the temperature of the furnace walls may rise above the fusing point of the brick. Such temperatures are often found in stoker-fired and oil installations, and care should be taken to see that there is no back pressure at any point within the boiler setting, or what is often referred to as a "bottling action" of the gases in the boiler furnace.

Steel Casing. Radiation losses from the surface of brick boiler settings, combined with losses due to air leakage, have been estimated as varying from 2 to 10 per cent., depending upon the amount of radiating surface and condition of the setting, which in turn depends upon the size of the boiler unit. In modern efforts to secure the highest possible plant economies, much has been done in reducing these losses by the use of an insulated steel casing. In a reasonably large-sized unit, such a casing, properly installed, will reduce the losses approximately 1 or 2 per cent. over what can be accomplished with a brick setting without a casing. Steel plate, or steel plate backed by asbestos millboard, is not as effective as a casing properly insulated from the brick portion of the boiler setting by magnesia block.

Table 18 gives the approximate brick quantities required in the setting of various-sized units of different types of boilers, and Table 19 the approximate floor space occupied by different types of boilers ranging from 100 to 500 h.p. in capacity.

Table 18. Comparative Approximate Brick Quantities Required in Settings of Different Types of Boilers

Type of boiler	Size of unit							
	100 h.p.		200 h.p.		400 h.p.		600 h.p.	
	Red	Fire	Red	Fire	Red	Fire	Red	Fire
Horizontal water-tube	14,500	3,500	16,900	4,150	21,400	5,450	22,600	6,500
Semi-vertical water-tube	14,900	4,800	17,000	5,400	20,100	6,800	30,250	8,850
Vertical water-tube	10,700	7,900	15,600	10,000	20,750	14,500	25,800	19,700

* Diam. and height.

Boiler Gaskets and Coverings*

Gaskets may be classified in four groups:

(1) Rubber, or partial rubber composition, gaskets. Tight joints can be made with these, though their use is limited to those places where they will only come into contact with water or saturated steam.

(2) Asbestos, or asbestos composition, gaskets. These, when properly "followed up" after being placed under steam, will neither leak nor blow out. Possibly, for most cases, a gasket with an asbestos fiber and litharge base will be found to give as satisfactory results as may be obtained.

* See Paulding's "Steam in Covered and Bare Pipes."

(3) All-metal gaskets. It is difficult to make tight joints between plane surfaces with soft metal interposed unless bolt holes be on 2½- to 3-in. centers. Some gaskets made entirely of metal have a tendency to break down mechanically under compression by bolts, and to be attacked by moisture resulting from incipient leaks.

(4) Metal and fiber, or metal and composition, gaskets. Such gaskets are ordinarily of copper and asbestos, copper and rubber, copper and lead. Copper gaskets with lead insertion are ordinarily used for water, and with asbestos insertion for steam.

A good gasket must not blow out under strains arising from temperature changes; must not harden; should be reversible and interchangeable; should not spread or stick to plates; should be such as to enable it to be used more than once.

Coverings. Exposed parts of boilers, if not properly covered, will radiate heat to the surrounding atmosphere at the approximate rate of 3 B.t.u. per sq. ft. of exposed surface per hour per deg. difference in temperature between the contained steam or water and the external air. With sufficient thickness of insulating material, this radiation may be reduced to approximately 0.5 B.t.u. (see pp. 305, 308 and 840).

Ordinarily, the tops of the drums of both water-tube and fire-tube boilers are covered with one row of brick on edge and a thin layer of cement. No figures are available on losses through such a covering, but the radiation is probably decreased to from 1.5 to 2 B.t.u. per sq. ft. In certain plants a thin layer of magnesia is placed on the drums, then a layer of cement, and an ash insulation built up.

Drumheads are ordinarily covered with magnesia block or plastic magnesia held in place by netting and covered with painted canvas. Connections from boilers to superheaters should be covered with 2-in. magnesia block, canvas-covered and painted.

Where steel casings are furnished over boiler brickwork, they should be insulated with 2-in. 85 per cent. magnesia block, between which and the brickwork should be inserted ¼-in. asbestos millboard.

SAFETY VALVES FOR STEAM BOILERS

The safety valve (or valves) should have a relieving capacity at least as great as the evaporative capacity of the boiler when operating at maximum capacity.

Safety valves are of two general types, lever and spring-loaded. The first, though still manufactured, is seldom used except in low-pressure work. The objections to this type are that there is no definite "pop" point, the valve lifting slowly in opening, and settling gradually in closing. A comparatively long range of blowing is necessary for the valve to effectively open, and a considerable overpressure is necessary in specifications for such valves. Spring-loaded valves, on the other hand, have a clean, positive opening to practically the full amount. At the popping point a properly designed spring valve will lift its maximum, say 0.15 in., and this lift will decrease approximately 0.01 in. per lb. that the pressure in the boiler falls below the setting point, until the closing point, which is at from 4 to 5 lb. below the popping point. Other pressures may force the lift slightly higher with such a valve, but not sufficiently to make these pressures necessary to obtain the full valve efficiency. In specifying spring valves, therefore, an overpressure should not be allowed, at least not over 1 or 2 lb.

Rules for Design. The following rules for the design and use of safety valves are given by the Massachusetts State Board of Boiler Rules, by the A. S. M. E. code, and by the United States Board of Supervising Inspectors.

(Mass. Board.) Table 20 gives areas of grate surfaces in sq. ft. for other than direct spring-loaded safety valves.

Table 20. Areas of Grate Surfaces for Other than Direct Spring-loaded Safety Valves

Diam. of valve, in.	Maximum allowable pressure on boilers, lb. per sq. in. — 0 to 25	Over 25 to 50	Over 50 to 100	Diam. of valve, in.	Maximum allowable pressure on boilers, lb. per sq. in. — 0 to 25	Over 25 to 50	Over 50 to 100
	Area of grate in sq. ft.				Area of grate in sq. ft.		
1	1.50	1.75	2.00	3	11.75	14.25	16.00
1¼	2.25	2.50	3.00	3½	16.00	19.50	21.75
1½	3.00	3.75	4.00	4	21.00	25.50	28.25
2	5.50	6.50	7.25	4½	26.75	32.50	36.00
2½	8.25	10.00	11.00	5	32.75	40.00	44.00

Each boiler shall have one or more safety valves.

Table 21 gives areas of grate surfaces in sq. ft. for direct spring-loaded safety valves.

Table 21. Areas of Grate Surfaces for Direct Spring-loaded Safety Valves

	$W=\frac{75}{3600}$ $P=40$ $A=0.401$	$W=\frac{100}{3600}$ $P=65$ $A=0.329$	$W=\frac{160}{3600}$ $P=115$ $A=0.297$	$W=\frac{160}{3600}$ $P=140$ $A=0.244$	$W=\frac{200}{3600}$ $P=190$ $A=0.224$	$W=\frac{240}{3600}$ $P=240$ $A=0.213$
Max. allowable pressure on boiler, lb. per sq. in.	0 to 25 lb.	Over 25 to 50 lb.	Over 50 to 100 lb.	Over 100 to 150 lb.	Over 150 to 200 lb.	Over 200 lb.

5	49.00	60.00	66.00	80.00	88.0	92.25

When the conditions exceed those on which Table 20 is based, use formula $A = 11(70\ W/P)$, in which A = area of direct spring-loaded valve in sq. in. per sq. ft. of grate surface; W = lb. of water evaporated per sq. ft. of grate surface per sec., and P = pressure (absolute) at which the safety valve is set to blow.

If more than one safety valve is used, minimum combined area to be in accordance with Table 20. More than one safety valve to be installed on a boiler carrying over 25 lb. pressure per sq. in.

Safety valves hereafter (1908) installed on boilers not to exceed 5 in. in diam., and to be of the direct spring-loaded type, with seat and bearing surface of the disk inclined at an angle of about 45 deg. to center line of spindle; designed with a substantial lifting device so that disk can be lifted from its seat with spindle, not less than ⅛ diam. of valve, when pressure on boiler is 75 per cent. of that at which the safety valve is set to blow.

(A. S. M. E. CODE). Each boiler shall have two or more safety valves, except a boiler for which one safety valve 3-in. size or smaller is required by these Rules.

The safety-valve capacity for each boiler shall be such that the safety valve or valves will discharge all the steam that can be generated by the boiler without allowing the pressure to rise more than 6 per cent. above the maximum allowable working pressure, or more than 6 per cent. above the highest pressure to which any valve is set.

One or more safety valves on every boiler shall be set at or below the maximum allowable working pressure. The remaining valves may be set within a range of 3 per cent. above the maximum allowable working pressure, but the range of setting of all of the valves on a boiler shall not exceed 10 per cent. of the highest pressure to which any valve is set.

Safety valves shall be of the direct spring-loaded pop type with seat and bearing surface of the disk either inclined at an angle of about 45 deg. or flat at an angle of about 90 deg. to the center line of the spindle. The vertical lift of the valve disk measured immediately after the sudden lift due to the pop may be made any amount desired up to a maximum of 0.15 in. irrespective of the size of the valve. The nominal diameter measured at the inner edge of the valve seat shall be not less than 1 in. or more than 4½ in.

Each safety valve shall have plainly stamped or cast on the body: (*a*) The name or identifying trade-mark of the manufacturer, (*b*) the nominal diameter with the words "Bevel Seat" or "Flat Seat," (*c*) the steam pressure at which it is set to blow, (*d*) the lift of the valve disk from its seat, measured immediately after the sudden lift due to the pop, (*e*) the weight of steam discharged in pounds per hour at the pressure for which it is set to blow.

The minimum capacity of a safety valve or valves to be placed on a boiler shall be determined on the basis of 6 lb. of steam per hour per sq. ft. of boiler heating surface for water-tube boilers, and 5 lb. for all other types of power boilers, and upon the relieving capacity marked on the valves by the manufacturer, provided such marked relieving capacity does not exceed that given in Table 22. In case the relieving capacity marked on the valve or valves exceeds that given in Table 22, the minimum safety valve capacity shall be determined on the basis of the maximum relieving capacity given in Table 22 for the particular size of valve and working pressure for which it was constructed. The heating surface shall be computed for that side of the boiler surface exposed to the products of combustion, exclusive of the superheating surface. In computing the heating surface for this purpose, only the tubes, shells, tube sheets and the projected area of headers need be considered.

Safety-valve capacity may be checked in any one of three different ways, and if found sufficient, additional capacity need not be provided: (*a*) By making an accumulation test by shutting off all other steam discharge outlets from the boiler and forcing the fires to the maximum. The safety-valve equipment shall be sufficient to prevent an excess pressure beyond 6 per cent.; (*b*) by measuring the maximum amount of fuel that can be burned and computing the corresponding evaporative capacity upon the basis of heating value of the fuel; (*c*) by determining the maximum evaporative capacity by measuring the feed water. The sum of the safety-valve capacities marked on the valves shall be equal to or greater than the maximum evaporative capacity of the boiler.

* The discharge capacity of a flat-seat valve of a given diameter with a given lift may be obtained by multiplying the discharge capacity given in the table for a 45-deg. bevel-seat valve of same diameter and same lift, by 1.4. Discharge capacity is proportional to the lift.

When two or more safety valves are used on a boiler, they may be either separate or twin valves made by mounting individual valves on Y-bases, or duplex, triplex or multiplex valves having two or more valves in the same body casing. The safety valve or valves shall be connected to the boiler independent of any other steam connection, and attached as close as possible to the boiler, without any unnecessary intervening pipe or fitting. Every safety valve shall be connected so as to stand in an upright position, with spindle vertical, when possible. Each safety valve shall have full-sized direct connection to the boiler. No valve of any description shall be placed between the safety valve and the boiler, nor on the discharge pipe between the safety valve and the atmosphere. When a discharge pipe is used, it shall be not less than the full size of the valve, and shall be fitted with an open drain to prevent water from lodging in the upper part of the safety valve or in the pipe.

Safety valves shall operate without chattering and shall be set and adjusted as follows: To close after blowing down not more than 4 lb. on boilers carrying an allowed pressure less than 100 lb. per sq. in. gage; after blowing down not more than 6 lb. on boilers carrying pressures between 100 and 200 lb. per sq. in. gage, inclusive; and after blowing down not more than 8 lb. on boilers carrying over 200 lb. per sq. in. gage.

Each safety valve used on a boiler shall have a substantial lifting device, and shall have the spindle so attached that the valve disk can be lifted from its seat a distance not less than one-tenth of the nominal diameter of the valve, when there is no pressure on the boiler. The seats and disks of safety valves shall be of non-ferrous material.

Springs used in safety valves shall not show a permanent set exceeding $\frac{1}{32}$ in. 10 min. after being released from a cold compression test closing the spring solid. The spring in a safety valve shall not be used for any pressure more than 10 per cent. above or below that for which it was designed.

(U. S. BOARD.) Area of all safety valves in boilers to be determined by the following formula: $A = 0.2074\ W/P$, where A = area of safety valve in sq. in. per sq. ft. of grate surface; W = lb. of water evaporated per sq. ft. of grate surface per hour, and P = absolute pressure, lb. per sq. in. The value of A so found multiplied by the sq. ft. of grate surface gives the area of safety valve, or valves, required. The seats of all safety valves to have an angle of inclination of 45 deg. to the center line of their axes. After 1911, no safety valves having a set-screw arrangement at top of the valve casing, designed to hold the valve down while the hydrostatic pressure is being applied, to be allowed.

Darling's Formulæ for Design. The factors entering into the discharge area or relieving capacity of a safety valve are the diameter of the inlet opening at the seat and the vertical valve lift. In figuring the valve capacity by either of the rules given above, it is assumed that the valve lift has a definite ratio to the diameter at the inlet opening. Philip G. Darling (*Trans. A. S. M. E.*, vol. 31, 1909, p. 109) has pointed out that such an assumption would make the relieving capacity of all valves of the same nominal diameter the same. Special experiments show that this is not the case; that the lift does not vary with the diameter, but is nearly a constant for any make of valve regardless of the diameter; and that the actual lifts are in some cases only approximately one-half the lifts as assumed above. Table 23 gives a comparison of lifts, discharge areas, and relieving capacities of several different makes of stationary boiler valves, all of the same nominal diameter.

Table 23. Comparison of Lifts, Discharge Areas and Relieving Capacities of Seven Different Makes of Boiler Safety Valves

(Diam. of all valves, 4 in.; popping pressure in all cases, 200 lb. per sq. in.)

Lifts		Effective area of discharge with opening lift, sq. in.	Per cent. of largest opening	Relieving capacities	
Opening, in.	Closing, in.			Lb. of steam per hour, from $E = 105\ LDP$	H.p. on basis of 30 lb. evap. per hour = 1 h.p.
0.064	0.024	0.568	46.6	5,780	193
0.031*	0.017	0.398	31.4	3,960	132

0.094	0.055	0.834	68.5	8,500	283
0.082	0.054	0.727	59.7	7,400	247
0.137	0.088	1.22	100.0	12,400	413

* Flat seat; all other valves with 45-deg. seats.

The conclusions reached by Mr. Darling were to the effect that the rules in use are not safe and should not be followed. A more satisfactory rule for determining valve capacity is obtained from Napier's formula for the flow of steam, combined with the actual discharge area of a valve as determined by its lift. The constant, or coefficient of flow, when applied to the irregular steam discharge passages of safety valves, was found by a series of actual tests to be 47.5, and Napier's formula modified becomes $E = 47.5aP$, where E = lb. of steam discharged per hour; a = effective discharge opening in sq. in., and P = absolute pressure in lb. per sq. in. Expressed in terms of valve diameter and lift, to make it generally serviceable, and assuming the almost universal 45-deg. valve seat, this formula becomes,

$$E = 105LDP \tag{1}$$

$$\text{or } D = 0.0095E/LP \tag{2}$$

where D = diam. in in., and L = lift in in.

It will be noted that the nominal area of discharge does not enter into this formula. If D is found to have a value of, say, 12, three 4-in. or four 3-in. valves will be necessary. Formula (2) is probably the best now available for use in designing safety valves.

To meet the demand for a formula expressed in terms of heating surface, modified values of the constant of flow have been advanced for various classes of work as follows, the nominal evaporation per sq. ft. of heating surface (H = heating surface in sq. ft.) and the maximum overloads being assumed as given:

For cylindrical multi-tubular and vertical water-tube stationary boilers,

$$D = 0.0068H/LP \tag{3}$$

where a nominal evaporation of 3½ lb. of water per sq. ft. of heating surface and a maximum overload of 100 per cent. (giving 7 lb. per sq. ft. of heating surface) are assumed.

For water-tube, marine and Scotch marine boilers,

$$D = 0.0095H/LP \tag{4}$$

where a maximum evaporation of 10 lb. of water per sq. ft. of heating surface is assumed.

For locomotive boilers (the constant being determined by actual test),

$$D = 0.0055H/LP \tag{5}$$

The constants given in the above formulæ are for 45-deg. angle seats. For flat seats these values become: (1) 149; (2) 0.0067; (3) 0.0065; (4) 0.090; (5) 0.052. Formulæ (1) and (2) are the most accurate, in that the total maximum evaporation is taken as a definite quantity, without any assumptions.

Installation and Care of Safety Valves. All safety valves should be connected directly to the boiler with a close nipple or a short steam nozzle of the full valve size, or larger. In attaching the flange, the bolts should be drawn up evenly, as distortion of the valve seat may otherwise occur. In making a hydraulic test on a boiler the valve should be properly gagged, and not made to blow at a higher pressure by screwing down the spring. Safety-valve springs are designed for a definite pressure, which is usually stamped on a tag fastened to the valve. If a valve is to be set at a pressure differing from the designed pressure by more than 5 or 10 lb. (depending upon the make of the valve), either above or below, a new spring should be furnished. Where safety valves are used with superheated steam, those of the outside-spring type should be used in order to protect the metal of the spring from the high temperatures. In operation, all valves should be made to blow periodically to avoid the danger of sticking.

CHIMNEYS AND DRAFT

The factors involved in designing a stack are so numerous that as yet no formulæ have been advanced that will take all of them satisfactorily into account. The existing formulæ are purely empirical.

The intensity of the draft, usually measured in inches of water, is equal to the difference in weight between the column of heated gas within a chimney and the weight of a similar column of external air. This difference in weight for a given temperature of gas and air will vary directly with the stack height, so that the height of a stack is the governing factor in the intensity or amount of draft to be expected. The draft must be sufficient to overcome the friction of the air in passing through the fuel bed, of the gases in passing through the boiler proper, and through the flues connecting the boiler to the stack.

The theoretical force or **intensity of the draft** obtainable from any stack is given by the formula:

$$D = 0.52\,PH[(1/T) - (1/T_1)],$$

in which D = draft produced, in in. of water; H = height of stack above grates, ft.; P = atmospheric pressure, lb. per sq. in.; T = atmospheric temperature, absolute, deg. fahr.; and T_1 = temperature of stack gases, absolute, deg. fahr.

For various stack temperatures, assuming atmospheric pressure and temperature as 14.7 lb. and 60 deg., respectively, the formula reduces to $D = KH$, in which the values of K for various stack temperatures are as follows:

Temp. of stack gases, deg. fahr.	750	700	650	600	550	500	450	400	350
Value of K in formula.....	0.0084	0.0081	0.0078	0.0075	0.0071	0.0067	0.0063	0.0058	0.0053

This draft is the theoretical draft and cannot be obtained in practice. The theoretical draft which a stack will give, less the loss in overcoming frictional and inertia resistance, will be the draft available at the stack base or at the point where a flue enters, provided the stack height be measured above that point. The **draft loss due to friction and inertia** is

$$d = fW^2CH/A^3,$$

where d = draft loss, in. of water; W = weight of gases passing per sec., lb.; C = circumference of stack, ft.; A = area of passage, sq. ft.; H = height of stack, ft.; and f is a constant having the following values: 0.0015 for steel stacks with gases at 600 deg. fahr. (0.0011 at 350 deg.), and 0.0020 for brick or brick-lined stacks with gases at 600 deg. (0.0015 at 350 deg.).

Available Draft. The available draft, d_1, for any stack is therefore $d_1 = KH - fW^2CH/A^3$.

Table 24, calculated from this formula, gives the available draft at the base of stacks of various sizes to which different horse powers of boilers are connected.

Of the empirical formulæ advanced for proper height and diameter of stack for various horse powers of boilers, one largely used by engineers is that of Wm. Kent (see *Trans. A. S. M. E.*, vol. 6), namely,

$$\text{H.P.} = 3.33\,(A - 0.6\,A^{1/2})H^{1/2},$$

where H.P. = horse power based on a coal consumption of 5 lb. per rated h.p. per hour; A = actual area of chimney, sq. ft.; and H = height of chimney, ft.

$(A - 0.6A^{1/2})$ = effective area of stack, based on the assumption that the retarding effect by friction of the ascending gases may be considered as equivalent to the diminution of the area of the stack equal to a layer of gas 2 in. thick about the perimeter.

The height must first be determined from the known or assumed resis ances. Table 25 gives the sizes of stacks for various horse powers of boilers based on this formula.

For approximate work Table 25 gives satisfactory results, but no stack table will satisfactorily serve all cases, there being too many varying factors which enter into each individual case.

Table 24. Available Draft for 100-ft. Steel Stacks of Different Diameters

(Based on a stack temperature of 500 deg. fahr.* and 100 lb. of gas per h.p. For other heights of stack, multiply draft by height ÷ 100)

A simpler formula, sufficiently accurate for approximate purposes in considering stacks for above 1000 h.p., as given by Wm. Kent, is, $H.P. = 2.5D^2H^{1/2}$.

A convenient and satisfactory method of determining the proper diameter of large stacks, 200 ft. and over in height, is to allow 30 sq. ft. of cross-sectional area for each 1000 nominal rated h.p. of boilers which the stack is to serve.

From the first formula and others of like nature, it will be seen that, by varying the height and diameter, different sizes of stacks will give the requisite theoretical draft for a given h.p. Among such various sizes there must be one cheaper than the others to build, and it appears from a study of stack costs that the minimum-cost stack has a diameter directly dependent upon the h.p. of the boilers it is to serve and a height proportional to the available draft required. Expressed as a formula, this diameter for unlined steel stacks is, diam. in in. $= 4.68\ (\mathrm{H.P.})^{2/5}$. This is based on the assumption of 120 lb. of flue gas per hour per boiler h.p., which figure is sufficiently high to take care of reasonable overloads and the use of poor coal. The diameter of stacks at sea level and the rated h.p. which they will serve by this formula are as follows:

Horse power of stack........	100	200	300	400	600	800	1000	1500	2000	3000	4000
Diameter of stack, in........	29	38.5	45	50.5	59	67	73.5	87.2	98	115	129

Draft Loss in Furnace. The draft loss in the furnace or through the fuel bed will vary widely with various grades of coal and different combustion rates. No fixed rules can be given for the draft required to burn certain quantities of different coals. Table 12 gives the furnace draft required at various combustion rates, allowing a fairly safe margin.

Draft Loss through Boiler. The draft resistance offered by the boiler heating surface will vary largely with the design of the boiler and the percentage of its capacity at which it is being run. This loss in a well-designed water-tube boiler will be about 0.25 in. at rating; 0.4 in. at 150 per cent. of rating; and 0.65 in. at 200 per cent. of rating.

Draft Loss in Flues. The draft loss in straight flues may be determined by the formula given for draft loss in stacks, in which case C is the circumference of flue in ft. when the flues are round, (if square or rectangular flues are used, the retarding effect will be approximately 12 per cent. greater than that of a circular flue of the same area), and H is the length of flue in ft. The draft loss due to right-angle turns in flues may be taken care of by an allowance of 0.05 in. loss for each such turn; the turns from a boiler into a flue and from a flue upward into the stack should be included in the calculation. Cross-sectional areas of flues should be ample, and a design allowing 35 sq. ft. per 1000 rated boiler h.p. is to be recommended.

Correction of Stack Sizes for Altitude. To develop a given boiler h.p. requires a constant weight of air for combustion. As the altitude is increased, the density is decreased, and the gas velocity must be increased. The mean velocity for a given boiler h.p. and constant weight of gas will be inversely proportional to the barometric pressure; and the velocity head, measured in column of external air, will be inversely proportional to the square of the barometric pressure. The added frictional loss due to added gas velocity and added height is compensated by an increase in diameter, such increase being proportional to the two-fifths power of the ratio of barometric pressures. Table 26 indicates the necessary changes in stack dimensions for varying altitudes above sea level.

Stack Sizes for Oil Fuel. The requirements for stacks for oil fuels are entirely different from those connected to coal-fired boilers, as there are certain losses through the boiler proper that are eliminated. Gas tempera-

Table 26. Stack Capacities. Correction Factors for Altitudes

Altitude, height in ft. above sea level	Normal barometer, in.	R Ratio barometer reading sea level to altitude	R^2 Ratio increase in stack height	$R^{2/5}$ Ratio increase in stack diam.
0	30.00	1.000	1.000	1.000

2,000	27.80	1.079	1.164	1.030
3,000	26.76	1.121	1.257	1.047
4,000	25.76	1.165	1.356	1.063
5,000	24.79	1.210	1.464	1.079
6,000	23.87	1.257	1.580	1.096
7,000	22.97	1.306	1.706	1.113
8,000	22.11	1.357	1.841	1.130
9,000	21.28	1.410	1.988	1.147
10,000	20.49	1.464	2.144	1.165

tures entering the stacks are lower for a given capacity, and the volume of gas is less than with coal. The cross-sectional area of the stack may therefore be less. In most instances this may safely be taken as 60 per cent. of the area that would be furnished for coal-fired boilers. In determining the height, care must be taken to design a stack that will give a sufficient draft for the maximum requirement of the boiler, but not more. In this way the efficiency is safeguarded, and the danger of a draft such as to pull through too large an excess of air is eliminated.

Table 27, adapted from one calculated by C. R. Weymouth (*Trans. A. S. M. E.*, vol. 34, 1912) and based on actual test data, will be found to give satisfactory results under the assumed conditions as given for stacks with oil-burning boilers. For stack sizes with blast-furnace gas, see p. 890.

Table 27. Stack Sizes for Oil Fuel

Stack diam., in.	Height in ft. above boiler-room floor					
	80	90	100	120	140	160
33	161	206	233	270	306	315

120	3060	3660	4207	5040	5660	6160

Figures represent nominal rated h.p.; sizes as given are good for 50 per cent. overloads. Based on centrally located stacks, short direct flues and ordinary operating efficiencies.

Stack Design and Construction

There are four methods of building stacks: (1) Masonry construction, in which the stability of the stack is dependent upon the dead weight; (2) reinforced-concrete construction, in which the tension of the stack is taken care of by the steel reinforcing members which also assist in securing stability;

(3) self-supporting steel construction, anchored to a foundation; (4) guyed steel stacks, which are carried on foundations or structural supports and depend largely for their stability upon guy wires. There are certain instances in which any of these methods may be the best construction to follow, though the reinforced-concrete construction may almost be considered in an experimental state. Steel stacks are not as long-lived as masonry stacks, but no definite figure can be given on their life, as it depends upon local conditions, the thickness of the material used, and upon the care given in the way of painting and cleaning. When properly constructed and cared for, a steel stack should last at least 15 to 20 years.

Masonry Stacks are ordinarily built of round, octagonal or square section. Square stacks are ordinarily limited to short heights. Octagonal stacks require special brick for the angles in alternating courses to produce the best work. Circular stacks are the most efficient for their area and take the least material.

Circular stacks are usually built of specially formed brick, known as radia brick. While common brick are sometimes used, it is not advisable when the diameter becomes less than 5 ft.

In designing stacks the wind pressure to be allowed for is frequently established by building ordinances. The ordinance of the city of Chicago reads: "All chimneys shall be so designed as to safely resist a wind pressure of 30 lb. per sq. ft. of surface exposed to the action of the wind." Such a value includes whatever suction there may be on the leeward side of the chimney. In ordinary calculations, 100 miles per hour is used as the maximum velocity of the wind. This is equivalent to 50 lb. pressure per sq. ft. on a flat surface, or, as is ordinarily assumed in the case of a circular stack, 25 lb. per sq. ft. of projected area.

Experiments made by Professor Kernot on the Forth Bridge showed that the average pressure on large surfaces does not exceed about two-thirds that upon small surfaces of 1 or 2 sq. ft. A pressure of 50 lb. per sq. ft. represents the maximum obtainable on a small surface with a wind velocity of 100 miles per hour, which would be classed as a severe hurricane. German practice is to ordinarily allow 33⅓ lb. per sq. ft. of projected area.

In the computation of stresses in a masonry stack, the stack is ordinarily considered as a hollow cantilever beam. This beam is acted upon by the force of wind and by gravity, the single or combined effect of which tends to (1) overthrow a part of the chimney, (2) crush the masonry at the leeward side of any section of the chimney, and (3) produce too great pressure on the soil under the leeward side of the foundation.

Stack Foundations. Table 28, for self-supporting stacks, gives foundation sizes based on 160 lb. per sq. ft. on the earth due to weight and 160 lb. due to wind, or 320 lb. per sq. ft. per ft. of depth of foundation.

In computing wind pressures (*Eng. Rec.*, Nov. 28, 1908), wind moments, section moduli and bearing pressures, a stack is divided into sections from the top downward, each section considered separately at its lower edge and computations made above such edge. The wind pressure on each section is determined by multiplying the projected area of the section by the unit wind pressure. In octagonal stacks, the wind-resisting area is ordinarily assumed as 70 per cent. of actual area.

Stack specifications ordinarily set the maximum wind pressure to be figured upon and the allowable compression or tension of the masonry in any portion of the stack. A safe figure to be used as a maximum bearing pressure due to both static load and wind pressure is 20 tons per sq. ft. of any section.

Self-supporting Steel Stacks. The following method of calculating stresses in self-supporting steel stacks has given successful results.

The pressure exerted by the wind is taken at 25 lb. per sq. ft. of projected area. The strains produced in the stack are such that there would be no danger of failure even should there be considerable corrosion so as to reduce the plate thickness, say, 1/16 in.

The stacks have a straight conical flare at the base, the apex of the cone being at the top of the stack and the height of the flared part made approximately one-fourth the height of the stack. This makes the diameter at the base about one-third larger than that of the straight part of the stack. The flared part is built of plates of a uniform thickness. This construction provides a larger diameter for admitting the flue opening to the side of the stack and leads to a more easy flow of the gases than in a cylindrical stack. Again, less reinforcement is necessary where the breeching joins the stack with the flared-base construction than would be necessary with a parallel stack.

The maximum stress S per lineal inch of circumference due to the wind pressure is determined by considering the stack to act as a beam, and represents the stress which acts on the part of the circumference most remote from the neutral axis; this stress will be $S = M/A$, where M = wind moment in in.-lb., and A = cross-sectional area of stack in sq. in.

For the parallel part of the stack, with a wind pressure of 25 lb. per sq. ft. of projected area, this reduces to $S = 150\ H^2D/A$, where H = height in ft. from section considered to top of stack; D = diam. of stack in ft. and A = cross-sectional area of stack in sq. in.

The maximum stress due to the wind pressure per lineal inch is determined at each of the joints.

Table 29 gives the basis of calculation used by The Babcock & Wilcox Co. in designing self-supporting steel stacks, and indicates the maximum allowable stress in plates of varying thicknesses and rivet data. The figures represent stresses due to a wind pressure of 25 lb. per sq. ft. of projected area without regard to the weight of stack, which will add to compression side and deduct from tension side from 5 to 12 per cent.

Table 28 gives foundation data, plate thicknesses, height of sections, etc., for a number of self-supporting steel stacks calculated on the basis of Table 29.

Table 29. Basis of Calculation of Self-supporting Steel Stacks

(The Babcock & Wilcox Co.)

Pull per in. of circumference, lb.	Plate thickness, in.	Diam. of rivets, in.	Pitch of rivets, in.	Stress at rivets, lb. per sq. in.			
				Bearing	Shear	Tension	Tension in body of plate
600	3/16	3/8	2	15,880	9,270	4,020	3,200
1,100	1/4	1/2	2	16,600	9,950	5,980	4,400
1,700	5/16	5/8	2	16,600	10,000	8,080	5,440
2,360	3/8	3/4	(2 rows) 4	16,100	9,860	7,830	6,295
3,100	7/16	3/4	(2 rows) 3	13,600	9,750	9,600	7,090
3,930	1/2	7/8	(2 rows) 3	13,000	9,150	11,400	7,690
4,800	9/16	1	(2 rows) 3½	14,480	10,050	12,100	8,545

The stacks of Table 28 are unlined. If a lining is to be installed, special calculations should be made for bearing and for shear of rivets, which should be kept within the limits of Table 29.

Guyed Steel Stacks. Guyed steel stacks are placed on a foundation on the ground, or are carried on a structural framework that may be a part of the boiler support. The material used in their construction is ordinarily lighter than that for self-supporting stacks. It need only be sufficiently heavy to allow a margin for corrosion, to support its own weight, and to give strength sufficient to prevent buckling under a wind pressure of 25 lb. per sq. ft. of projected area. The tendency of wind and weight to overthrow the stack is taken care of by the guy wires. Such guys are ordinarily furnished in two sets of three each, attached to guy bands at two points in the height of the stack, the guys being at an angle of approximately 60 deg. with the vertical.

A satisfactory basis of calculation for loads on base, stress in guys due to wind pressure and initial stress, for stacks guyed as described, is as follows:

$$\text{Total wind pressure} = 25DL;$$
$$\text{Overturning moment} = 12.5DL^2.$$

where D = diam. of stack, ft., and L = height of stack, ft.

Horizontal pull on each guy = overturning moment divided by the sum of the heights of the guy bands = $12.5DL^2/(h_1+h_2)$, where h_1 and h_2 are heights in ft. of first and second guy bands from ground.

Direct pull on each guy due to wind = horizontal pull × cosecant 60 deg.

Initial stress on each guy = ½ × direct pull due to wind.

Therefore,

$$\left.\begin{array}{l}\text{Maximum stress in}\\ \text{guys due to wind}\\ \text{and initial stress}\end{array}\right\} = \frac{21.65\,DL^2}{h_1+h_2} \qquad \left.\begin{array}{l}\text{Vertical load due}\\ \text{to maximum stress}\\ \text{in guys}\end{array}\right\} = \frac{50.53\,L^2D}{h_1+h_2}$$

$$\left.\begin{array}{l}\text{Vertical load due}\\ \text{to weight of stack}\end{array}\right\} = W \qquad \left.\begin{array}{l}\text{Total vertical load}\\ \text{on base}\end{array}\right\} = \frac{50.53\,L^2D}{h_1+h_2} + W$$

Where a number of guyed stacks are placed in one continuous row, instead of two sets of three guy wires being furnished, a lattice bracing is frequently used between stacks, each stack having in addition two sets of two guy wires each, and the end stacks having two sets of three each.

Table 30 gives the approximate weight per foot of guyed steel stacks of varying thicknesses. To these figures there should be added 10 per cent. for guy ropes, bands, clips, etc.

Table 30. Approximate Weight of Guyed Stacks per Foot of Height

(Including laps, rivets, and manufacturer's maximum allowance for overweight)

Stack diam., in.	Material				
	No. 12 B. W. G.	No. 10 B. W. G.	No. 8 B. W. G.	3/16 in.	¼ in.
30	41.2 lb.	50.6 lb.	....	....	....
33	45.2	55.5	....	....	....
36	49.3	60.6	74.5 lb.	....	....
39	53.2	65.4	80.5	91.4 lb.	....
42	57.1	70.4	85.4	97.0	129.3 lb.
48	65.2	80.2	97.2	111.1	150.0
54	....	91.1	110.9	124.6	168.2
60	....	101.0	122.7	139.9	183.8
66	....	....	134.8	153.8	202.3
72	....	....	146.7	167.2	219.7

All steel stacks should be supplied with a top band, painter's trolley and suitable clean-out doors. A stack ladder is frequently advisable.

Table 31 gives the approximate comparative costs of guyed steel stacks, self-supporting steel stacks, brick stacks and concrete stacks.

Table 31. Comparative Approximate Costs of Chimneys

Height, ft.	Diam., in.	Horse power	Brick, cost	Concrete, cost	Self-supporting steel		Guyed steel	
					Weight, lb.	Cost	Weight, lb.	Cost
100	42	258	$1,400	$1,300	....	....	8,250	$420
150	54	551	2,700	2,150	....	....	21,080	850
150	72	1,023	3,500	2,800	51,750	$2,200	31,450	1,230
175	84	1,531	4,300	3,500	76,250	3,250	53,230	2,075
200	96	2,167	5,600	4,500	108,100	4,600	....	....
200	120	3,448	7,200	5,800	117,000	4,975	....	....
225	132	4,455	8,700	7,000	155,980	6,650	....	....
250	144	5,618	10,000	8,100	206,800	8,800	....	....

All costs include foundation material and erection. Freight not included in steel stack costs. Costs of brick and concrete stacks will vary from 5 to 15 per cent. with local prices. Total cost of steel stacks will vary with freight charges.

Mechanical Draft

Mechanical draft may be divided into three classes: (1) That produced by a steam jet or jets; (2) that produced by suction on the stack side of a boiler, or induced draft; and (3) that produced by a pressure under the grates or forced draft.

Mechanical draft produced by steam jets is either forced, as when jets are introduced into the ash pit, or induced, as when jets are installed in the flue or stack. The advantage of draft produced by this means lies almost entirely in its cheapness of installation and low cost of repair. Its use in general is confined to small plants where the cost of a fan is not warranted, or in larger plants to help carry an occasional peak load. Its disadvantages are large steam consumption, the limitations of draft that may be produced by this means, and noise.

The steam consumption of simple steam jets, either under grates or in the stack, may run as high as 30 per cent. of the total amount of steam generated, a fair figure being from 5 to 10 per cent. For some systems of ash-pit steam blast the steam consumption may be as low as 2½ per cent. under test conditions. A good system, under ordinary operating conditions, will probably require from 4 to 6 per cent. of the total steam generated.

The maximum ash-pit blast that can be obtained with steam jets with a reasonable economy, is approximately 1 in. of water. Where steam jets are placed in the flue or stack, the draft suction ordinarily cannot be increased more than 0.75 in. over what the stack alone would give. If but a single jet is supplied, the increase in draft may be inappreciable in a stack of a moderate diameter, regardless of the amount of steam used. A ring of jets or two such rings should be used in a stack of medium or large diameter.

A jet or jets of steam improperly introduced into the ash pit may lead to an uneven distribution of the draft pressure beneath the grates and cause the blowing of holes in the fire. The combustion of many coals that have a tendency to fuse or mat on the grates may be materially aided by the introduction of steam beneath the grates, and a steam-jet blast so used serves a double purpose. In certain cases steam is so used without any intention of producing blast pressure.

Induced-draft Fans are introduced in the stack side of a boiler. The fan handles gases of a high temperature which are frequently dust-laden.

This severe service often results in excessive maintenance cost. In early constructions the bearings were exposed to the heated gases and frequently required cooling. In modern designs the bearings are usually out of the path of the gases.

The nature of the service of an induced-draft fan is necessarily more severe than that of a forced-draft fan, and as the temperature of the gases handled by an induced-draft fan is higher and the weight of the gases passing through the fan is greater than that of the air that would be handled by a forced-draft fan, it might seem that a forced-draft apparatus could be used to advantage in all cases. In most constructions; however, it is important that a draft suction be maintained within the boiler setting, and this may necessitate the use of an induced-draft fan. There is no danger of an uneven distribution of draft suction over the surface of the fire with an induced-draft fan, whereas, with forced draft, care must be taken that the air is introduced properly.

The steam consumption of an induced-draft fan, when in good order, will be approximately 2 to 4 per cent. of the total steam generated. In waste-heat work, induced-draft fans are the only type practicable.

Forced-draft Fans. With this type of apparatus the fan forces air drawn from the boiler room into a closed ash pit. The steam consumption of a forced-draft fan, when new, will be from 2 to 4 per cent. of the total steam generated.

In the installation of a forced-blast fan it is necessary to ensure that the stack is capable of maintaining a suction throughout all parts of the boiler setting under all conditions of operation. If a suction is not maintained, trouble will result with the brickwork of the setting, as the high-temperature gases will tend to pass out through cracks in the setting and will cause the brickwork to "soak up" heat, whereas with a draft suction the cold air from the outside percolates inward through the brickwork or through any cracks in the setting and reduces the temperature.

In installing a forced-blast apparatus the air should be introduced in such a manner as to give an even pressure under all portions of the grate. Such an even distribution is best accomplished by introducing the air through a blast box in the bridge wall extending approximately the full width of the furnace. It is necessary that the ash pit be air-tight.

It is generally desirable that an induced- or forced-draft apparatus be controlled by some automatic means. The automatic control may be (1) by the steam pressure, or (2), where it is desired to keep a constant suction in the furnace, by the draft suction.

Where the steam pressure is utilized to control the mechanical draft, a damper regulator is ordinarily employed to give the initial movement to an actuating lever with but a slight variation in steam pressure. In most instances the fan engine is not placed wholly under such automatic control, but a by-pass connection is provided in the steam-supply line to allow a partial hand regulation. The fan engine should never stop, as if it does it ceases to be automatic, and if the balanced throttling valve is retained in a position where a small volume of steam is passing through at a high velocity it will cut the valve and valve seat. The adjustment on the balanced throttling valve should be such that when the fan speed is minimum it will be in a closed position and be tight, and to start the fan at its minimum speed the steam required will go through the by-pass valve and pipe.

In any plant where a number of boilers are in operation, the main flue damper is ordinarily under some method of automatic control. Where this exists in a plant utilizing forced draft, there is danger that as the steam pressure increases and the main damper closes, the blast will cause the gases to come out into the fire room through the firing or inspection doors. Aside from the inconvenience to the operatives, a back pressure within the boiler setting is detrimental to the setting. Devices actuated by the pressure of the gases within the furnace may so regulate the damper that any suction desired may be obtained, and in this way eliminate the difficulties above outlined.

Where a stack of sufficient size may be used to give the required draft and combustion rate, natural draft is preferable to mechanical draft. Mechanical draft has advantage over natural draft in the ease with which it may be controlled, and in the ability to start the fire.

MANAGEMENT AND INSURANCE

Economical Boiler-plant Loads

The rating at which a boiler plant should be run depends solely upon the nature of the load it carries. The controlling factor in the cost of a plant, regardless of the nature of the load, is the capacity to carry the maximum peak load that may be thrown on the plant under any condition.

Loads may be grouped in three classes: (1) The approximately constant 24-hr. load; (2) the steady 10- or 12-hr. load, usually with a noon-day period of no load; (3) the 24-hr. variable load found in central-station practice. The economical load at which a boiler plant may be run will vary with these groups.

(1) **For a constant load, 24 hr. a day,** the economical load, or that at which, all things considered, a given amount of steam can be produced most cheaply, is ordinarily considerably over the boiler's rated capacity. What this overload will be is dependent very largely upon the cost of coal at the plant. The capital investment must be weighed against the coal saving through added thermal efficiency, and the labor account, which increases with the number of units installed, must be given proper consideration. The economical rating will ordinarily be between 25 and 50 per cent. above the rated capacity of the boilers.

Where this question arises in the case of a plant already installed the conditions may be different from those that will exist in a new plant. If there are enough boilers to operate at lower ratings the capital investment leads only to a fixed charge, and the gain in thermal efficiency due to low ratings will make it advisable to run at lower capacities than in a contemplated plant.

(2) **For a 10- or 12-hr. load,** either approximately constant or one in which a peak occurs, the economical load will ordinarily be found to be somewhat higher than in (1). This is due to the fact that the return on the invested capital will increase, with the capacity secured, to a point where the actual boiler efficiency decreases sufficiently to offset such added return. Here again the determining factors are the fuel and labor lost as against thermal efficiency.

Due to operating difficulties that may be encountered at high overloads, the rating to show the best return on invested capital will for a load of this nature be ordinarily found to be between 150 and 175 per cent. of the rated capacity of the boilers.

The necessity for "spares" (see below) may change the aspect from which the economical rating for a load of this nature is to be considered. Their presence leads to a fixed charge and it may be advisable to use such spare boilers as part of the regular equipment, except at such times as certain boilers are off for cleaning and repairs, and in this way secure an added thermal efficiency through decreased capacity of the plant as a whole. Under such conditions these boilers could only be considered as spares during such time as actual cleaning or repairs are being done. The feed water available is the governing factor in such a consideration.

(3) **For the 24-hr. variable load** the point of maximum plant economy is, to an extent greater than in the other groups, dependent upon individual plant conditions, and the methods of handling a load of this nature will vary widely with fuel, labor, flexibility of apparatus, type of boiler and stoker, etc. Under ordinary conditions in city central-station plants, where the maximum peaks occur but a few times a year, the installation should be such as to enable these peaks to be carried with the boilers operating at their maximum capacity, a margin being allowed for insurance and continuity of service. Provided these maximum peaks can be so carried, a large sacrifice in thermal efficiency is permissible.

Some methods of handling a load of this nature are:

(*a*) The carrying of whatever load is on the plant at any time on only such boilers as will furnish the requisite power when operated at from 150 to 200 per cent. of rated capacity. All boilers in operation are run at such ratings at all times, increasing loads being handled by cutting in banked boilers. This method of handling central-station loads is probably the most generally used in practice to-day and under many conditions the ratings described are the economical loads.

(*b*) Other conditions of operation make it advisable to carry the load on a definite number of boiler units, operating such units slightly below their rated capacity at light plant loads, and carrying the peaks on the same number of boilers operated at high capacities. In such a method there are no boilers on bank and the spares are such in all senses of the word.

(*c*) A third method is that of considering the plant as divided into two parts, one of which handles the constant load, and the other the fluctuating load. That portion of the plant carrying the constant load is designed to operate at a maximum thermal efficiency, this point being raised to such a maximum by the installation of any apparatus by which such result may be obtained. The portion carrying the variable load is operated by either method (*a*) or (*b*), with the efficiency as high as the nature of load and ability to carry peaks allow.

The foregoing paragraphs have dealt largely with central-station practice; they are, however, generally applicable to smaller plants.

Spare Boilers. Where the load is to be reasonably constant it is advisable to install at least two spare boilers if continuity of service is essential. This permits the taking off of one boiler for cleaning and repair, and still allows a spare boiler in the event of the blowing out of a tube or some other unforeseen occurrence. In small plants two spares are not warranted. A large plant is ordinarily laid out in sections or panels, and each section should have its spare boiler, or boilers, even though the sections be cross-connected.

Stand-by Boiler Losses. The amount of fuel required to carry a boiler on banked fires is approximately the same as that required to maintain full steam pressure. Some approximate figures of tests for this requirement are as follows:

A hand-fired boiler of 640 (rated) h.p., using W. Va. bituminous coal, required (on a 72-hr. test) 1 lb. of coal per sq. ft. of grate surface per hour, or approximately 0.2 lb. of coal per rated h.p. This was the best figure obtained in a number of trials, the average being from 1.25 to 1.50 lb. per sq. ft. of grate per hour, or 0.25 to 0.30 lb. per (rated) h.p. per hour. These figures would indicate that a 600-h.p. unit would require for banking over a 24-hr. period between 3000 and 4000 lb. of coal.

A hand-fired boiler, rated at 604 h.p., using No. 3 anthracite buckwheat, required approximately 0.33 lb. of coal per rated h.p. per hour, or 4800 lb. for 24 hr. A stoker-fired boiler rated at 600 h.p. required 8000 lb. of coal for a period of 24 hr. or 0.55 lb. per h.p.-hour. This figure is probably higher than will ordinarily be found necessary.

The lay-over losses as above noted are with reasonably tight ash pits and proper damper regulation.

The exact quantity of oil fuel required for maintaining full pressure is difficult to determine. Two per cent. of the fuel ordinarily used in generating a boiler's rated capacity will maintain the full steam pressure for an indefinite period. This 2 per cent., however, does not represent the total stand-by loss, for the reason that during lay-over periods the setting is cooled, and on taking a load again, the rate at which oil is burned will be, for a period after starting, considerably in excess of that rate when the setting has been brought up to its normal operating temperature.

Boiler Insurance and Inspection

(Charles S. Lake, in *The Locomotive*, Oct., 1910)

Insurance policies agree within certain limits to indemnify absolutely the assured's property, boilers, buildings, machinery or stock, and personal injuries for which the assured may be liable, provided such injuries and losses are caused directly by the explosion of the insured boiler. Boiler insurance policies do not cover fire, whether caused by an explosion or not.

Ordinarily, the insurance policy states what maximum working pressure the insured boiler may carry, though in some policies this is based upon inspectors' reports or certificates, this latter system allowing a change in working pressure during the life of a policy. An increase in the working pressure over that allowed makes a policy void in all instances.

Table 32. Summary of Defects Found in 352,674 Boiler Inspections Made in 1911

(Hartford Steam Boiler Inspection and Insurance Co.)

Nature of defect	Total	Dangerous	Nature of defect	Total	Dangerous
Cases of deposit of sediment	19,710	1,400	Cases of leakage around tubes	11,188	1,627
Cases of incrustation and scale	42,879	1,699	Tubes too light	1,901	521
Cases of internal grooving	2,756	305	Leakage at joints	5,417	373
Cases of internal corrosion	14,083	649	Water gages defective	3,447	773
Cases of external corrosion	9,755	898	Blow-offs defective	4,509	1,373
Defective braces and stays	2,485	545	Cases of deficiency of water	313	90
Settings defective	5,686	741	Safety valves overloaded	1,124	319
Furnace out of shape	7,191	397	Safety valves defective	1,225	329
Fracture of plates	3,479	440	Pressure gages defective	7,836	525
Burned plates	4,837	477	Boilers without pressure gages	532	71
Laminated plates	509	44	Unclassified defects	29	19
Cases of defective riveting	3,026	636			
Defective heads	1,349	234			
Cases of defective tubes	9,447	2,935	Total	164,713	17,410

The definition of an explosion, as covered by practically all policies, is "a violent separation of the metal or the component parts of the boiler," and the contract is usually extended to all water or steam pipes up to and including the first shut-off valve on each pipe. As a necessary provision of practically all policies, a statement is made to the effect that the explosion must be caused by steam pressure.

No company agrees in its policy contract to make inspection, though all policies provide that a company's inspectors be given reasonable opportunity to inspect insured boilers and appliances upon which their safety depends. All companies reserve the right to suspend insurance at any time.

The Hartford Steam Boiler Inspection & Insurance Co. in 1911 inspected 352,674 boilers in 180,842 visits of inspection, inspected 140,896 boilers both internally and externally, subjected 12,724 to hydrostatic pressure, and found 653 unsafe for continued insurance. The total number of defects discovered was 164,713, of which 17,410 were considered dangerous. Table 32 indicates the nature and proportion of the number of defects thus found.

Boiler-room Management

For any plant, a standard of operating efficiency should be set, and a knowledge of operating results should be secured through a continuous record of plant conditions.

Some of these records are: The amount of fuel burned; the calorific value; and the ash content of the coal used. The ash content compared with the actual weight of ash found acts as a check on the grate efficiency. The weight of water evaporated. A record of flue-gas analysis, which is important as a check on the furnace efficiency. The flue temperature, which serves as a check on stack losses, and in general indicates the state of cleanliness of the boiler heating surfaces. The feed temperature, which is an indication of the degree of utilisation of exhaust steam. Steam temperature, where superheated steam is used. Draft records, as an indication that proper draft conditions exist for the particular combustion rate necessary to correspond to the evaporation.

Recommendations Leading to Economy, Safety and Continuity of Service. When placing a new boiler in service, a quantity of soda ash should be placed within it, the boiler filled with water to its normal level and a slow fire started. After 12 hr. of slow simmering, the fire should be allowed to die out, the boiler cooled slowly and then opened and washed out thoroughly. Such a proceeding will **remove all oil and grease from the interior** and prevent the possibility of foaming and tube difficulties when the boiler is placed in service.

A **boiler** should not be **cut into** the **line** with other boilers until the pressure within it is approximately that in the steam main. The boiler stop valve should be opened very slowly until it is fully opened. The arrangement of piping should be such that there can be no possibility of water collecting in a pocket between the boiler and the main, from which it can be carried over into the steam line when a boiler is cut in.

The **water column** should be **blown down** thoroughly at least once on every shift and the height of water indicated by the glass checked by the gage-cocks. The bottom blow-offs should be kept tight. These should be opened at least once daily to blow from the mud drum any sediment that may have collected and to reduce the concentration.

In case of **low water,** resulting either from carelessness or from some unforeseen condition of operation, the essential object to be obtained is the **extinguishing of the fire** in the quickest possible manner. A method generally recommended is to cover the fire with wet ashes or fresh fuel. A boiler so treated should be cut out of line after such an occurrence and a thorough inspection made to ascertain what damage, if any, has been done before it is again placed in service.

The **efficiency and capacity depend** very largely **upon** the **cleanliness of the heating surfaces,** both externally and internally. The most efficient way of **blowing soot from** the **tubes** is by means of a steam lance, with which all parts of the surfaces are reached and swept clean. If permanent soot-blowing devices are fixed within the boiler setting, certain features must be watched to avoid trouble. If there is any leakage of water of condensation within the setting coming into contact with the boiler tubes, it will tend toward corrosion, or, if in contact with the heated brickwork, will cause rapid disintegration of the setting. If the steam jets are so placed that they impinge directly against the tubes, erosion may take place.

A large percentage of **tube losses is due** directly **to** the presence of **scale.** The **internal cleaning** can best be accomplished by means of an **air- or water-driven turbine,** the cutter heads of which may be changed to handle various thicknesses of scale. Where a water-driven turbine is used, it should be connected to a pump which will deliver at least 120 gal. per min. per cleaner at 150 lb. pressure. This pressure should never be less than 90 lb. if satisfactory results are desired. Where an air-driven turbine is used, the pressure should be at least 100 lb., though 150 lb. is preferable, and sufficient water should be introduced into the tube to keep the cutting head cool and assist in washing down the scale as it is chipped off.

Where scale has been allowed to accumulate to an excessive thickness, the work of removal is difficult and tedious. Where such a **heavy scale** is of sulphate formation, its removal may be assisted by filling the boiler with water to which there has been added a quantity of soda ash, a bucketful to each drum, starting a low fire and allowing the water to boil for 24 hr. with no pressure on the boiler. It should be cooled slowly, drained, and the turbine cleaner used immediately, as the scale will tend to harden rapidly under the action of the air.

Where **pitting** or **corrosion** is noted, the parts affected should be carefully cleaned and the interior of the drums should be painted with white zinc if the boiler is to remain idle. The cause of such action should be immediately ascertained and steps taken to apply the proper remedy. See p. 558.

Boilers should be taken out of service at regular intervals for **cleaning** and **repairs.** When this is done, the boiler should be cooled slowly, and, when possible, be allowed to stand for 24 hr. after the fire is drawn before opening. The cooling process should not be hurried by allowing cold air to rush through the setting, as this will invariably cause trouble with the brickwork. When a boiler is off for cleaning, a careful examination should be made of its condition, both external and internal, and all leaks of steam, water and air through the setting stopped. If water is allowed to come into contact with brickwork that is heated, rapid disintegration will take place. If water is allowed to come into contact with the metal of the boiler when out of service, there is a likelihood of corrosion.

If a boiler is to remain idle for some time, its deterioration may be much more rapid than when in service. If the period for which it is to be laid off is not to exceed 3 months, it may be filled with water while out of service. The boiler should first be cleaned thoroughly, internally and externally, all soot and ashes being removed from the exterior of the pressure parts and any accumulation of scale removed from the interior surfaces. It should then be filled with water, to which five or six pails of soda ash have been added, a slow fire started to drive the air from the boiler, the fire drawn and the boiler pumped full. In this condition it may be kept for some time without bad effects.

If the boiler is to be out of service for more than three months, it should be emptied, drained and thoroughly dried after being cleaned. A tray of quicklime should be placed in each drum, the boiler closed, the grates covered and a quantity of quicklime placed on top of the covering. Special care should be taken to prevent air, steam or water leaks into the boiler or on to the pressure parts, to obviate danger of corrosion. See also p. 558.

Cost of Boilers and Equipment. The cost of boilers and their equipment, in dollars per boiler h.p., for medium- and large-size plants varies roughly as follows: Boilers without setting, 8.00 to 11.00; superheaters about 3.00; stokers, 3.00 to 5.50; masonry setting, 2.00 to 3.50; flues, 0.75 to 1.50; stacks, 2.00 to 4.00; economisers, about 4.00; mechanical draft, about 3.00; feed pumps, 0.50 to 1.50; feed heaters, 0.40 to 1.00; piping and pipe covering, 6.00 to 10.00; coal chutes and ash hoppers, up to 1.25; miscellaneous, 0.50 to 1.00. The total costs average from \$30 to \$40 per boiler h.p.

THE STEAM ENGINE

BY

WILLIAM D. ENNIS

WORK AND DIMENSIONS OF THE STEAM ENGINE

Simple Engines Using Saturated Steam

Ideal Hyperbolic Diagram. Fig. 1 shows the **typical indicator diagram** *abcdef*. Nomenclature as to valve action is shown at the points *a*, *c*, *d* and *f*. Nomenclature as to behavior of steam is designated on the intervening lines. The **idealized diagram** on which design is based is *ghjkl*, which differs from the actual diagram in showing no clearance or compression, in extending between the throttle pressure *P* and atmospheric or condenser pressure *p*, in showing sharp corners at *h*, *j* and *k*, and in following the law, pv = constant, between *h* and *j*.

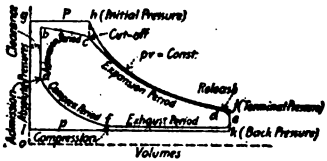

FIG. 1.—Typical Steam-engine Indicator Diagram.

Note the nomenclature adopted for pressures at *h*, *j* and *k*. The volume ratio $v_j \div v_k = R$ is called the **ratio of expansion.**

The average ordinate or **mean effective pressure** of the diagram *ghjkl* is, in lb. per sq. in.,

$$p_m = P\frac{(1 + \log_e R)}{R} - p, \tag{1}$$

in which *P* and *p* are taken in lb. per sq. in., absolute. Table 1 gives the ratio p_m/P for zero back pressure ($p = 0$) for various values of *R*.

Table 1. Ratio of Mean Effective Pressure to Initial Pressure for Various Ratios of Expansion (Zero Back Pressure)

Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)	Ratio of expansion, R	Ratio of mean to initial pressure (p_m/P)
1.67	0.907	3.33	0.662	6.67	0.435	18	0.216
1.82	0.874	3.64	0.631	7.00	0.421	20	0.200
2.00	0.847	4.00	0.597	8.00	0.385	22	0.186
2.22	0.810	4.44	0.561	10.00	0.350	24	0.174
2.50	0.766	5.00	0.522	12.00	0.290	26	0.164
2.67	0.744	5.71	0.481	14.00	0.260	28	0.155
2.86	0.717	6.00	0.465	16.00	0.236	30	0.147

Pressures and Expansion Ratios [for Equation (1)]. In ordinary practice, *P* ranges from 75 to 250. Common values for simple engines are from 95 to 115. For non-condensing engines exhausting to the atmosphere at sea level, *p* is between 15 and 17. For condensing engines, *p* is between 1 and 2½. The value 2 should be used in design (Ennis, "Vapors for Heat Engines," 1912, p. 38). If the exhaust steam from an engine is used for heating buildings or in manufacturing processes, *p* may have any value from 15 upward.

The value of *R* is commonly around 4 in simple engines. It should increase as *P* increases and as *p* decreases, being usually between 3 and 5. It should be higher in jacketed than in unjacketed engines. The efficiency of the engine depends largely on the value chosen for R (see pp. 954, 955; also see under "real" and "apparent" ratios of expansion, p. 941). High values of R will be adopted for an engine to be used where fuel is costly or the load steady. The overload capacity is similarly influenced: low values of R lead to high mean effective pressures—and hence to large output from a cylinder of given size—but also to low overload capacities. In general European practice cut-off is fixed so as to give $p_m = 1.2 + 0.2\,P$.

The **maximum overload capacity** (ratio of maximum excess load to the load for which the engine is designed) with unvarying pressure limits is

$$\frac{P - p}{\frac{P}{R} + \frac{P}{R}\log_e R - p} - 1 = \frac{P-p}{p_m} - 1 \qquad (2)$$

Upper Limits of Cut-off for Maximum Overall Efficiency and Least Steam Consumption (Hrabak)

Throttle pressure, lb. per sq. in. abs.	Non-condensing		Condensing		
	Simple		Simple		Compound
	Slide valve	Expansion valve	Unjacketed	Jacketed	
60	0.53–0.42	0.39–0.31	0.20–0.14	0.15–0.10	....
75	0.46–0.32	0.33–0.27	0.17–0.13	0.13–0.09	0.10–0.08
90	0.40–0.28	0.28–0.23	0.15–0.125	0.11–0.08	0.09–0.07
120	0.34–0.25	0.22–0.19	0.14–0.12	0.09–0.07	0.08–0.06
150	0.29–0.20	0.19–0.17	....	....	0.07–0.05

The higher values are for operation with maximum commercial efficiency; the lower values for minimum steam consumption. The higher values given are the upper limits (latest desirable cut-off) and apply with such conditions as small engines, cheap fuel and intermittent operation; with large engines, high-priced fuel and continuous operation, the cut-off for maximum commercial efficiency should be made earlier.

Mean Effective Pressures Realized. The values of p_m, obtained from (1), are multiplied by a **diagram factor**, f, always less than 1.0, to obtain the mean effective pressure likely to be realized in the actual engine. The value of f is always between 0.45 and 0.95 and usually between 0.80 and 0.95. Values given by Seaton are

Type of Engine	f
Independent cut-off, cylinder jacketed....................	0.90
Single valve, automatic cut-off, cylinder jacketed............	0.86 to 0.88
Single valve, automatic cut-off, without jacket...............	0.77 to 0.82
Unjacketed throttling engines of small size and high speed....	0.58 to 0.77

The following summarizes the principal influences which determine the value of f:

Influence	Effect on the Value of f
Governing by throttling as compared with cut-off regulation....................................	decrease 0.10 to 0.25
Jackets..	increase 0.05 to 0.15
Very early cut-off (prior to ⅛ stroke)............	decrease 0.025 to 0.125
High speed (above 225 r.p.m.).................	decrease 0.025 to 0.10
Excessive clearance (over 5 per cent.)...........	decrease up to 0.08
Abnormally small ports and passages..............	decrease 0.025 to 0.10
Interrelated valve movements (as with a single valve)....................................	decrease 0.025 to 0.175

Cylinder Dimensions.

$$\text{h.p.} = \frac{fp_mAS}{33{,}000} = \frac{fp_mALN}{16{,}500} = fp_mK \qquad (3)$$

$$A = \frac{33{,}000 \times \text{h.p.}}{fp_mS} = \frac{16{,}500 \times \text{h.p.}}{fp_mLN} \qquad (4)$$

in which

h.p. = indicated horse-power to be expected from the engine,
A = average effective area of the piston, sq. in.,
L = stroke of piston, ft.,
N = revolutions per minute (r.p.m.),
S = $2LN$ = piston speed, ft. per min.,
K = $ALN/16{,}500 = AS/33{,}000$, a constant for a given engine.

In an ordinary double-acting engine, A is the cross-sectional area of the cylinder *minus* half the cross-sectional area of the piston rod. When a tail rod is used, the deduction is the whole cross-sectional area of the rod.

Piston Speed, Revolutions per Minute [for Equation (4)]. Values of S range from 500 upward, with 800 as the usual limit excepting in very large engines. The higher the value of S the greater is the power realised from an engine of given size; or the less is the weight, size and cost of an engine of given power. With very high values of S the question of port size and arrangement becomes especially important. Maximum values of S usually accompany maximum values of L.

The value of N is chiefly limited by the type of valve and gear. It may be fixed by the mode of application of the power. Releasing-gear engines seldom run over 100 r.p.m. Rotary-valve engines without releasing gear may work up to N = 240. Ordinary slide- and piston-valve engines may run as fast as 350 r.p.m.; the Porter-Allen engine (see p. 976) runs up to 600 r.p.m.; poppet-valve engines to 225 r.p.m. for horizontal and 350 r.p.m. for vertical engines. Large engines with releasing gear almost always run between 80 and 100 r.p.m. Small engines generally employ maximum values of N for the type of valve gear used. At 24-inch stroke, the speed with any type of valve gear seldom exceeds 175 r.p.m.

Strokes of engines running around 100 r.p.m. vary from 1½ to 3 times the piston diameter, the ratio being less with larger-size engines. In engines running above 150 r.p.m., the stroke is short, usually about equal to the diameter. Pumping engines, which must run at low piston speeds, have long strokes, and even then the value of N is abnormally low. Long strokes favor low clearances.

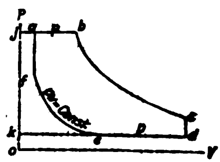

FIG. 2.—Modified Hyperbolic Diagram.

Modified Hyperbolic Diagram. In Fig. 2, the ideal diagram *abcdef* includes the influences of clearance and compression, and thus more closely approximates the indicator card than the diagram of Fig. 1. The mean effective pressure is

$$p_m = \frac{P}{R}(1 + c - cR) + \frac{P}{R}(1 + c)\log_e R - p[1 + c(1 - R_c)] - pR_c c \log_e R_c \qquad (5)$$

in which c = proportion of clearance = $v_a/(v_e - v_a)$, R_c = ratio of compression = v_a/v_f. When Equation (5) is used for p_m, corresponding values of f are usually between 0.90 and 1.0.

Clearance depends upon the size of the engine, its ratio of diameter to stroke, and the type and location of valves. The **clearance volume** includes all spaces between the piston and the valve faces, when the former is at the (adjacent) end of its stroke. The **linear clearance** (distance from piston to cylinder head) may account for only a small part of the total clearance volume. The clearance volumes at the two ends of the cylinder are usually unequal. Designers aim to **keep clearance low.** This is more important in simple engines than in compounds, and is most important with high ratios of expansion. In the low-pressure cylinders of compounds, clearances are relatively high, on account of the large ports.

Clearance data	Percentage of piston displacement
Extreme range	1 to 15
Range with	
Flat slide valves at the side of the cylinder	5 to 10
Piston valves " " " " " "	7 to 15
Corliss valves	2 to 8
Poppet valves, mean for 1000 h.p. (Lens)	4
Flat or piston valves in the cylinder heads	2 to 7
High-speed engine } comparative values	8 to 12
Slow-speed engine } comparative values	4 to 6

"Real" and "Apparent" Ratios of Expansion. The ratio $(v_e - v_a)/(v_b - v_a)$, Fig. 2, is the "apparent" ratio of expansion. Following the notation of Equation (5), its value is

$$R_a = R/(1 + c - Rc) \tag{6}$$

and

$$R = (R_a c + R_a)/(R_a c + 1) \tag{7}$$

Engines are usually designed by assuming R_a and c, and then finding R from Equation (7).

Table 2. Real Ratio of Expansion
[Values of R calculated from Equation (7)]

Apparent ratio, R_a	Fraction of stroke at which cut-off occurs	Clearance, per cent. (= 100 c)							
		1	2	3	4	5	6	8	10
10	0.10	9.18	8.50	7.92	7.43	7.00	6.63	6.00	5.50
8⅓	0.12	7.77	7.30	6.86	6.50	6.18	5.89	5.40	5.00
7 1/7	0.14	6.73	6.37	6.06	5.78	5.53	5.30	4.91	4.58
6¼	0.16	5.94	5.67	5.42	5.20	5.00	4.82	4.50	4.23
5	0.20	4.81	4.64	4.48	4.33	4.20	4.08	3.86	3.67
4	0.25	3.88	3.77	3.68	3.58	3.50	3.42	3.27	3.14
3⅓	0.30	3.26	3.19	3.12	3.06	3.00	2.94	2.84	2.75
2½	0.40	2.46	2.43	2.40	2.36	2.33	2.30	2.25	2.20
2	0.50	1.98	1.96	1.94	1.92	1.90	1.89	1.86	1.83
1⅔	0.60	1.66	1.65	1.64	1.63	1.62	1.61	1.59	1.57

Compression has for an **extreme limit** the condition $p_f = p_a$, Fig. 2. Values of R_c, Equation (5), reach a maximum at normal values of R, falling off at extreme values. The "apparent" compression ratio $(v_e - v_f)/(v_c - v_a)$ varies from 0.08 to 0.65 at 7 per cent. clearance. Where Equation (4) is used in design, compression is regarded only as influencing the value of f. These values are low for high-speed engines partly because such engines use excessive compression. They are low for single-valve engines because such engines have high compression at light loads (see p. 970). Practical limits of value of p_f, Fig. 2, may be taken at $0.7(P - p) + p$ for high-speed and $0.1\ (P - p) + p$ for low-speed engines.

Illustrative Design. Assume a simple condensing engine to develop 500 i.h.p. at 115 lb. initial absolute pressure, with an overload capacity of about 0.80, the engine to have Corliss valves and to be unjacketed.

First, assume a piston speed of 800 ft. per min. and 2 lb. back pressure, the engine being double-acting. Also 100 r.p.m. as an allowable rotative speed (p. 940).

From Equation (2), $0.80 = [(115 - 2)/p_m] - 1$, or $p_m = 62.9$. Also, $p_m/P = 62.9/115 = 0.547$. Table 1 shows that this ratio is obtained when R is slightly over 4.5. To be on the safe side, make $R = 4.5$. Then, from Equation (1) $p_m = [(115/4.5) \times (1 + \log_e 4.5)] - 2 = 62$.

From p. 939, the value of f for an unjacketed Corliss engine may be taken at 0.85. Applying Equation (4), $A = (33{,}000 \times 500)/(0.85 \times 62 \times 800) = 390$ sq. in. If the piston-rod diameter be assumed to be 1/10 the diameter of the piston, the latter is $\sqrt{(4 \times 390 \times 200)/199\pi} = 22.4$ in.

The stroke is $L = S/2N$ [nomenclature of Equation (4)] or $800/200 = 4$ ft. The engine is 22.4 by 48 in. Its piston-rod diameter must be not far from 2.24 in. Its apparent ratio of expansion with, say, 4 per cent. clearance (p. 941) is, from Equation (6), $4.5/[1 + 0.04 - (4.5 \times 0.04)] = 5.22$: or, cut-off will occur at $1/5.22 = 0.191$ of the stroke. The ratio of stroke to piston diameter is $48/22.4 = 2.15$ (see p. 940). The probable mean effective pressure in the actual engine is $0.85 \times 62 = 52.8$ lb. per sq. in. With p_f, Fig. 2, $= 15$, Equation (5) would have given an ideal mean effective pressure of 58.3 lb. The diagram factor which would just reduce this to the value here employed would be $52.8/58.3 = 0.905$ (see p. 939).

Simple Engines Using Superheated Steam

The ideal diagram of Fig. 2 represents the action of a simple engine using highly superheated steam, excepting that the expansion curve bc no longer approximates the hyperbolic. Its equation is, pv^n = constant, where n has a value depending on the amount of superheat and the ratio of expansion, as follows:

Ratio of Expansion	Superheat, deg. fahr. 200	250	300	350	400	450	500
	Values of exponent n						
8.0	1.05	1.07	1.09	1.11	1.13	1.15	1.18
7.0	1.06	1.08	1.10	1.12	1.14	1.16	1.19
6.0	1.07	1.09	1.11	1.14	1.16	1.18	1.21
5.0	1.08	1.10	1.12	1.15	1.17	1.19	1.22
4.0	1.09	1.11	1.13	1.16	1.18	1.20	1.23
3.0	1.10	1.12	1.15	1.17	1.20	1.22	1.25

With nomenclature as in Equations (5) and (6), the **mean effective pressure** is (8)

$$p_m = \frac{P}{R_a} + \frac{P}{n-1}\left(\frac{1 + cR_a}{R_a} - \frac{1+c}{R^n}\right) - p\left\{1 + c(1 - R_c)\right\} - cpR_c \log_e R_c$$

compression being assumed to be still hyperbolic. With $n > 1.0$ this equation gives values always less than those by Equation (5), as the latter gives values less than those by Equation (1). **Diagram factors** will be usually between 0.95 and 0.98, though throttling, excessive speed, large clearance, restricted ports and passages or interrelated valve movements may cause fluctuations as listed on p. 939. Jackets are not used. Ratios of expansion may be 40 per cent. higher than with saturated steam, without reduction of diagram factor. Piston speeds may be higher without causing undue port friction. Corliss valves are rarely if ever used with high superheat: the gridiron slide, poppet or piston valve may be employed.

Having determined fp_m, the **cylinder dimensions** are obtained from Equation (4).

With slight superheat, Equation (1) is used for determining p_m, and the value of f will be governed by the considerations of p. 939, superheating being here regarded as equivalent to jacketing.

Compound Engines

Preliminary Diagram. In Fig. 3 let the ideal diagram $habg$ correspond with $ghjkl$ of Fig. 1. The diagrams differ in that with the former the terminal pressure equals the back pressure. There is no "terminal drop" (jk, Fig. 1). In Fig. 3, the line bg represents the flow of steam, without fall of pressure, from the "high-pressure" cylinder to the "receiver." The latter in turn delivers steam to a "low-pressure" cylinder, the action of which is represented by the diagram $gbcef$. The two cylinders constitute a compound engine.

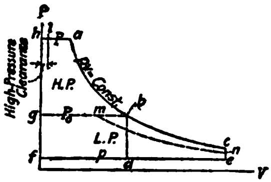

FIG. 3.—Ideal Diagram for Compound Engine.

To avoid noticeable fluctuations of pressure along gb, the receiver must be large, from ½ to 1½ times the size of the high-pressure cylinder; the former ratio being used for tandem engines, the latter for cross-compounds, in which the cranks are usually 90 deg. apart.

Maximum stresses are greater in tandem engines than in cross-compounds, and close regulation of speed is more difficult. On the other hand, the tandem costs less and occupies less space.

If this ideal diagram correctly represented the action, then a single simple cylinder of the same size as the low-pressure cylinder of the compound, working between the same extreme pressure limits and with the same ratio of expansion $R = v_c/v_a$, would give the diagram $hacef$. The simple cylinder would give the same power, then, as the compound engine.

Basis for Design. The diagram $hacef$ of Fig. 3 and the output of the whole engine are determined when P, p and R ($= v_c/v_a$) are given. The proportion of work done by each cylinder depends upon the receiver pressure, P_o. The designer may proceed in any one of five ways:

(1) The **receiver pressure** may be **assumed.**

(2) The **temperature ranges** may be made **the same** in both cylinders. This is probably the best basis with modern high initial pressures. Then $T_b = (T_a + T_e)/2$, where T_b, T_a and T_e are (for saturated steam) the temperatures corresponding respectively with the pressures P_o, P and p, from which T_b and P_o may be found.

(3) The **cylinders** may develop the **same power,** in which case

$$\log_e P_o = \tfrac{1}{2}\left(\log_e R + \frac{Rp}{P} - 1\right) - \log_e \frac{R}{P} \tag{9}$$

(4) The total maximum **piston pressures** may be **equalized,** when

$$P_o = P^2/(P + P_oR - pR) \tag{10}$$

(5) The **ratio of volumes** of the **cylinders** may be assumed, as $C = v_c/v_b$;

$$P_o = CP/R \tag{11}$$

Mean Effective Pressures. Having determined P_o by any one of these five methods, and having noted the corresponding value of $C = RP_o/P$, the **approximate mean effective pressures** are, based on Fig. 3,

high-pressure, $p_{mh} = [P/R_h] \log_e R_h = [PC/R] \log_e R_h$ (12)

low-pressure, $p_{ml} = [(P_o/R_l)(1 + \log_e R_l)] - p = [(P/R)(1 + \log_e C)] - p$ (13)

where R_h = ratio of expansion in high-pressure cylinder $= v_b/v_a$;

R_l = ratio of expansion in low-pressure cylinder $= v_c/v_b = C$;

other symbols being as in Equation (1).

Discussion of Factors. The value of C is usually from 3 to 4 in non-condensing and from 4 to 5 in condensing engines. It should vary directly with R. If it is made too great, the engine will, though probably economical of steam (p. 956), be costly to build and deficient in overload capacity; for the maximum power of the engine, working as a compound, is obtained when $R = C$, the low-pressure cylinder receiving steam at full boiler pressure, and the high-pressure doing no work. In usual practice, the low-pressure cylinder is not built to withstand full boiler pressure, but only a lower pressure P_1, which is realised either by raising the receiver pressure to P_1 or (in unusual emergencies) by running the two cylinders as two simple engines between the pressure limits P and p and P_1 and p, respectively. The maximum overload capacities for the two cases [defined as in Equation (2)] with the high-pressure cylinder receiving steam throughout the stroke are respectively

$$\frac{\dfrac{P_1}{C}\left(\dfrac{P}{P_1} + \log_e C\right) - p}{\dfrac{P}{R}(1 + \log_e R) - p} - 1, \qquad (14) \qquad\qquad \frac{\dfrac{P - p}{C} + P_1 - p}{\dfrac{P}{R}(1 + \log_e R) - p} - 1 \qquad (15)$$

In the latter case there is no cut-off in either cylinder.

At a fixed ratio of expansion R, the output of the engine is independent of the size of the high-pressure cylinder. Exceptionally high efficiencies have been obtained with values of C around 6 or 7 (see p. 956). When on account of having reached the limit of size (about 100 in. diameter), more than one low-pressure cylinder is used, the value of C is the ratio of the combined volumes of the low-pressure cylinders to that of the high-pressure cylinder. Following are proposed values of R for maximum thermal efficiency in compound condensing engines with initial pressure P, lb. per sq. in. abs. See also p. 945, under "Size of Cylinder."

P....	90	120	150	180	200	220	250	275
R....	10 to 13	11 to 14	13 to 17	16 to 21	19 to 23	22 to 27	25 to 32	28 to 36

P will range from 115 to 265, preferably not under 165 for condensing engines. Values of p, non-condensing, are from 15 to 17; condensing, 1 or 2, but preferably 1. Half the tabulated values of R may be used for compound non-condensing engines. Generally, in such engines, p_c is between 18 and 25 lb., increasing as P increases. The use of jackets warrants high values for R. High values are indicated when fuel is costly or the load is steady.

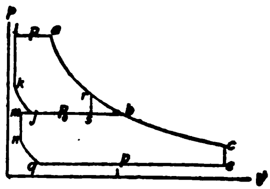

FIG. 4.—Diagram for Compound Engine with Clearance and Compression.

Definitive Diagram. Equations (12) and (13) may be employed in connection with Equation (4) for the immediate determination of **cylinder dimensions.** Some refinement is added by considering the diagrams *labjk*, *mbceqn*, Fig. 4, in which the effects of clearance and compression are included. With these diagrams,

$$p_{mh} = (Pc_h/R_h)[\log_e R_h - R_h + R_{hc}(1 - \log_e R_{hc})] + (P/R_h)\log_e R_h \qquad (16)$$

$$p_{ml} = (P/R)(1 + c_l - c_lR_l) + (P/R)(1 + c_l)\log_e R_l - p[1 + c_l(1 - R_{lc})] - pR_{lc}c_l\log_e R_{lc} \qquad (17)$$

in which $c_h = v_l/(v_b - v_l)$ = clearance of high-pressure cylinder;

$R_h = v_b/v_a = P/P_e$ = real ratio of expansion, high-pressure cylinder;

$R_{hc} = v_j/v_k = p_k/P_o$ = real ratio of compression, high-pressure cylinder;

$c_l = v_m/(v_c - v_m)$ = clearance of low-pressure cylinder;

$R_l = v_c/v_b = C = P_oR/P$ = real ratio of expansion, low-pressure cylinder;

$R_{lc} = v_q/v_n = p_n/p$ = real ratio of compression, low-pressure cylinder;

nomenclature being otherwise as in Equations (12) and (13). Also,

$p_h = 0.1(P - P_o) + P_o$ for slow speeds up to $0.4(P - P_o) + P_o$ for high speeds;

$p_n = 0.1(P_o - p) + p$ for slow speeds up to $0.3\ (P_o - p) + p$ for high speeds.

Clearances in compound engines are about the same, proportionately, as in simple engines. Usually $c_l > c_h$.

Diagram Factors for compound engines expanding R times are about the same as those for simple engines with the $\sqrt{R}$ ratio of expansion (see p. 939). High compression and excessive clearance reduce the value of f less than they do in simple engines. The value of f for Equations (16) and (17) may be taken at 0.92 to 1.0. Superheat less than 150 deg. fahr. may be regarded as equivalent to jackets. Excessive terminal drop in the high-pressure cylinder (p. 946) reduces the value of f. The use of a reheater between the cylinders is assumed; its omission may reduce the value of f by 0.05.

Size of Cylinder. Given f, p_{mh}, p_{ml},

$$\text{h.p.} = (LNA_lf/16{,}500)[(p_{mh}/C) + p_{ml}] \tag{18}$$

$$A_l = (\text{h.p.} \times 16{,}500)/LNf[(p_{mh}/C) + p_{ml}] \tag{19}$$

$$A_h = A_l/C$$

where A_h and A_l denote the net piston areas, other symbols being as in Equations (3) and (17). (The strokes of the pistons are usually equal, although other obvious methods of arrangement are possible.) The quantity $[(p_{mh}/C) + p_{ml}]$ is **the mean effective pressure referred to the low-pressure cylinder** ("equivalent mean effective pressure"). This important design constant is usually between 23 and 31 lb. in present power-station practice. In Europe, it is about $1.2 + 0.05\ P$ for best thermal efficiency, increasing to $1.2 + 0.12\ P$ for best commercial efficiency, in condensing engines. The outputs of the two cylinders will have the ratio

$$(\text{h.p.}_h/\text{h.p.}_l) = (p_{mh}/Cp_{ml}),\ \text{where h.p.}_h + \text{h.p.}_l = \text{h.p.} \tag{20}$$

Note also that $2LN = S$. Values for L, N and S are as given on p. 940. Common values of p_{ml} in stationary practice are between 8 and 15; with the usual division of work and cylinder ratio the corresponding values of $(p_{mh}/C + p_{ml})$ are from 24 to 32.

Illustrative Design. To outline a **500-i.h.p. compound engine,** condensing, with reheater, without jackets, piston speed 800 ft., r.p.m. 100, releasing gear, $P = 120$, $p = 2$, $R = 25$, the maximum pressure allowable in the low-pressure cylinder being 60 lb.

From Table 1 (interpolating) for $R = 25$, $p_m/P = 0.169$, or $p_m = 0.169 \times 120 = 20.2$ which, less back pressure p ($= 2$) gives the equivalent mean effective pressure as 18.2. Using $f = 0.9$, this gives in Equation (19),

$$A_l = (16{,}500 \times 500)/(4 \times 100 \times 0.9 \times 18.2) = 1260 \text{ sq. in.},$$

while A_h may have any value whatever. If temperature ranges are to be equalized, the steam table and p. 943 give $T_b = (T_a + T_c)/2 = (341 + 126)/2 = 233.5$ and $P_o = 22$, which would make $C = RP_o/P = (22 \times 25)/120 = 4.6$. If maximum piston pressures are equalized, $P_o = 120 \times 120/(120 + 25P_o - 50)$ and $P_o = 22.7$ [Equation (10)]. Again, if the two cylinders are to develop equal power, Equation (9) gives $\log_e P_o = [(2.3 \log 25 + 0.417 - 1)/2] - 2.3 \log 0.208$, whence $P_o = 17.8$, which would make $C = 3.7$. This is a reasonable value for the low initial pressure prescribed, and will be adopted. Following Equations (14) and (15), the overload capacities are (a) working compound, with increased receiver pressure and no high-pressure cut-off,

$$\frac{\frac{60}{3.7}\left(\frac{120}{60} + 2.3 \log 3.7\right) - 2}{\frac{120}{25}\left(1 + 2.3 \log 25\right) - 2} - 1 = 1.85;$$

or (b) with both cylinders running without expansion and exhausting to the atmosphere,

$$\left[\left(\frac{120-2}{3.7}+60-2\right)\Big/\left\{\frac{120}{25}\left(1+2.3\log 25\right)-2\right\}\right]-1=3.92.$$

Using Equations (16) and (17), and assuming $c_h = 0.025$, $c_l = 0.03$, p_b (Fig. 4) $= P_o$, $p_n = 0.1(P_o - p) + p = 3.6$,

$$p_{mh} = 32.3,\quad p_{ml} = 8.8,\quad R_{ho} = 1.0,\quad R_{lo} = 1.79,\quad (p_{mh}/C) + p_{ml} = 17.6,$$

the last result being of course somewhat below 18.2, found from Table 1. Using 18.2, with $f = 0.90$ [the corresponding value of f for Equations (16) and (17) would be $(18.2/17.6) \times 0.90 = 0.93$], the low-pressure piston area is 1260 sq. in., that of the high-pressure piston is $1260/3.7 = 340$ sq. in., the stroke is 48 in., and Equation (20) gives the check result that the cylinders develop equal amounts of power.

Receiver Steam Used for Heating. When the receiver delivers part of its steam for heating or process work, the action is as suggested by the diagrams *habg*, *gmnef*, Fig. 3, and the mean effective pressure of the low-pressure cylinder becomes

$$p_{ml} = \frac{P_o}{C}(1-x)\left(1+\log_e\frac{C}{1-x}\right)-p \qquad (21)$$

where x is the proportion of steam supplied to the high-pressure cylinder which is drawn off for heating. Equations (18) and (19) should then be used in design. A simple engine should be used if a large amount of low-pressure waste steam can be utilized.

Superheated Steam in Compound Engines. With superheat exceeding 150 deg. fahr., Equations (12), (13), (16) and (17) are invalid. The curve *abc*, Fig. 3, may be represented by pv^n = const., the value of n for the R ratio of expansion being that given on p. 942 for a simple engine in which the ratio of expansion is $\sqrt{R}$. **For equal division of work between the cylinders,**

$$C = \left[\frac{1}{2n}\left\{\frac{p}{P}R^n(n-1)+nR^{n-1}+1\right\}\right]^{\frac{1}{n-1}},\ \text{and}\ P_o = P\left(\frac{C}{R}\right)^n \qquad (22)$$

Applying this to Fig. 3,

$$p_{mh} = \frac{n}{n-1}\left(\frac{P}{R_h}-P_o\right),\quad p_{ml} = \frac{P_o n}{C(n-1)}-\frac{P}{R^n(n-1)}-p \qquad (23)$$

With these mean effective pressures, the value of f to be employed is that for a jacketed simple engine expanding $\sqrt{R}$ times (see p. 939).

Governing Compound Engines: High-pressure Terminal Drop. In early (Woolf) compound engines, without a receiver, the arrangement was necessarily either tandem or opposed and the low-pressure cylinder admitted steam throughout the full stroke. Present-day engines may have the pistons out of phase, the receiver and pipes storing steam between the cylinders; and the low-pressure cylinder works expansively while the division of work between the cylinders is controlled by variation of receiver pressure.

In Fig. 4, *larsjk* and *mbceqn* represent the action with "terminal drop" (*rs*) in the high-pressure cylinder. Such drop occurs whenever the high-pressure terminal pressure (at r) exceeds the receiver pressure. Its effect is to reduce the value of f, say, by about 0.05.

If an engine with any definite amount of drop at normal load has a fixed point of low-pressure cut-off, increase of load will increase the receiver pressure and the proportion of work done by the low-pressure cylinder without changing the drop. German engines are thus designed, with rather low values of C.

With variable low-pressure cut-off, as in American practice, delay in such cut-off lowers the receiver pressure and increases the drop, without any appreciable influence on the output of the whole engine. The output of the low-pressure cylinder is decreased because of the reduced receiver pressure, in spite of its later point of cut-off. The output of the whole engine is increased by delaying high-pressure cut-off. The division of work between the cylinders may then be kept equal by also delaying low-pressure cut-off; but this will cause increased drop.

Whether any **drop** should be permitted **at normal load** is a controverted subject (see B. C. Ball, *Trans. A. S. M. E.*, vol. xxi, p. 1002). There should certainly be none in an engine intended for frequent overload conditions. To eliminate drop at normal load, the normal point of low-pressure cut-off must be fixed to suit the type of engine, size of receiver and cylinder ratio. The graphical determination is described by Ennis in "Applied Thermodynamics for Engineers," chap. xiii. For **tandem compounds,** $R_{la} = (QC + 1)/(Q + 1)$, and for **cross compounds** with normal low-pressure cut-off not later than half stroke, $Q[(C/R_{la}) - 1] = 0.5 - (\sqrt{R_{la}} - 1/R_{la})$, where R_{la} = apparent ratio of expansion in low-pressure cylinder $= (v_c - v_m)/(v_b - v_m)$, Fig. 4, Q = ratio of receiver volume to volume displaced by high-pressure piston, and C = cylinder ratio.

Triple and Quadruple Engines

In Fig. 5, the **ideal diagrams** for a triple engine are 1234, 4378 and 87*a*09. For a quadruple, let the middle diagram be divided into 4365 and 5678, the pressures noted being absolute pressures. For equalization of work,

$$\left.\begin{array}{l} \log_e P_1 = \log_e P - \dfrac{\log_e R}{3} + \dfrac{pR}{3P} - \dfrac{1}{3}, \\ P_2 = \dfrac{P_1^2}{P}, \qquad C_2 = \dfrac{v_7}{v_3} = \dfrac{P_1}{P_2}, \qquad C_3 = \dfrac{v_a}{v_7} = \dfrac{P_2}{P_a} = \dfrac{P_2R}{P}, \end{array}\right\} \text{in triples;}$$

$$\left.\begin{array}{l} \log_e P_1 = \log_e P + \dfrac{pR}{4P} - \dfrac{\log_e R}{4} - 0.25, \\ P_1 = \sqrt{PP_2}, \quad P_2 = \sqrt{P_1P_3}, \quad C_2 = \dfrac{P_1}{P_2}, \quad C_3 = \dfrac{P_2}{P_3}, \quad C_4 = \dfrac{P_3R}{P}, \end{array}\right\} \text{in quadruples;}$$

in which C_2, C_3, C_4 denote the successive cylinder ratios. (Equalization of maximum total piston pressures is a more common requirement in marine design.) The **equivalent mean effective pressures referred to the low-pressure cylinder** are,

$$\text{for triples, } p_e = \frac{P}{R}\left(\log_e \frac{P}{P_1} + \log_e \frac{P_1}{P_2} + \log_e \frac{P_2R}{P} + 1\right) - p;$$

$$\text{for quadruples, } p_e = \frac{P}{R}\left(\log_e \frac{P}{P_1} + \log_e \frac{P_1}{P_2} + \log_e \frac{P_2}{P_3} + \log_e \frac{P_3R}{P} + 1\right) - p.$$

European designers keep this value around $1.2 + 0.05\,P$ for ordinary engines, or $1.5 + 0.07\,P$ for marine triples with large drop. The **diagram factor,** f, is that for a simple engine of $\sqrt{R}$ expansions, and the **low-pressure piston areas** are $A_3 = 33{,}000 \times \text{h.p.}/fSp_e$ for triples and $A_4 = 33{,}000 \times \text{h.p.}/fSp_e$ for quadruples. Values of R range from 20 to 36. **The terminal pressure** P_a, Fig. 5, should be between 7 and 10 lb. (condensing). **Cylinder ratios are about** $\sqrt[m]{R}$, where m denotes

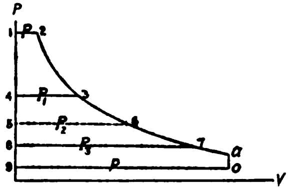

FIG. 5.—Ideal Diagrams for Triple and Quadruple Engines.

the number of expansive stages; they may successively somewhat increase, *e.g.*, $C_3 > C_2$. The overall cylinder ratio varies as the initial pressure.

Factors Beyond the Cylinder

Mechanical Efficiency. The power lost in friction, f.h.p., may be regarded as constant (see p. 960), so that the brake horse power, b.h.p., is i.h.p. − f.h.p. at all loads. The mechanical efficiency at full load is

$$M = \text{b.h.p./i.h.p.} = (\text{i.h.p.} - \text{f.h.p.})/\text{i.h.p.}$$

i.h.p. being taken at full load. **As** the **load increases,** the **mechanical efficiency** steadily **increases.** At the Q proportion of full rated load, it is

$$M_1 = (Q + M - 1)/Q$$

The **commercial efficiency** of the engine is determined jointly by its thermal and mechanical efficiencies, and the most economical ratio of expansion is commercially somewhat less than that which gives highest thermal efficiency. From a standpoint of capacity alone, moreover, the maximum practicable value of R is determined by the expression

$$\frac{P}{R} - p = (1 - M)\left[\frac{P(1 + \log_e R)}{R} - p\right] \qquad (24)$$

Values of M range from 0.82 to 0.97, tending to vary inversely with the initial pressure, the number of cylinders, number of journals and size of journals, and directly with the size of engine and the ratio of mean effective to maximum pressure. These variations are obscured by the factors of workmanship and lubrication, so that definite values for standard types of engine cannot be given.

Non-rotative Engines (direct-acting pumps) must give a fluid pressure p_p (lb. per sq. in.) in the pump at the lowest steam pressure, p_s (lb. per sq. in.). If A_p and A_s are the respective pump and steam cylinder areas, $p_pA_p = Mp_sA_s$. In duplex pumps or where inertia may be depended on, p_s may be taken as the fp_m of Equation (3), providing P is the lowest pressure likely to be reached under plant operating conditions. With a single cylinder and no inertia, p_s may be as low as fP/R, the value of R for ordinary small pumps, running almost without expansion, being taken at 1.5.

Traction and Hoisting Engines. In a double-acting single-cylinder engine

$$F = p_m ASM/S_1 \qquad (25)$$

where F = tractive or hauling force exerted, in lb.; p_m = average net piston pressure (the mean effective pressure, in expansive engines), lb. per sq. in., A = piston area, sq. in., S = piston speed, ft. per min., M = mechanical efficiency, and S_1 = speed of part at which the tractive force is applied—the peripheral speed of locomotive drivers or of hoisting engine drum—ft. per min.

Cost of Engines

(See also pp. 1102 to 1104)

Prices per horse power range from $4 to $30, increasing with the number of expansive stages and the ratio of expansion. Prices per lb. vary from 6 to 10 cents, or higher, inversely with the size. The more economical engines are generally higher priced. At present (1916), engines are relatively cheap. Comparative costs per i.h.p. are as follows (Gebhardt):

Simple high speed, $8 to $11
Installation of same, $0.80 to $1.35
Compound high speed, $16 to $25
Compound low speed, $13.40 to $23
Simple low speed, $11 to $20
Installation of same, $1.80 to $6.30

Depreciation on low-speed engines is 3 to 5 per cent. annually; on ordinary high-speed engines, 5 to 10 per cent.

STEAM-ENGINE ECONOMY

Variables Affecting Economy

The influences which determine steam-engine efficiency may be studied partly by thermodynamic analysis and partly by experiment. Both methods are here employed.

Initial Pressure. The efficiency varies directly with the initial pressure. With slight expansion the variation is unimportant. At high ratios of expansion, high initial pressures have marked influence on efficiency. The **ideal economies** of Tables 3 to 8, computed for **adiabatic expansion** and **no compression,** illustrate these points. The results of varying initial pressure with superheated steam are shown in Tables 5 to 8. In condensing engines with superheat, high pressure is less important than in non-condensing engines.

Fig. 6 gives typical experimental results. The "total steam" lines illustrate the **Willans Law**, that at fixed cut-off and variable initial pressure the steam consumed per hour is $a + bh$, where h = i.h.p. and a and b are constants. Simple non-condensing engines, as built in this country, with initial pressures seldom much over 100 lb., use 24 to 28 lb. of steam per i.h.p-hr. The corresponding steam rates in German practice with 150 to 180 lb. steam pressure, are 19 to 23 lb.

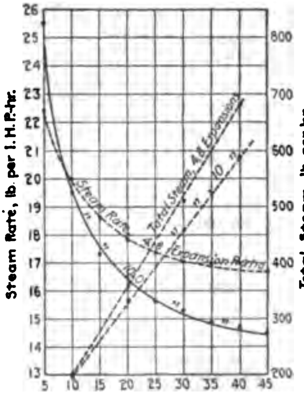

FIG. 6.—Diagram Illustrating Willans' Law of Steam Consumption.

Initial Dryness. Thermodynamic analysis shows that no variation of moisture content at the throttle to be reasonably expected can have appreciable influence on economy. The experimental evidence leads to an even bolder statement. Carpenter and Marks (*Trans. A. S. M. E.*, vol. xv) have shown that the **introduction of water** in proportions from 1 to 42 per cent. is practically **without influence on** the **dry steam consumption.** The water remains inert, neither helping nor hindering.

Superheat. Tables 5 to 8 show that **superheat increases efficiency,** and that ideally the efficiency is very nearly in direct proportion to the amount of superheat. In practice, superheat is justified by its **influence on cylinder condensation** rather than on thermodynamic grounds. Cylinder condensation is practically eliminated when the steam is kept dry at the point of cut-off. This requires ordinarily about 150 deg. (fahr.) of superheat (Ripper, "Steam Engine Theory and Practice," 1905, p. 150). The gain by superheating is progressive, probably up to that point at which the exhaust becomes superheated. **Factors favoring superheat** are slow speed, high ratios of expansion, high fuel cost and steady load.

With constant initial pressure and constant superheat, the total hourly steam consumption varies directly with the output (Ripper, *op. cit.*, p. 151; see Fig. 7). Experiments on H.M.S. "Brittania" show, moreover (Fig. 8), that the variation with load in overall efficiency of plant is about the same with saturated as with superheated steam.

The tests quoted in Table 9 show, in general, an increase in economy with

increasing superheat. This is illustrated (for compound condensing engines) in Fig. 9. High superheat (to a temperature of 600 deg. fahr.) causes a saving of about 20 per cent. in simple engines, 16 per cent. in compounds and 8 per cent. in triples (see Table 10). The simple engine with superheated steam is as good as the compound engine with saturated steam, and **superheating** may be regarded **as a substitute for compounding.** The compound engine with superheated steam excels the triple using saturated steam.

Back Pressure. Unnecessary back pressure causes absolute loss. Comparison of experimental results from condensing and non-condensing engines illustrates the effect of changing the back pressure from 1 or 2 to 15 or 16 lb. Such a comparison is made in Table 11. It shows that the condensing engine saves 26 per cent. over the non-condensing engine in simple four-valve types and 35 per cent. in releasing-gear compounds (both with saturated steam). The automatic engines profit less when running condensing, partly on account of their high compression. The simple condensing engine is more efficient than the ordinary compound non-condensing engine. With superheat, the condensing engine is more efficient than the non-condensing by 20 to 30 per cent. for simple types and by 23 per cent. for compounds.

Table 11. Performance of Condensing and Non-condensing Steam Engines

(Mostly from Barrus, "Engine Tests," 1901)

Type of engine	Non-condensing			Condensing			Difference in steam rate, per cent.

[1] Figures in parentheses in this column denote number of records. [2] See Table 9. [3] See Table 10.

Altitude correspondingly **affects** engine **efficiency and capacity,** since atmospheric pressure varies about 1 lb. per 2000 ft. of elevation. In non-condensing engines, the mean effective pressure varies about ¾ lb. for simples and nearly 1 lb. for compounds, for this elevation. The efficiencies of such engines vary directly with the altitude. With condensing engines, the variation is in the other direction, but is so slight as to be negligible.

Ratio of Expansion. Tables 3 to 8 show that ideally the **efficiency varies directly with the ratio of expansion,** and that a given amount of increase in cylinder volume pays better when the ratio is previously low than when it is high. From this standpoint, some expansion is certainly, and complete expansion probably, desirable. (By "complete" expansion is to be understood expansion continuing until the terminal pressure is that in the exhaust pipe). Complete expansion leads to excessive cylinder condensation, so that the ratio is standardized between 3 and 5 for simple engines and between 6 and 36 for multiple-expansion engines—multiple expansion itself serving to mitigate the influence of cylinder condensation. **Maximum economy** is obtained with relatively high ratios of expansion where jackets, reheaters or superheat are used, and where the initial pressure is high or the engine runs condensing. Low ratios may be employed, regardless of thermal efficiency, to secure low first cost (*Trans. A. S. M. E.*, vol. ii, pp. 147-281).

Most stationary engines are governed by varying the ratio of expansion, so that the change in economy with load illustrates the effect of ratios of expansion on efficiency. The curves of Fig. 10 show this. The flatter curves represent the type of engine best adapted for running economically over a wide range of loads. (For the shape of such curves with superheated steam, see p. 952.) The effect of engine friction on desirable ratio of expansion is discussed on p. 948.

Cylinder Condensation. The walls of a steam cylinder are alternately heated and cooled during each revolution. The cold walls cause condensation of steam during admission and possibly during the early part of expansion, the heat transfer being at the rate of 20 to 25 B.t.u. per sq. ft. per deg. of temperature difference per min. This is followed by a drying of the steam during late expansion or exhaust; but even if the reverse transfer covered the same amount of heat as was first lost, a reduction of efficiency would ensue. This action would go on even in a cylinder perfectly insulated.

See Callendar and Nicolson, *Proc. Inst. C. E.*, vol. cxxxi, pp. 147–268; Duchesne, *Révue de Mécanique*, vol. xix, pp. 1–40; Mallanby, *Proc. Inst. Engrs. and Shipbuilders of Scotland*, 1911; Barraclough and Marks, *Min. Proc. Inst. C. E.*, vol. cxx, ii.

Since most of the condensation occurs during admission, the dryness at cut-off is a measure of economy. This may be ascertained by comparison of the indicator diagram with the experimentally determined steam consumption. The dryness at cut-off, and the economy, are directly influenced by the size of the engine, its speed and, chiefly, by its ratio of expansion. Fig. 11 shows the direct relation between cut-off dryness and ratio of expansion. It must be remembered, however, that up to a certain point there is a thermodynamic gain associated with high expansive ratios which more than offsets initial condensation (p. 954).

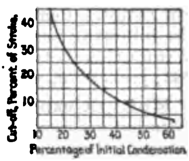

FIG. 11.

J. P. Clayton (*Bulletin* No. 58, Engineer. Exper. Station, Univ. of Illinois; also *Trans. A. S. M. E.*, vol. xxxiv) found that for non-condensing, unjacketed engines, unless excessive leakage exists, the expansion curve follows the law pv^n = constant, and the value of n depends on the quality, x, of the steam at cut-off. With superheated steam, the the value of n is higher than 1.0 and as high as 1.34; for small engines using saturated steam n is lower than 1.0 and may be as low as 0.70. For unjacketed engines exhausting at or near atmospheric pressure, the relation between n and x is given by $x = 1.258n - 0.614$. By means of this relation the value of x, and consequently the steam consumption of an engine, may be determined very closely from an accurate indicator diagram. This method applied to a large number of tests of engines of all sizes, with different pressures and speeds, yields a maximum difference of 4.6 per cent. between the calculated steam consumption and that determined from the test. Further experiments are required to establish relations between n and x for jacketed engines and for condensing engines.

Jackets. The steam jacket, by keeping the walls at constant maximum temperature, may eliminate heat transfer. The jacket should be supplied with high-pressure steam. The circulation must be free, and air pockets must be avoided. Excellence of circulation involves large condensation in the jacket. A separator should be used on the steam supply to the cylinder. Conditions favoring jackets are those already listed for superheat (p. 951). In large power stations they are mostly used to keep engines ready for service. Superheat is a better device than jacketing if high thermal efficiency is sought. Jackets should not be needed when superheat is used. Heck ("The Steam Engine and Turbine," 1911) reports for three compound condensing engines with slight superheat 235 B.t.u. consumed per i.h.p-min. without jackets or reheaters, 233 B.t.u. with both jackets and reheaters (average results). See also *Trans. A. S. M. E.*, vol. xiv, xvi; *Stevens Institute Indicator*, 1905.

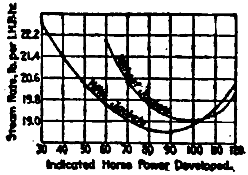

FIG. 12.—Saving Due to Jacketing.

In nearly all tests reported the jacket shows some net gain; but unfavorable results are apt not to be published. From 0 to 30 per cent. (usually 0 to 10 per cent.) saving in total steam consumption may be effected, the jacket meanwhile consuming 7 to 16 per cent. (usually 7 to 10 per cent.) of the total steam. (Heck, *op. cit.*: Average in 10 compounds, 10.2 per cent.; in 5 triples, 5.6 per cent. The lower percentages occur when superheated steam is used in the cylinders. See p. 957 as to the omission of low-pressure jackets when reheaters are used. See also *Trans. A. S. M. E.*, vol. xiv, p. 1412; *Proc. Inst. Mech. Eng.*, 1886; Isherwood, "Experimental Researches;" Barrus, *Eng. Rec.*, 1902, vol. ii, p. 436.) Fig. 12 shows results of a test by Carpenter, the saving by jacketing varying directly with the ratio of expansion and becoming negative at very low ratios. Peabody ("Thermodynamics of the Steam Engine," 1907) gives the following heat rates—B.t.u. per i.h.p-min.—on a triple expansion engine: Without jackets, 274, jackets on heads, 261, jackets on whole of cylinders, 233; jackets on whole of cylinders and receivers, 239.

Multiple expansion permits of a high ratio of expansion without excessive cylinder condensation, and therefore **increases efficiency**. Roughly, the compound uses 20 to 30 per cent. less steam than the simple engine. The triple may use 10 to 15 per cent. less than the compound. These savings (particularly those of the compound over the simple engine) are due partly to the higher initial pressure and lower leakage and clearance losses usually associated with multiple expansion. Willans (*Proc. Inst. C. E.*, vol. xciii) obtained the following results on a triple expansion engine:

Running normally	18.7 lb. steam per i.h.p-hr.
Running compound (high-pressure cylinder eliminated)	19.2 lb. steam per i.h.p-hr.
Running simple (low-pressure cylinder only)	26.0 lb. steam per i.h.p-hr.

Table 12. Average Steam Rates (Lb. per I.h.p-hr.) with Saturated Steam

(From Stanwood, Barrus, *Proc. Inst. C. E.*, vol. xciii, Willans, Clark, *Trans. A. S. M. E.*, vol. xxi, etc.) Compare with Table 9

Type of engine	Non-condensing			Condensing		
	Single valve	Double valve	Four valve	Single valve	Double valve	Four valve
Simple	33	30	28	27	24	21
Compound	24	23	22	20	16	14
Triple	..	..	18½	..	..	12

High-ratio Compounds. The best triples have only slightly surpassed the best compounds. With high cylinder ratio, 6 or 7 to 1 (p. 943), about

30 expansions, and 150 to 200 lb. initial pressure, jacketed compound engines have repeatedly consumed about 12 lb. of steam per i.h.p-hr. (*Trans. A. S. M. E.*, vol. xiii, p. 647; xix, pp. 155, 167, 189; *Power*, July, 1904, p. 424; Barrus, "Engine Tests," No. 47). Very few triple engines are used in power-station service in this country.

Non-condensing Compound Engines are generally regarded as commercially undesirable (Church, *Am. Mach.*, Nov. 19, 1891). A large unit has, however, reached a steam rate of 16.13 lb. per i.h.p-hr. (*Jour. A. S. M. E.*, March, 1910).

Reheaters. The reheater does for the low-pressure cylinders of a multiple-expansion engine just what superheat does for a single cylinder (*Trans. A. S. M. E.*, vol. xxv, 482–492). Adequate reheat involves superheating the steam in the receivers by from 30 to 100 deg. fahr. With the latter amount, Marks has shown (*op. cit.*) that the efficiency of the (compound) engine may be increased 6 to 8 per cent. Good reheating makes low-pressure jackets unnecessary. As a rule, not nearly enough reheating surface is installed. With moderately superheated steam in both cylinders, the steam consumption per i.h.p-hr. is about constant for the range from ½ load to 1¼ load.

Speed and Size. Cylinder condensation is reduced by high rotative speed, but the efficiency is not usually increased thereby. Along with high speed comes a limitation of choice of valve gear and (usually) imperfect distribution of steam. Best efficiencies are mostly obtained with speeds at or under 100 r.p.m. (With poppet valves, somewhat higher.) Slight variations in speed are practically without effect on the economy.

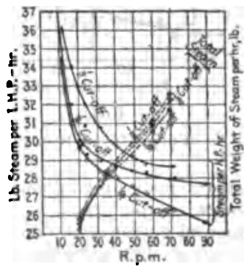

FIG. 13.

Fig. 13 shows results of a test by Denton and Jacobus, Fig. 14 those of a test by Willans. In both cases the dotted lines are based on the assumption (only approximately true) that the output is directly proportional to the r.p.m. These dotted lines show perceptible curvature; yet Marks has found (*Min. Proc. Inst. C. E.*, vol. cxx, ii) in a 9 by 36-in. condensing engine with constant initial pressure and practically constant cut-off, a straight-line relation between total steam consumed per hour and indicated horse power (compare the Willans Law, p. 951). In this as in the Denton and Jacobus tests the range of speeds was within that at which impairment of steam distribution was unlikely, so that the variation in efficiency was due to changes in cylinder condensation alone. The tests agree in showing that for slow speeds, the efficiency varies directly with the speed.

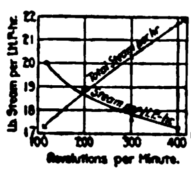

FIG. 14.

As to size, small engines are usually wasteful; more wasteful, in fact, than they need be. (Still, *St. Ry. Jl.*, Dec. 1, 1906, p. 1058: Carpenter, *Trans. A. S. M. E.*, 1907, p. 579.) In sizes from 2 to 5 h.p., non-condensing, a compound engine used 42 lb. of steam per i.h.p-hr., simple engines, 78 to 89 lb. (*Engg.*, June 27, 1890). So far as indicated thermal efficiency is concerned, there is no argument in favor of engines of particularly large size; some of the best records have been made by units of not much over 100 h.p. capacity.

Clearance and Compression. Clearance is a necessary evil and should be kept as small as possible. The heat losses to the walls increase as the clearance increases. This is one of the reasons why small engines (with relatively large clearances) are wasteful and compound engines (which usually have small clearance) are economical. Klemperer gives (*Z. V. D. I.*, 1905, vol. i, p. 797), for a 7 by 18-in. Corliss engine, non-condensing, with 4½ per cent. clearance, 25.6 lb. steam per i.h.p-hr.; with 15.2 per cent., 28.5 lb.

Compression improves the mechanical action of the engine, but advocacy thereof as a means for warming the cylinder walls prior to the supply of steam rests on a fallacious basis. A moderate amount of compression (varying with the speed) is justified on mechanical grounds, and from the experimental evidence of Figs. 15 and 16. These warrant the conclusions that

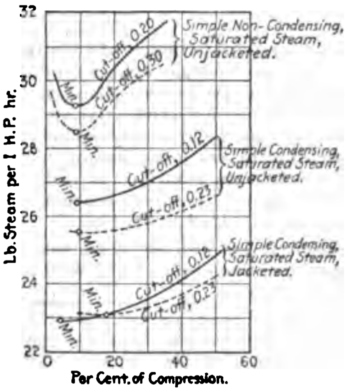

FIG. 15.

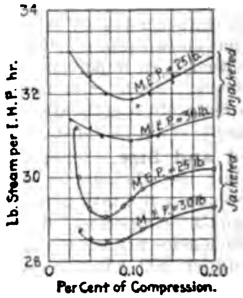

FIG. 16.

Variation of Steam Consumption with Percentage of Compression.

(*a*) Jacketing reduces the desirable amount of compression and makes low compression particularly advisable at early cut-off.

(*b*) Changes of 20 per cent. in mean effective pressure or of 50 per cent. in cut-off are practically without effect on the desirable amount of compression.

(*c*) Under only one condition did the desirable compression exceed about 10 per cent. Multiple-expansion engines should have relatively small compression. Superheat warrants exceedingly small compressions.

Valve and Port Details. With respect to these points the efficiency may be modified by: (*a*) throttling by inadequate ports, which by reducing the initial pressure or raising the back pressure may increase the steam consumption. **Governing** by throttling the supply of steam gives close regulation and makes an engine easy to handle and start under load. Moderate throttling with steady loads, slow speeds and high ratios of expansion may even be thermally desirable, but with ordinary variable loads an excellent steam rate for a throttling engine—simple non-condensing—would be 33 lb. per i.h.p-hr., and cases have been known—small direct-acting pumps—where it reached 300 lb. The great majority of constant-speed stationary engines are governed by adjustment of cut-off.

(*b*) Speed of valve movement. Quick opening and closure are necessary to avoid wire-drawing, the effect of which is shown by a rounding of the corners of the indicator diagram. To reduce friction, the movements of the valves at other parts of their travel should preferably be of small amplitude and slow speed.

(c) Interrelation of valve movements. For each end of the cylinder, four events are to be separately controlled, if highest efficiency is to be reached. This involves the use of two valves for each end. The common slide valve, with its correlation of functions, cannot control admission independently of compression, or cut-off independently of release (see p. 970).

Valves may be considered as having evolved in the following order: (1) The single valve, with interrelation and speed dependent on travel: the lowest type. (2) The double valve, which makes cut-off independent and in some cases rapid. (3) Four valves, all of the events of the stroke independently controlled; and (4) Four-valve releasing, giving especially rapid cut-off: the highest type. The last type is costly, is not applicable to very small engines, and is for the most part limited to speeds not over 100 r.p.m. (The question of leakage in relation to type of valve is considered below.) Table 13 is perhaps unduly favorable to the four-valve (type 3) engine, in that most of the rotative speeds were low, so that cut-off was fairly sharp even without releasing gear.

Table 13. Typical Steam Rates (Lb. per I.h.p-hr.) with Various Valves

Type of engine	Single valve	Double valve	Four valve	Releasing
Simple non-condensing	33	30	29	26*
Simple condensing	27	23	21½	21½*
Compound non-condensing	25½	23	22	22
Compound condensing	20	17	15	15
Average	26⅜	23⅝	21⅞	21⅛
Progressive saving, per cent	..	12	7	3

* See Table 10 as to exceptional records in German practice.

Leakage may occur past either steam valve, exhaust valve or piston. In single-valve engines, steam may escape directly from the chest to the exhaust port. The amount of leakage varies directly with the pressure difference and (in a vague way) inversely with the amount of seal of the valve. It is somewhat reduced by jacketing. The Callendar and Nicolson experiments cited on p. 955 showed that the unaccounted-for cylinder loss was largely leakage. A valve may be tight when cold or stationary, and leak when heated or moving. The steam-valve leakage in a small engine was 300 lb. per hour. Through an unbalanced slide valve, known to be tight when stationary, 29 to 38 lb. of steam escaped per hour. In a small automatic engine leakage of 10 lb. per hour was reduced to 2 lb. by refitting.

In the tests of Table 14 the valves were adjusted but not refitted. The differences between the last two columns indicate that after from 1 to 5 yr. of 24-hr. service steam rates with either flat- or piston-valve engines may be 1 to 45 per cent. (average 16 per cent.) higher than those known to be attainable with the same types of engine when new.

The figures in Table 15, though less extreme, show loss due to leakage ranging up to 12 per cent. (In this tabulation, engines have been classed as "tight" which are described as "fairly tight," "tight" or "practically tight." Those called "leaking" were originally described by such expressions as "some leakage," "considerable leak" or "excessive leakage." Presumably all of the engines were in fair shape.)

Table 14. Tests of Engines with Leaky Valves
(Dean and Wood, *Trans. A. S. M. E.*, vol. xxx, p. 6)

Type of engine	Valves	Load, per cent. of rating	Previous length of service, hours	Lb. steam per i.h.p-hr.—By test	Lb. steam per i.h.p-hr.—Computed, new engine*
(*a*) Simple non-condensing...	Single, flat	5/8	15,200	43.5	36.3
Simple non-condensing	Single, flat	5/8	20,000	38.5	36.3
Simple non-condensing	Single, flat	5/8	28,644	37.4	36.3
(*a*) Simple non-condensing...	Four, flat	3/4	719	43.9	39.2
Compound condensing	Single, piston	3/4	15,000	22.6	20.8
Simple non-condensing	Single, piston	3/4	32,000±	34.8	34.3
Simple non-condensing	Single, piston	5/8	5,600	42.4	36.3
Simple non-condensing	Four	7/8	10,800	38.3	29.3

Cases marked (*a*) were with slightly superheated steam; others with saturated steam.

* These figures are based on Table 13, modified to suit the load in accordance with curve 7*a*, Fig. 10.

Table 15. Steam Consumption of Engines with Tight and Leaky Valves
(Barrus, in "Engine Tests")

Class of engine	No. of tests Tight	No. of tests Leaking	Lb. steam per i.h.p-hr. Tight	Lb. steam per i.h.p-hr. Leaking	Per cent. difference in steam rate
Simple non-condensing, single-valve.....	4	6	31.6	34.4	+ 8.8
Simple non-condensing, four-valve	10	4	28.8	32.3	+ 12.2
Simple condensing, four-valve	4	5	21.0	21.2	+ 1.0
Compound non-condensing, single-valve..	2	4	22.7	23.2	+ 2.2
Compound condensing, single-valve......	2	4	18.6	20.5	+ 10.2
Compound condensing, four-valve.......	7	11	14.2	13.9	+ 2.1
Triple condensing.....................	1	1	12.6	12.7*	− 1.0

* Steam slightly superheated.

(See Clayton's paper, *Trans. A. S. M. E.*, vol. xxxiv, for a study of the indicator diagram for the detection of leakage.)

Friction. The known laws of friction indicate that the power lost in friction should increase somewhat with the load in either a variable-cut-off or a variable-speed engine. Conditions of workmanship and lubrication make it difficult to confirm this by actual tests of engines (see p. 948), and the friction loss is usually regarded as constant for all loads—an assumption which underlies the determination of mechanical efficiency by taking a "no-load" or "friction" indicator diagram.

The mechanical efficiency in important engines is usually between 0.9 and 0.96 at full load. The highest record seems to be nearly 0.98. Values below 0.85 are exceptional. The steam rate and thermal efficiency may be referred to brake output by introducing the mechanical efficiency as a factor.

The greater part of engine friction occurs at main bearings. Friction of piston rings and stuffing boxes comes next in importance, and the latter item may be considerably varied in operation. Unbalanced slide valves add greatly to friction losses.

Records by Special Types of Engine

Rotary Engines, since the advent of the turbine, have ceased to be even desirable. Of the thousands which have been invented and forgotten, practically all manifested excessive leakage due to the substitution of line contact of wearing parts for the surface contact of an ordinary piston. Even those which were tight at first soon developed leakage.

Fireless Engines (using stored hot water, vaporized by expansion to a lower pressure) are in occasional use. (Zeuner, "Technical Thermodynamics," Klein Ed., 1907, vol. ii, p. 449; Riedler, *Z. V. D. I.*, vol. xxvii, p. 729; Gutermuth, *op. cit.*, vol. xxviii, pp. 69, 533; xxix, p. 101.) The same principle underlies the Halpin plan for equalizing the load on power plants.

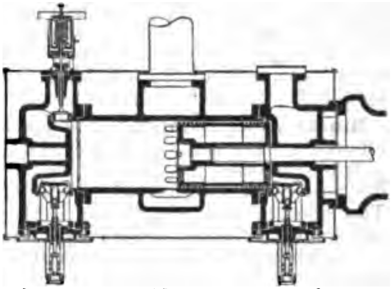

FIG. 17.—Uniflow Engine (built by Nordberg).

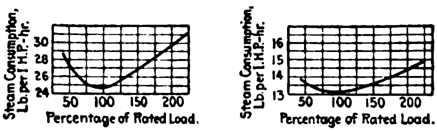
The Stumpf (Uniflow) Engine. In this (Fig. 17), the long piston acts as an exhaust valve, the ports being slots in the middle of the cylinder barrel, uncovered at 9/10 stroke. Piston leakage is reduced, exhaust valve leakage eliminated, back-pressure is slight and the uni-directional flow of steam decreases cylinder condensation. On the other hand, compression is (in non-condensing engines) excessive, a difficulty which is overcome by a special piston construction at the cost of some disadvantages. Clearances are 1½ to 2 per cent. The mechanical efficiency (simple) is 0.88 to 0.89. Fig. 18 shows results of tests with saturated steam. Other tests (on condensing engines) follow (*Power*, Oct. 31, Dec. 26, 1911).



Non-condensing Condensing

FIG. 18.—Test Results on Nordberg Uniflow Engines with Saturated Steam.

Observer	Engine	Steam	Lb. steam per i.h.p-hr.
Burmeister and Wain....	184 h.p.	Saturated, 140 lb.	13.64
Stumpf................	24½ by 39 in.	140 lb., 376 deg. fahr.	12.25
Stumpf................		120 lb., 490 deg. fahr.	10.85
Stumpf................		162 lb., 518 deg. fahr.	9.9
Burmeister and Wain....	115 to 220 h.p	140 lb., 667 deg. fahr.	9.06 to 9.68

These unjacketed simple engines are thus about equal in economy to our best compounds. Tests on 100-h.p. condensing engines by Lentz (*Zeit. Oest. Ing. u. Arch. Ver.*, Nos. 45, 46, 1911) gave the following results:

Initial steam pressure, lb. absolute..................	235.0	461.0
Steam temperature, deg. fahr	923.0	1018.0
Lb. steam per i.h.p-hr..................	6.52	5.67
B.t.u. per i.h.p-min..................	162.0	144.0

The Locomobile is a compact engine and internally-fired boiler outfit using high superheat and multiple expansion, with flue-gas jackets, economisers and (sometimes) flue-gas reheating. It originated in Germany under the name "lokomobile." It is reported to have developed, with 220 lb. boiler pressure and 660 deg. fahr. steam temperature, an indicated horse power on 8.25 lb. of steam or 0.97 lb. of fuel, with mechanical efficiencies between 0.70

and 0.80 (compound condensing). Tests of both Wolf and Lanz machines are given by Josse, "Neuere Kraftanlagen," Berlin, 1911. (See papers by Miller, *Eng. Mag.*, Oct., 1910, p. 64; and by Junge, *Power*, Dec. 31, 1912, p. 966.) A Buckeyemobile of 169 h.p., with steam at 209 lb. per sq. in. superheated 218 deg. fahr. and with 25.7 in. vacuum, has developed an i.h.p-hr. on 9.2 lb. of steam and on 1.08 lb. of coal of calorific value 14,209 B.t.u. per lb. The locomobile uses particularly high ratios of expansion.

Binary Vapor Engines. The principle of the steam-ether engine of 1850 (Rankine, "The Steam Engine," 1897, p. 444) has been revived by Josse, in a triple-expansion machine for steam (initially superheated) which finally discharges to a condenser in the coils of which sulphur dioxide is circulated. This substance is vaporized and works in a fourth cylinder at a pressure of 120–180 lb. The best record made was 167 B.t.u. per i.h.p-min.

Condensing engines have frequently been built to use various vapors other than steam, alone. The thermal properties of a vapor influence its efficiency in a heat engine, and under certain conditions it appears possible that a substitute vapor might lead to a heat saving of 10 to 20 per cent. over steam, along with some increase in cylinder capacity. (Ennis, "Vapors for Heat Engines," 1912.)

Regenerative Cycle: Quadruple Engines. By using the receivers as successive feed-water heaters, remarkably high thermal efficiencies have been reached in certain quadruple engines. The cycle of such engines is approximately that of Carnot (p. 319). The action is described in *Trans. A. S. M. E.*, vol. xxi, p. 181; xxviii, No. 2, p. 221; and by Ennis, "Applied Thermodynamics," 1913, Art. 550. The Wildwood pumping engine, 712 h.p., 200 lb. pressure, partly jacketed, used 186 B.t.u. per i.h.p-min. A 1000-h.p. Nordberg compressor with 257 lb. steam pressure used 169 B.t.u. (The steam rate does not measure the efficiency in this type of cycle.) These results were reached with saturated steam.

Summary of Recorded Engine Performances

The data on pp. 951–960 are typical for saturated and superheated steam in usual engines. Those in Table 16 may be regarded as best results attainable.

Table 16. Best Performances of Reciprocating Steam Engines

Type of engine	Saturated steam, lb. per i.h.p-hr.	Superheated steam,* B.t.u. per i.h.p-min.
Simple non-condensing.............	21–26 (*a*)	300 (*b*)
Simple condensing..................	18½ (*c*)	226 (*d*)
Compound non-condensing.........	16	245 (*e*)
Compound condensing.............	12	200
Triple condensing..................	10½ (*f*)	190
Quadruple condensing (regenerative)	(169 B.t.u. per i.h.p-min.)	...

* High superheat (exceeding 150 deg. fahr.) presupposed.

(*a*) German practice—American practice. 23.4 lb. has been realized in an American locomotive. With slight superheat (50 deg. fahr.), a Lentz engine gave 19.2 lb. (*Power*, Jan. 28, 1913, p. 104.)

(*b*) German practice. There seems to be no American record below 500 B.t.u.

(*c*) Barrus, "Engine Tests," No. 22. In German engines, 16.3 lb. has been realized.

(*d*) Barrus, *loc. cit.*, reaches 336 B.t.u. Figure given (corresponding with 10 lb. steam rate) is not reached in American practice.

(*e*) Carpenter, *Trans. A. S. M. E.*, 1907, p. 579. Motor-car engine.

(*f*) *Eng. News*, Aug. 23, 1900, p. 125.

Ratio of Actual and Ideal Efficiencies. Where E is the efficiency of the actual engine and E_1 is the efficiency of the ideal cycle (Tables 3 to 8), the quantity E/E_1 is called the efficiency ratio, E_R. The B.t.u. consumed per i.h.p-min. by the actual engine will be $42.42/E_R$. Average values of E_R are as follows:

	Saturated steam Condensing	Saturated steam Non-condensing
Simple	0.4	0.6
Compound	0.5	0.65
Triple	0.6	....

With high superheat, E_R lies between 0.6 and 0.7. Jackets on an engine using saturated steam increase E_R by 0.03 to 0.05.

Table 17. Historical Development of the Reciprocating Steam Engine

Engine	Ratio of expansion	Boiler pressure, lb. per sq. in.	Type	Lb. steam per i.h.p-hr.
Cornish pumps, 1840	1½ to 3½	45	Simple condensing	16½ to 24
Marine, 1850–1890	6	60 to 80	Simple or compound, condensing	19½
Marine, 1850–1890	14	150	Triple condensing	15
Marine, 1850–1890	15	210	Quadruple condensing	13½
Leavitt at Lawrence, 1872	16	120	Compound (Woolf) condensing, 12 r.p.m.	16½*

Mostly quoted by Denton, *Stevens Institute Indicator*, Jan., 1905; all engines used saturated steam except the last five. * Engines jacketed. † 196 B.t.u. per i.h.p-min. (A) 169 B.t.u. per i.h.p-min. ‡ 192 B.t.u. per i.h.p-min. (steam superheated 307°). § Steam superheated to 667°. (B) 167 B.t.u. per i.h.p-min. (steam superheated). ‖ Steam superheated to 660°. (C) 144 B.t.u. per i.h.p-min. (steam superheated to 1018°).

Efficiencies of Practice. The records given above are, except as specified, test records, that is, exceptionally good records. The tests giving high economies were made in most cases at full steady load, with good vacuum, on engines of fair size and good design, with leakage eliminated and valves properly adjusted. The figures reported may be duplicated under duplicate conditions in these respects, and with the same features of valve gearing, jackets, reheaters, speed and clearance. They will not be guaranteed by manufacturers without a margin of about 10 per cent.

In ordinary operation, with allowance made for the proportion of load carried, in accordance with Fig. 10, the steam consumptions should not exceed those here given by more than 15 per cent., assuming good design, no leakage and proper speed.

Efficiency may be increased by: A change of cycle, as in the regenerative quadruples; increase of temperature range, by special vapors or superheating; increase of efficiency ratio by better design. Development is going on in all of these directions. The last decade has seen marked progress in the development of the reciprocating engine, particularly in increasing the efficiency attainable in the average plant.

VALVES AND VALVE GEARING

REFERENCES: Peabody, "Valve Gears for Steam Engines"; Zeuner, "Treatise on Valve Gears (Klein tr.)"; Spangler, "Valve Gears"; Furman, "Valves, Valve Gears and Valve Diagrams"; Dalby, "Valves and Valve Gear Mechanisms"; Ewing, "The Steam Engine" (1906), chap. viii, for a brief treatment.

Valves and Valve Diagrams

Action of the Valve. In Fig. 1, the **slide valve,** shown in central position, admits steam from the steam chest, *A*, through the steam ports *a*, *a'*, and allows exhaust steam to flow from the cylinder through *a*, *a'*, to the exhaust port *b*. **Steam laps** (or "laps") are represented by *de* and *nm*; **exhaust laps** are represented by *fg* and *jk*. (Either or both may be negative. A negative exhaust lap must be less than the adjoining steam lap.) **Admission** occurs through *a* when the valve is displaced to the right by the lap *de*; or through *a'* when it is displaced to the left by the lap *mn*. **Maximum port opening,** usually less than the **port width,** *ef*, which is designed for the passage of exhaust steam, is attained (on the left side of the piston) when the valve is displaced its maximum distance to the right; or (on the right side of the piston) when the valve is displaced its maximum distance to the left. **Cut-off** occurs when the valve is displaced as for admission, but is traveling in the opposite direction to that which produces admission. **Release** occurs through *a* when the valve is displaced by the amount *fg* of exhaust lap to the left; or through *a'* when it is displaced by the exhaust lap *jk* to the right. **Compression** occurs at the same displacements, the directions of valve movement being opposite to those for release. Admission, cut-off, release and compression are described as **critical events.** For B-valves see p. 1494.

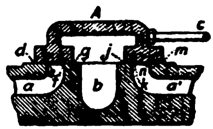

FIG. 1.—Slide Valve.

Valve and Piston Positions. Usually, the valve will have moved a greater distance than *de* when the piston has reached the left-hand end of its stroke. The excess of movement over *de* is called the **lead.** It is the amount of opening of the steam port when the piston is on the (adjacent) dead center. There may also be (and usually is) **exhaust lead,** defined as the amount of opening of the port on the exhaust side when the piston is at the (more remote) dead center.

The valve is moved by an eccentric, equivalent to a crank, the eccentric rod being of great length in proportion to the eccentric throw. Displacements of the valve are therefore regarded as equal to horizontal displacements of the eccentric center, and the **travel** of the valve is equal to **twice the eccentric radius.** If a rocker is used, it may be necessary to write "proportional" for "equal" in these two statements.

With neither laps nor lead, the valve would be central (*i.e.*, in mid-travel) when the piston was at dead center: the two would be 90 deg. out of phase. Steam would flow into the cylinder throughout one stroke, and out of it throughout the succeeding stroke. Lap permits of cut-off and expansive working. With lap, a 90-deg. phase difference between piston and valve would delay admission, and to avoid this disadvantage the phase angle is increased, the valve being displaced from its central position by an amount equal to (**lap + lead**) when the piston is on dead center. The increase of phase angle is called the **angle of advance,** $= j$. The total phase angle is 90 deg. $+ j$.

Choice of a Valve Diagram. For most purposes the Reuleaux diagram offers the most convenient method of solving problems connected with a simple eccentric valve gear. If the travel of the valve is not given, the Bilgram diagram should be used. The Zeuner diagram is best for Meyer gear, or other double eccentric gears.

The Reuleaux Valve Diagram. In Fig. 2, describe about the center *o* a circle of horizontal diameter *aok*, representing the valve travel. Through *o* draw *bo*, making the angle *boa* = *j*; and *oz*, perpendicular to *bo*. Lay off *oc* = lap, *op* = exhaust lap. Draw *af*, *dcm*, *qpr*, parallel to *bo*. Then the lead is *cf*, and the four critical events occur at piston-crank positions denoted by the points *d*, *m*, *r*, *q*. In interpreting these, the large circle is to be regarded as that described by the piston crank, rotating clockwise. The laps are those for the left-hand side of the valve (*de* and *fg*, Fig. 1) and the crank positions found are those for the critical events referred to that side of the piston which is controlled by the left-hand side of the valve.

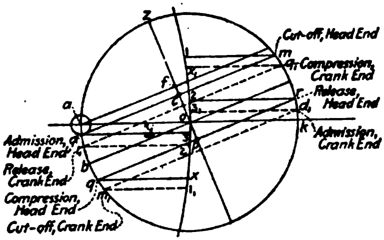

FIG. 2.—Reuleaux Valve Diagram.

On *ka* produced, find the center for an arc *ox*, described through *o*, with radius representing the length of connecting rod to the same scale as *ak* now represents the stroke of the piston. For an engine running "over," this center will be to the left of the diagram. For one running "under," it will be to the right. Then horizontal lines *qx*, *d*3, *m*1, *r*2, represent by their lengths the displacements of the piston from its central position at the critical points, again to the same scale as *ak* represents the piston stroke.

The dotted lines show the construction for the other side of the valve and the other end of the piston. Angularity of the eccentric rod may be allowed for by replacing *af*, *dcm* and *qpr* by circular arcs with centers on *of* produced, and radii representing the length of eccentric rod to the same scale as *ak* represents the travel of the valve. On account of angularity of the connecting rod the steam distribution is different on the two sides of the piston. Cut-off may be equalised by using different steam laps on the two sides of the valve, but this would lead to inequality of lead. For the effect of a reversing rocker in correcting distribution, see Furman, *op. cit.*, p. 23. The distance cs, Fig. 2, represents the maximum port-opening (scale oc = lap). Note that **(lap + lead) > exhaust lap,** if release is to occur prior to the end of the stroke.

Examples. (1) **Given travel, admission, release and cut-off.** Draw the circle (Fig. 2). Fix points d and m. Draw dm, determining **angular advance.** Fix r and draw rq parallel to dm, determining q. Draw ps perpendicular to dm and qr. Then oc = **lap,** op = **exhaust lap.** Through a draw af parallel to dm. Then cf = **lead,** cs = **maximum port opening.**

(2) **Given travel, lead, angle of advance and release.** Draw the circle. About a draw a circle of radius = lead. Tangent to this circle, draw dcm making the angle j with the horizontal, determining d, m. Fix r and draw rq parallel to dm, determining q. **Laps** and **maximum port opening** are found as in Case (1).

(3) **Given port opening, cut-off, angular advance and release.** Draw the circle ask of any convenient radius. Fix m. Draw md making the angle j with the horizontal, determining d. Similarly, fix r and draw rq parallel to md to determine q. Through a draw af parallel to md. Through o draw os perpendicular to md. Let p = required port opening. Then

$$\text{travel} = p.\frac{ak}{cs};\quad \text{lap} = p.\frac{oc}{cs};\quad \text{exhaust lap} = p.\frac{op}{cs};\quad \text{lead} = p.\frac{cf}{cs}.$$

The action of the valve depends on the four variables, lap, exhaust lap, angle of advance and travel. These determine port opening, lead, and the timing of the four events of opening and closure. If the timing of a related pair of these four events is specified, the angle of advance is fixed, and only one of the other two events may be independently assumed. The specification of an *unrelated* pair (admission and compression or cut-off and release) leaves the designer free to assume independently, either: one of the laps, the angle of advance, or (within certain limits) the lead; but only one of these three assumptions is possible.

The Zeuner Diagram. In Fig. 3, draw jl horizontally, AB vertically, intersecting at o; aok making the angle j with the vertical, and the large circle about o of diameter representing the valve travel. On the diameters ok, oa, describe the small circles. For any crank position 2 the valve displacement is $o3$, determined by drawing the vector $o2$. About o describe arcs bc, de, of radii equal to lap and exhaust lap, respectively. Through the intersecting points b, c, e, d, draw radii from o, determining g, f, m and n as the critical piston-crank positions. The distance ih is the

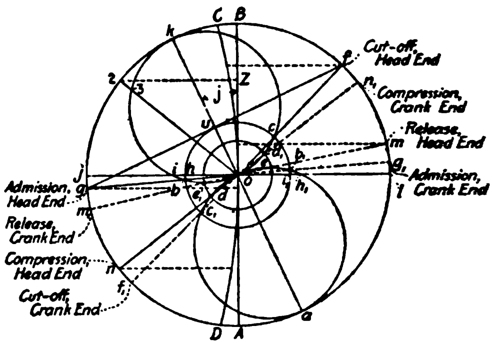

FIG. 3.—Zeuner Valve Diagram.

lead, and uk is the maximum **port opening.** Piston positions are found as in Fig. 2, by drawing the circular arc CD through o, and drawing horizontal lines from g, f, m and n to this arc. This construction gives the piston positions for the left-hand (head end) side of the piston in an engine running "over," rotation in Fig. 3 being clockwise. The positions for the crank end are worked out by dotted lines.

The Zeuner diagram gives valve displacements and port openings for all crank positions in a satisfactory way, but is **less accurate than** the **Reuleaux diagram** for determining the crank positions at which the critical events occur.

Example. Given cut-off, angle of advance and port opening. Draw (in Fig. 3) *AB*, *jl* and *aok*, and the circle on *jl*, of any convenient radius. Fix *f*, and draw *of*. Draw *fg* perpendicular to *aok*, determining *g*. On *ok* as diameter describe the small circle, fixing *c*. About *o* describe the arc *cb* through *c*, determining *h* and *u*. Let *p* be the required port opening. Then **lead** $= p.\frac{ih}{uk}$; **travel** $= p.\frac{jl}{uk}$; **lap** $= p.\frac{oc}{uk}$.

The Bilgram Diagram. (Hugo Bilgram, "Slide Valve Gears," 1878.) In Fig. 4, draw *ab* horizontally and 34 vertically, and about their intersection *o*, describe the large circle of diameter = valve travel. From *o* draw *oe* making the angle *eoa* = angle of advance, *j*. To find the valve displacement for any position *d* of the piston crank, draw the crank radius *od* and from *e* draw *ef* perpendicular to *od*. The length of *ef* represents the displacement of the valve from mid-travel. About *e* describe circular arcs *hi*, *jk*, of radii representing the lap and exhaust lap, respectively. From *o*, draw radii tangent to these arcs, cutting the large circle at the critical crank positions *A*, *B*, *C*, *D*. Draw *et* perpendicular to *oa*. Then *st* is the **lead.** *Eo* is the **maximum port opening.** The locus of the point *f* is the circle whose diameter is *eo*. Piston positions are found as in Figs. 2 and 3. Dotted lines show the construction for the crank end. With negative exhaust lap = *er*, release would be determined by DoD_1 (produced) and compression by *ok*.

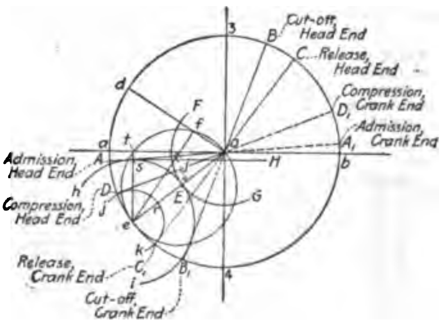

Fig. 4.—Bilgram Valve Diagram.

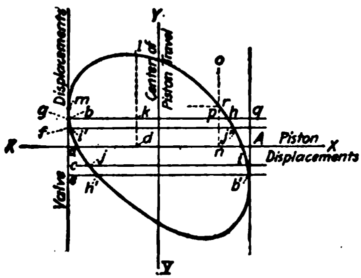

Fig. 5.—Valve Ellipse.

Example. Given port opening, cut-off, release and lead. In Fig. 4, through *o*, draw *aob* horizontally. Fix the angular position of cut-off by the line BoB_1. About *o* describe the circular arc *FEG*, of radius = port opening. Draw *sH* parallel to *aob* and distant from it by the amount of lead. Find a center, *e*, for a circle *hi*, which shall be tangent to *sH*, oB_1 and *FEG*. The angle *aoe* is the **angle of advance.** A radius from *o* tangent to the upper limit of the circle *hi* determines the angular position of the crank at **admission.** Fix the crank angle at release by the line CoC_1. About the center *e*, describe the circle *jk* tangent to this line. From *o*, draw *oD* also tangent to *jk*, determining the crank angle at **compression.** Then **travel** = 2*oe*, **lap** = *eB*, exhaust lap = *eK*.

Valve and Piston Positions and Velocities—The Valve Ellipse. In Fig. 5, ordinates are vectors of Fig. 3; abscissæ are corresponding piston displacements, *i.e.*, the co-ordinates of the point 2 (Fig. 3) are $o3$ and $2Z$. In the lower portion of this diagram, the valve displacements are taken from the lower of the two small circles of Fig. 3. The departure of the diagram from the form of an ellipse is due to angularity of the connecting rod.

Lay off $ag = ae$ = **lap**, $af = ac$ = **exhaust lap.** Draw gq, eb', fj', ci, horizontally. Then the four critical events occur at b, h, i, j. At the piston position d, the port opening is kl. This is the **maximum port opening** if the vertical line dl strikes the highest point of the curve at l. If the curve is tangent to eg at m, the distance gm is the **lead.**

Table 18. Crank Angles and Piston Positions for Connecting Rods of Different Lengths

For the other end of the cylinder, critical events occur at b', h', i', j', cut-off being earlier on this side. Cut-off might be equalized thus: Lay off $An = eh'$, draw no vertically, and make the lap nr instead of np on that side of the piston the forward action of which is described by the upper half of the diagram. But this would practically eliminate lead and would decrease the maximum port opening.

The "steepness" of the curve measures the relative rapidity of valve movement. Thus the valve is moving at nearly maximum speed during admission.

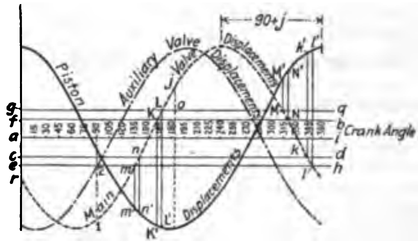

FIG. 6.—Sinusoidal Valve Diagram.

Crank Angles and Piston Positions for various ratios of connecting-rod length to length of stroke are given in Table 18. See also p. 771 for piston positions corresponding to different crank angles.

Sinusoidal Diagram. In Fig. 6 the dotted "main valve" curve represents valve displacements on a crank-angle base, the angle 0 deg. = 360 deg. corresponding with crank position j, Fig. 3. Similarly, the solid line curve represents piston displacements (to a different scale). The valve curve is truly sinusoidal. The shape of the piston curve depends on the ratio of lengths of connecting rod and crank. Draw qg and he distant from the horizontal axis by the amount of lap, and bf and dc distant therefrom by the amount of exhaust lap. The critical events occur (on one side) at valve positions L, M, N, K and (on the other side) at l, m, n, k. Vertical lines from these points give the corresponding piston positions, L', M', N', K' and l', m', n', k'. Vertical lines gr, oj, through crank angles 0 deg. and 180 deg., show **lead** = er or oj. Changes in angular advance may be studied by shifting one of the curves horizontally. The "steepness" of the valve curve again measures the speed of valve movement. This diagram illustrates lead more clearly than Fig. 5.

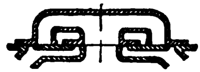

FIG. 7.—Multiported Valve.

Piston Valves may be analyzed as in Figs. 2, 3, and 4, but with "inside edge" distribution the displacement of the valve is (Fig. 1) to the left for admission to the left-hand side of the piston.

Multiported Valves reduce friction and clearance. Fig. 7 shows one form. With a large number of ports, this becomes the **gridiron valve.**

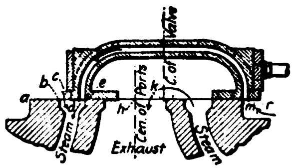

FIG. 8.—Allen Valve.

The Allen Valve is shown in Fig. 8. The passage in the valve gives double the opening for admission, with travel equal to that of a plain valve. In the figure, the valve is in its extreme right-hand position. The steam lap = $kc - hb$, should exceed ce. Also, $cb = mr = de$. The distance from a to d, when the valve is at mid-travel, must equal the steam lap at the *other end of the valve.* (Furman, *op. cit.*, p. 28.) Also called "trick" valve.

For descriptions of various "divided port" valves—Straight Line, Woodbury, Armstrong, Rice, Armington and Sims, Ide and Giddings—both with and without balance plates, see Halsey, "Slide Valve Gears," 1890, pp. 70–76.

The Shifting Eccentric—Limits of the Plain Valve. Early cut-off is impracticable with the plain slide valve. The point of admission being fixed, hastening of cut-off involves larger lap, earlier release and compression, and either increased travel or reduced maximum port opening. Release can then be delayed by increase of exhaust lap, but this makes compression still earlier. The plain valve and gear, moreover, must work always with the fixed point of cut-off for which they were designed.

Change in Advance and Travel. In Fig. 9, let *ab*, *cod*, *ef* and *iA* be the elements of a Zeuner diagram fixing the four critical events at *h*, *g*, *k* and *j*. Let it be required to fix cut-off at *l*, without change in admission. Draw *ol*, and *om* bisecting the angle *hol*. Find a center, on *om*, for a circle *epn*, which shall pass through *o* and *n*, the point of intersection of *ol* and *ef*. The required conditions are met when *epn* becomes the valve circle; *i.e.*, when the angle of advance is increased by *com* and the travel is reduced from *cd* to 2 × *op*. The symmetrically placed circle on *oB* now fixes release at k_2 and compression at j_2, the latter event being considerably hastened. Maximum port opening is decreased, but the distribution is superior to that in a plain slide-valve gear.

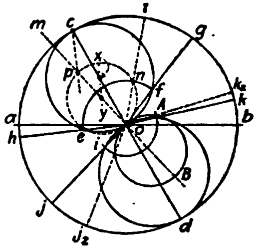

FIG. 9.—Zeuner Diagram for Slide Valve Operated by Shifting Eccentric.

The **change in throw and angle of eccentric** is accomplished in various ways: by a combination of two eccentrics (Armington and Sims); by the use of a shaft guide in which wings attached to the eccentric move back and forth (Russell, Giddings); or, as in recent practice, by using a pivoted arm on the flywheel, under governor control. The action may be described by plotting the "path of the eccentric center," *cp*, Fig. 9. If this path is *straight* and *vertical*, the lead will be constant. (Equality of lead does not imply an unchanged crank position at admission.) If it is *convex* toward *o*, the travel will be relatively great at late cut-off, and port openings small at early cut-off. Equalization of steam distribution is facilitated when the path is *concave* toward *o*.

Separate Cut-off Valves. Some of the disadvantages of the plain valve are overcome by employing a second, auxiliary mechanism, driven from an independent eccentric, for control of cut-off only, the point of cut-off being varied by hand or by the governor. In the **Gonzenbach valve** this was accomplished by control of the supply to the steam chest. (Bilgram, "Slide Valve Gears," 1878, pp. 91–96; Halsey, "Slide Valve Gears," 1890, pp. 102–108.) In the **Meyer valve** (Fig. 10) cut-off occurs (on the left-hand side of the piston) when the auxiliary valve has moved *to the left* a *relative* distance equal to its lap, *l*. The *absolute* movement of the auxiliary necessary to produce this relative displacement depends on the amount of movement of the main valve meanwhile taking place. The lap (and point of cut-off) may be varied by hand, by turning the valve rod; or the latter may be under the control of a governor which shifts the eccentric so as to change the angle of advance of the auxiliary.

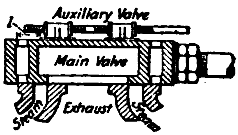

FIG. 10.—Meyer Cut-off Valve.

Fig. 11 gives the Zeuner diagram of a Meyer valve, *cod*, *aob*, *vep* and *tsf* being the elements of the main valve. Lay off *og* determining the angle $K = goc$, usually 45 deg., the **relative angle of advance**. The length of *og* represents half the travel of the auxiliary valve. On the diameter *og* describe the auxiliary valve circle *gjo*. Draw *gc*, and *oh* parallel to *gc*. On *oh* lay off $oi = gc$ and on the diameter *oi* describe the circle *olim*, vectors to which represent **relative displacements** of main and auxiliary valve. Then for a crank position 9, the main valve displacement is *ok*, that of the auxiliary is *oj*, and the relative displacement is $ok - oj = kj = ol$.

Suppose cut-off to be desired at 9. Draw *o*9, intersecting the circle *olim* at *l*. Through *l*, with *o* as a center, describe the arc 3*lm*1. The radius of this circle is the auxiliary lap, *l*, Fig. 9. Readmission by the auxiliary valve occurs at *n*, determined by the intersection *m*; but before this, the main valve will have closed at *q*. The four events occur (for one side of the piston) at *w*, 9, *r*, *u*; for the other side (with the same laps), at *y*, 2, 6, 8, the circle on *ox* being symmetrical with that on *oi*. To equalise cut-off, $(j + K) = Aog$ may equal 90 deg.; but this may lead to sluggish action at cut-off. Inequality of auxiliary laps is preferable. By increasing the travel of the auxiliary valve, greater port openings could be obtained. At very late cut-off, the point *n* might precede *q*, which would be inadmissible.

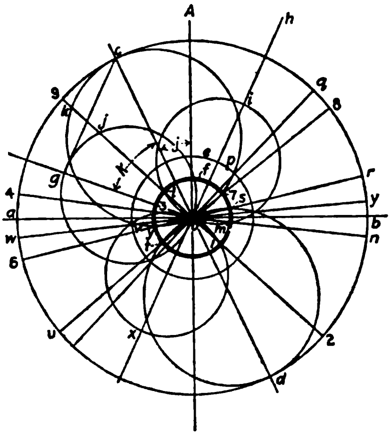

Fig. 11.—Zeuner Diagram of Meyer Valve.

In Fig. 6, the auxiliary valve displacements are plotted for a case in which both main and auxiliary valves have the same travel, the ordinates of the curve being the vectors of the circles *gjo*, Fig. 11. Vertical distances between main and auxiliary curves represent relative displacements. Cut-off occurs when this relative displacement equals the auxiliary lap. Thus if it be desired to cut off at 90 deg. crank angle, the necessary auxiliary lap is 12. With very early cut-off (about 20 deg. crank angle) the auxiliary valve is unfortunately moving at minimum speed.

The **Rider valve,** like the Meyer, incorporates an auxiliary cut-off member, but the lap is changed either by rotating or transversely moving the auxiliary. In the former case, the expansion valve is of the piston type, working in a hole bored lengthwise in the main valve. From this passage the steam ports are cut obliquely, as are also the lap ends of the auxiliary. When transverse displacement is practiced, the auxiliary is flat and of trapezoidal outline.

In the **Polonceau valve,** one long block is substituted for the two short ones of Fig. 10. Cut-off is controllable from the eccentric alone. A multiported ("gridiron") Polonceau valve has been used on recent important engines. The objections to it are its high first cost, limited range of cut-off and exceedingly small linear lead of the main valve.

The **Buckeye valve** has a pair of auxiliary blocks, like the Meyer, but fixed on the valve rod. The auxiliary moves in a steam-tight box formed in the main valve, its stem being within the main valve stem and the two being operated from a special compound rocker. Both valves have the same travel. Clearance is small and cut-off sharp.

Poppet Valves have vertical spindles, and usually lift to open. There are commonly four independent valves per cylinder. They may be located like Corliss valves, or as in gas engines, or may connect with the cylinder heads. In vertical engines, they may be on meridian planes at the sides of the cylinder. The exhaust valves are always below the steam valves. The seats are usually double (occasionally single, and sometimes, to decrease travel, quadruple), and are nearly balanced, a sufficient unbalanced pressure being provided to insure tightness when closed. The maximum angle of seat with a plane perpendicular to the spindle is 65 deg. It is usually attempted to equalize the two steam-passage areas provided. Fig. 12 shows some forms.

FIG. 12.—Poppet Valves.

In some types of engine the valves are operated direct from eccentrics, the minimum number of the latter being two, one each for steam and exhaust valves. More commonly, a pair of **miter gears** connects the engine shaft with a valve shaft, from which the valves are driven by eccentrics and cams. **Variation of cut-off** is accomplished by (*a*) a shifting eccentric (Widnmann); (*b*) **change** in angular advance and travel (old Collmann gear); or by (*c*) disengagement, as in the Corliss gear. (The later Collmann gear has disengagement control.)

In the design of poppet valves, the desired distribution of steam is assumed as in Figs. 5 and 6, and the operating cams are proportioned to give the movement necessary by ordinary kinematic methods.

Valve Gears

Rotary Gear. The **Corliss valve** is skeleton-cylindrical, located transversely. It rocks back and forth through a small arc. Separate steam and exhaust valves are provided at each end of the cylinder. Some forms are shown in cross-section in Fig. 13. The **Wheelock valve** (Fig. 14), though of Corliss form, belongs in principle with the Gonzenbach class (p. 970). The **typical Corliss valve gear** is shown in Fig. 15. In more elaborate design separate eccentrics are used for steam and exhaust valves. With releasing gear, this is usually necessary if releasing cut-off is to be effective at cut-off later than half-stroke. The **diameters of** such **cylindrical valves** range from 4 to 5 times the maximum port opening (less, if "trick" ports are used). The actuating crank attached to the end of the valve is ½ in. to 1 in. longer. The **length of ports** is about equal to the bore of the cylinder.

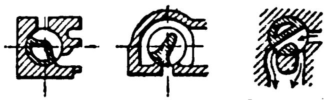

FIG. 13.—Corliss Valves.

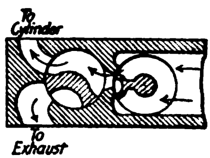

FIG. 14.—Wheelock Valve.

Valves on horizontal engines are usually located at the ends of the cylinder, the steam valve above and the exhaust valve below. The Corliss gear has small travel and slight friction. It gives particularly small clearances, though designs differ somewhat in this respect. Live steam and exhaust steam

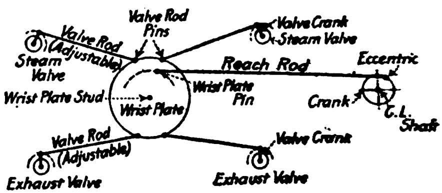

FIG. 15.—Typical Corliss Valve Gear.

never pass through the same port. The valve is **not suitable for use with high steam temperatures.**

A fundamental feature of a Corliss engine is the **releasing gear.** In Fig. 16, the crank A is loosely mounted on the valve stem, and the grab hook H is loose on a pin fixed in A. The spring S presses the grab hook against the knock-off cam C, the position of which is controlled by the governor. C rocks freely on the valve stem, but the lever B is keyed to the stem.

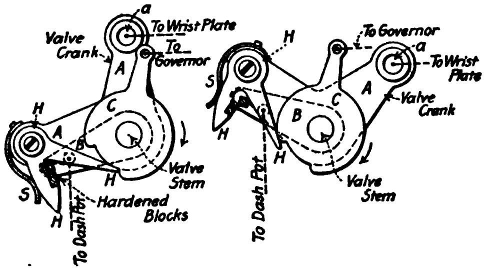

FIG. 16.—Releasing Gear of Corliss Engine.

In the left half of Fig. 16 the valve is about to rotate clockwise. This rotation is produced by the train A, H, B. Simultaneously, the rod running from H to the dash pot rises. As the motion proceeds, the upper of the hardened-steel blocks slides to the right, disengaging from the lower block—as indicated in the right half of Fig. 16. A vacuum dash pot then pulls down on H by means of the vertical rod, closing the valve by a quick counter-clockwise rotation. The point of disengagement is determined by the position of the cam C.

Ordinary **releasing gears do not work well** at speeds **above 100 r.p.m.** Corliss valves without disengagement, operated by one fixed exhaust eccentric and a steam eccentric under control of the shaft governor, are a feature of the so-called "four-valve" engine.

Design of Corliss Valves. In Fig. 17, the circle 79 is described about the center of the wrist-plate stud with a radius equal to half the horizontal travel of the point, H, midway between the valve-rod pins. Assuming harmonic motion, divide this circle into equal arcs, corresponding with equal angular movements of the eccentric. From the points of division, 1, 2, 3, . . ., draw vertical lines intersecting the line of travel of the valve-rod pins at 1′, 2′, 3′, etc. These determine successive positions of the point H. From these, by laying off the distance HF to the left, we find 1″, 2″, 3″ . . . as the positions of the left-hand valve-rod pin corresponding with eccentric positions represented by 1, 2, 3 . . .

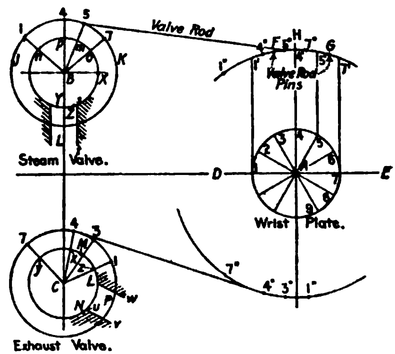

FIG. 17.—Layout of Corliss Valve Gear.

About B draw the circle JK of radius equal to length of valve crank. From 1″, 2″, 3″, . . . with radii equal to the length of the valve rod, strike arcs intersecting JK in 1, 2, 3 . . . which points thus determine valve-crank positions. Also, about B, describe the circle no of **radius representing the valve diameter** (this doubles the scale for this part of the construction). To the same scale, indicate the steam port, L. From s, lay off sZ = lead. Then the right-hand (active) edge of the valve, moving clockwise to open, is at Z when the piston is on dead center. The eccentric will than be ahead of the dead center; at 5, if the angle of advance is made 30 deg., the valve crank will be at the point 5 on JK.

Draw the radii $B1$, $B2$, $B3$ . . From Z lay off $ZY = mo$, $ZX = mn$, determining Y and X as the two extreme positions of the right-hand edge of the valve. The left-hand edge must fully cover the left-hand edge of the port when the active right-hand edge is at X. The valve face may then be described as **width of port** $+ sX + a$, where a is the amount of cover required. The **lap** is $mp - Zs$, where $Bp4$ represents the midway phase of the valve crank.

For the exhaust valve, valve-crank positions on the valve-crank circle are found in the same way. The valve outline $4s$ and exhaust port P being indicated (again preferably to double scale), note that the valve rotates counter-clockwise to close. Then the right-hand edge of the valve must be at L when release or compression occurs. Suppose these events to be prescribed at 30 deg. before the (piston) dead center is reached. The eccentric will then be at mid-throw, and the valve crank at 4. From L lay off $LM = xy$, $LN = xz$, determining M and N as the extreme points of valve travel, referred to the right-hand edge. The maximum port opening slightly exceeds the port width. The valve face must cover the arc $uL + LM +$ **desired amount of seal**. The central position of the valve is at L, so that it has no lap. Care should be taken to provide **ample seal** or cover for the valves for all possible adjustments of valve-rod length.

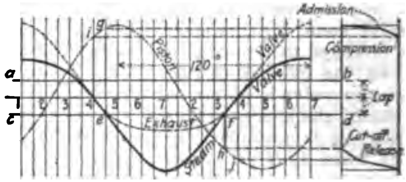

FIG. 18.—Harmonic Valve Diagram, Corliss Gear.

The **harmonic or sinusoidal diagram** is plotted in Fig. 18, with eccentric positions as a base and the rectified travel arcs xy, xz, np, pm_r etc., as ordinates of the valve curves (see Fig. 6 and explanation). The piston positions g, h, j, i, being found for one end of the cylinder, the indicator card may be sketched by projecting these points horizontally to the right. Cut-off may be independently changed by the releasing gear. The four critical events occur at maximum valve speeds.

Typical Laps for Corliss engines are as follows (exhaust laps being negative):

Cylinder diam.. in.	12	14–16	18–22	24–28	30–36	38–42
Lap, in.	1/4	5/16	3/8	7/16	1/2	9/16
Exhaust lap. in.	−1/32	−1/32	−1/16	−3/32	−1/8	−1/16

Reversing Gears. An engine may be arranged to run in either direction at will, by (a) interchanging steam and exhaust ports; (b) using two alternative eccentrics, with optional engaging grabs (as in the Stevens gear, p. 977); (c) shifting the eccentric back by an angle exceeding 180 deg. $+ j$; (d) using a reversing gear.

The **reversing gear is virtually equivalent to a shifting eccentric,** but with greater flexibility of control, since it changes both position and travel of the valve. In addition, the linkage may correct inequality of distribution due to angularity of connecting rod. It does not actually move the eccentric, but its effect is the same as that due to a movement of the extremity of the valve circle from c along some such path as cp, Fig. 9. This path being determined, the steam distribution may be examined as in Fig. 9. Where the path cannot be predicted, the action may be studied by models (Bilgram, *op. cit.*, pp. 59–71), or by more or less approximate graphical methods (*e.g.*, for the Stephenson link, see Furman, *op. cit.*, p. 85). A reversing gear may be used for gradual variation of cut-off to give constant speed at variable loads or (as usually) to give constant power at various speeds.

In the **Stephenson link** (Fig. 19), the eccentrics are treated as equivalent to two short cranks, driving the eccentric rods, which are hinged to the link.

The radius of curvature of the link is equal to the length of eccentric rods. The valve is moved by the link by means of the slide block, rocker and valve rod. The link may be raised or lowered by the reversing lever, reversing rod, bell crank and link hanger. When the link is in its lowest position, the valve derives its motion from the upper eccentric rod entirely, the lower rod serving merely to rock the link about the slide-block pin as a fulcrum. In its uppermost position, the link and valve are effectively moved by the lower eccentric rod alone. At these positions, the valve travel is a maximum. At mid-height of the link, the travel is a minimum, and the motion is determined by both eccentric rods. The movement of the link from one extreme position to the other thus gradually changes the angle of advance and the travel; and both may be fixed temporarily at any desired value between the extreme limits. To minimize slip at the slide-block bearing, the slide block should be immediately under the saddle block at the usual running adjustment.

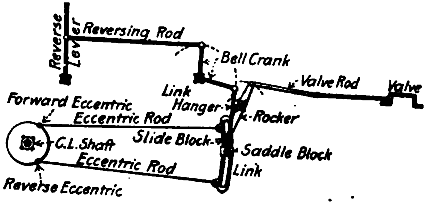

FIG. 19.—Stephenson Link Reversing Gear.

Fig. 19 shows a link motion with "open" rods. Sometimes the rods are "crossed;" *i.e.*, when the crank is at left dead-center and the eccentrics are between it and the link, the projections of the rods cross each other. (In either construction, the rods appear crossed at certain crank positions.) With crossed rods, the supply of steam may be cut off at mid-position of the link. With open rods, there is positive lead at all positions.

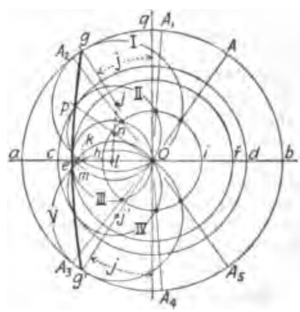

FIG. 20.—Diagram of Stephenson Link Motion.

Fig. 20, following the construction of Fig. 9, shows the successive equivalent valve circles I, II, III, IV, V, as the link is shifted from "forward" to "reverse" position. The "equivalent eccentric path" is *gpeg'*. In progressing from "full" to "mid" gear, travel and port opening decrease and lead increases. The crank positions at cut-off are A, A_1 and A_2. Proceeding from mid gear to full reverse, cut-off occurs successively at A_3, A_4, A_5 (rotation now counter-clockwise).

With constant lead, the path *gpeg'* would be a straight vertical line. In the Stephenson link, it is a parabola, closely coinciding with a circular arc drawn through g, g' and e, such that $oe = og\,(\cos goa \pm m \sin goa)$, where m is the ratio of link length to rod length. (The + sign is for open rods, the − sign for crossed rods.) Lead at full gear, with open rods, is usually from 1/16 to 3/16 in.

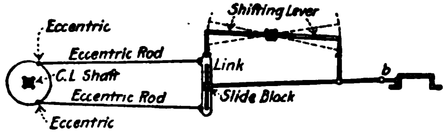

FIG. 21.—Allen Valve Gear.

Fig. 21 shows the **Allen gear**, which differs from the Stephenson in providing a simultaneous and opposite shifting of link and slide block, so that a straight slot may be employed. It is so proportioned as to cause the slide block to move nearly in a circular arc about b, as the position is varied by the shifting lever. If this were accomplished, the lead would be constant, and the path *gpeg'*, Fig. 20, would be a straight vertical line. In usual designs, the path resembles that produced by the Stephenson link with open rods, but its curvature is less.

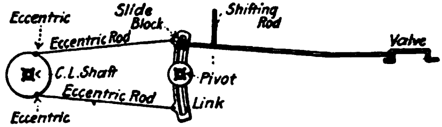

FIG. 22.—Gooch Valve Gear.

Stationary Link Gears. The **Gooch gear** (Fig. 22) suspends the link at constant height. The slide block is moved at the end of a rod of length equal to the link radius. The lead is constant and the path *gpeg'*, Fig. 20, is a straight vertical line.

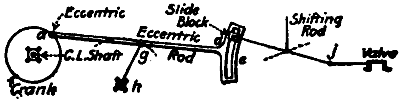

FIG. 23.—Fink Valve Gear.

In the **Fink gear** (Fig. 23) a single eccentric is placed opposite the crank, and the eccentric rod is guided by the arm *hg* so as to move nearly in a straight line. The construction from link to valve may be as in the Gooch gear, and the action is the same. The **Porter-Allen gear** is of the Fink type, the distance *ag* being greatly reduced so that the arm *ag* is a part of the eccentric strap; point *d* coincides with *g*, and (since reversing is not contemplated) the lower half of the link is omitted (Fig. 24). As used in high-speed automatic engines, this gear includes a separate radius bar, pivoted at *p* to operate the exhaust valve with constant release and compression.

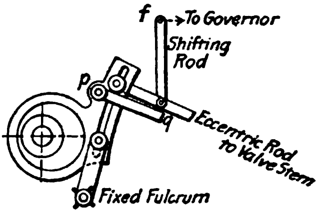

FIG. 24.—Porter-Allen Valve Gear.

Radial Gears employ a guiding arm in place of a link. In most of them the lead is constant, and the path *gpeg'*, Fig. 20, is a straight vertical line.

The **Hackworth gear** (Fig. 25) has the eccentric rod, *EQ*, terminating at *Q* in a slide block. This block moves in a straight slot, the position of which is adjustable. The pin *P* moves in an ellipse, the proportions of which are determined by the position of the slide-block slot. The gear gives good steam distribution with sharp cut-off, and is compact. In the alternative **Marshall** (or **Bremme-Marshall**) **gear**, the slot is replaced by the end of lever which rotates about an adjustable center, constraining the pin *Q* to move in some one of a series of circular arcs. This form is largely used in marine engines, particularly with "inside edge" steam distribution. The **Brown gear** is like the Hackworth, but the slotted guide (Fig. 25) is placed *between E* and *P*.

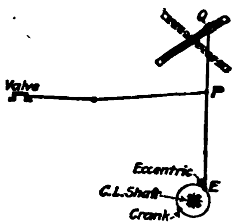

FIG. 25.—Hackworth Valve Gear.

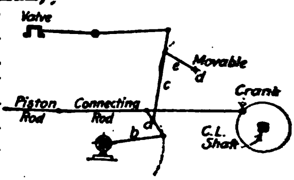

FIG. 26.—Joy Valve Gear.

In the **Joy gear** (Fig. 26) the valve is moved partly from the connecting rod by the linkage *a*, *b*, *c*, but the movement is modified by the position at which the movable fulcrum *d* of the radius bar *e* is set. There is no eccentric. A slotted guide (as in the Hackworth gear) may replace *e*. The Joy gear gives quick cut-off, well balanced, and moderate compression.

The **Walschaerts gear**, Fig. 27, also combines two methods of driving: one from the cross-head, through *e, f, g, h*, and one from the eccentric (90 deg. out of phase with the crank) through the eccentric rod, link and radius rod attached at *g*. The slide block by which the radius rod is moved from the link is vertically adjustable. When the slide block is in line with the link fulcrum, the valve is moved by the cross head alone. The link radius is equal to the length of the radius rod. If when the piston is on dead center the center of the link arc coincides with *g*, the lead will be constant. Without the cross-head linkage, there would be no lap or lead or expansion. The effect of this linkage is to increase the displacements of the valve. Minimum travel is determined by analyzing this linkage as it operates when the slide block is under the link fulcrum. Maximum travel occurs when the slide block is at one of the ends of the link. Unless the prescribed proportions are followed, the lead will vary about as it does in the Stephenson gear. The Walschaerts gear as applied to **locomotives** uses a supplementary outside crank in place of an eccentric. The mechanism is all outside, and occupies little width. Cut-off and lead may be equalized for the two ends.

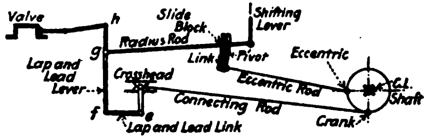

FIG. 27.—Walschaerts Valve Gear.

The **Stevens gear**, used on paddle-wheel steamers, is applied to poppet valves. The valves are operated by separate steam and exhaust eccentrics. Cut-off is fixed and the speed is varied by throttling. Reversing is accomplished either by throwing out the gear and moving the valves by hand, or by shifting to a secondary set of reversing eccentrics.

The **Lentz gear** is **used** not for reversing but **for regulation.**

Floating Gears are used on steam hammers, steering engines, etc. Fig. 28 shows one used to shift a Stephenson link. The cylinder, etc., are parts of the gear; the engine cylinder, not shown, is vertical. The link is shown in mid-position at *rs*. Its position is controlled by the linkage *ompq*, the lever *po* being pinned to the shaft *o*.

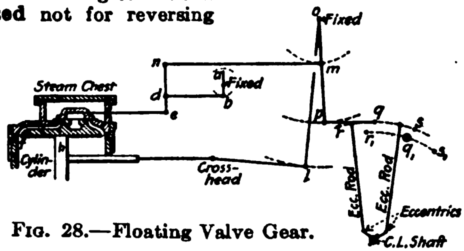

FIG. 28.—Floating Valve Gear.

The lever *ab* is thrown counter-clockwise. This gives the lever *nde* a counter-clockwise rotation about *n*, moving the valve to the right and admitting steam through the port *f*. The lever *ab* is then locked, fixing the position of *d*. The piston moves to the right, throwing the lever *lo*, pinned at *o*, and moving the link to the position r_1s_1 by means of the linkage *ompq*. The pin *m* thus pulls the pin *n* to the right, rocking the lever *edn* about the new center *d* and returning the valve to its original position. Small steam lap and about ¼ in. exhaust lap are used. Should the piston move the link further than is desired, the valve would be displaced to the left, admitting steam to stop the piston. (Furman, *op. cit.*, p. 115.)

STEAM TURBINES

BY

L. C. LOEWENSTEIN

Martin, "Steam Turbines," Longmans, Green & Co. Guido Zerkowitz, "Thermodynamik der Turbomaschinen," Oldenbourg. Thomas, "Steam Turbines," Wiley. Moyer, "Steam Turbines," Wiley.

A steam turbine consists of a rotor (one or more wheels or drums) carrying blades or buckets against which one or more jets of steam impinge.

Classification. Steam turbines are classified as follows:

1. According to the method of steam expansion: (*a*) **Impulse turbines,** with steam expansion only in the stationary blades or nozzles; (*b*) **reaction turbines,** with steam expansion both in the stationary and in the moving blades.

2. According to the method of subdividing the available energy: (*a*) **Pressure-stage turbines,** where the available steam pressure drop is subdivided among two or more successive sets of rotating blades, each set taking care of a part of the drop of pressure; (*b*) **velocity-stage turbines,** where the steam at constant pressure passes through two or more successive sets of rotating blades, starting with a high steam velocity and decreasing the same from set to set.

3. According to the direction of the principal part of the steam flow with relation to the shaft: (*a*) **Axial-flow turbines** (flow parallel to the shaft); (*b*) **radial-flow turbines** (flow radial or at right angles to the shaft); (*c*) **tangential-flow turbines** (flow tangential to the rotor or shaft).

In a **pure impulse turbine** steam passes through stationary nozzles where it suffers a drop of pressure, the energy of which is converted into kinetic energy. The steam then impinges on the blades or buckets of the rotor, producing rotation and thereby mechanical work. There is no drop of pressure in the steam as it passes through the rotating blades. In a **pure reaction turbine** the steam passes through a set of stationary blades or guide vanes which direct the steam against the rotating blades. As the steam passes through these rotating blades, there is a drop of pressure from the entrance side to the exit side, which increases the velocity of the steam and produces rotation by the reaction of the steam on the buckets. The energy of the pressure drop is converted into kinetic energy in the moving blades, producing rotation and thereby mechanical work. In practice, impulse turbines work with some reaction, and reaction turbines work with some impulse; but each type is designated according to whether its predominant feature is impulse or reaction.

The energy of the total available pressure drop cannot usually be efficiently converted into mechanical work with one set of moving blades or buckets, and **pressure staging** is resorted to. In a reaction turbine this is accomplished by alternating rows of stationary and moving blades. Each set of moving blades takes care of a small drop of pressure. In an impulse turbine each pressure stage has a set of stationary blades or nozzles in which a drop of pressure occurs, the steam being directed against the rotating blades or buckets on the wheel of that stage. By sufficient subdivision of the total available pressure drop the steam velocities produced are such as can be efficiently utilized in the moving blades of a turbine. Velocity staging is also resorted to in impulse turbines. If the velocity of the steam from a nozzle is high, several sets or rows of moving blades can be used alternating with sets of stationary blades or reversing vanes. The kinetic energy is abstracted progressively in the succeeding rows of moving blades.

Applications. Steam turbines are necessarily high-speed prime movers and are most efficiently used direct-connected to electrical generators, centrifugal pumps, centrifugal compressors and ship propellers. They can be built to operate with **high-pressure** steam, running condensing or non-condensing; or with **low-pressure** steam only, running condensing; or as **mixed-pressure turbines**, utilizing any available low-pressure steam, but automatically resorting to the high-pressure steam supply if the low-pressure supply is insufficient; or as **steam-extraction turbines**, in which low-pressure steam can be extracted from the turbine for heating or other purposes; or as a combination high-pressure condensing or non-condensing unit, low-pressure unit, mixed-pressure unit, or steam-extraction unit controlled automatically to suit the user's requirements.

Advantages. Compared with other prime movers, steam turbines require less floor space, lighter foundations and less attendance, have better utilization of high vacuum and lower oil consumption, eliminate reciprocating masses and their resulting vibrations, have no rubbing parts outside of the bearings; they have extreme overload capacity, and freedom of the exhaust steam from oil, increased reliability due to simplicity of construction, excellent regulation and with favorable conditions as regards to steam pressure, superheat and vacuum, economies as good as steam engines for moderate powers and much better economies for units of larger sizes and greater powers.

Utilization of Vacuum. High vacuum can be better utilized in a steam turbine than in a reciprocating engine. The steam turbine can use advantageously a vacuum of more than 98 per cent. High vacuum reduces the windage or rotation losses of the rotor. Condensing turbines usually have from 27 to 29 in. vacuum, based on a 30-in. mercury barometer. The power required for producing this vacuum when the cooling-water conditions are favorable is, for large units, from 1½ to 3 per cent. of the turbine output. Low temperature of the cooling water is highly important, and separate condensing plant for each large turbine is desirable.

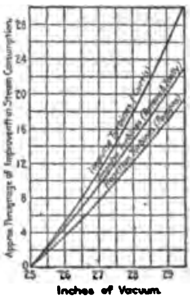

Fig. 1.—Influence of Vacuum on Steam Consumption of Turbines.

The **effect of vacuum on the steam consumption** varies greatly with the type and size of the turbine, so that no general statement is of value. For high-pressure units there is a decrease in steam consumption of about 5 per cent. for each inch of vacuum secured between 24 and 27 in. vacuum, a saving of 6 to 7 per cent. between 27 and 28 in., and of 7 to 8 per cent. between 28 and 29 in. For low-pressure units the gain due to increase of vacuum is greater. If the velocity of the steam as it leaves the last rotating buckets reaches the acoustic velocity (about 1400 ft. per sec.), further increase of vacuum has no effect on the steam economy. Fig. 1 shows the saving in steam consumption with improved vacuum for several types of steam turbines.

Effect of Superheat. Owing to the absence of rubbing parts in contact with the steam, steam turbines can work without difficulty with steam temperatures up to 650 deg. fahr., and have been designed for temperatures up to 800 deg. fahr. It is important, however, to keep the high-temperature steam away from the wheel casing and the turbine blading on account of its destructive effect on cast iron and other metals, and also because the great expansion interferes with small clearances. High steam temperatures are most easily applied with turbines having a large drop of pressure in the first stage, in which case the very-high-temperature steam comes only in contact with the steam passages to the first-stage nozzles. Single-stage impulse turbines are most suitable, while multi-stage reaction turbines are least suitable for use with steam of high initial superheat. Multi-stage units which have velocity stages in the first pressure stage, are more suitable than those without velocity stages. Superheat, besides improving the steam consumption, eliminates the erosion of the turbine blades by moisture and reduces the rotation losses of the turbine rotor. In high-pressure turbines, the steam consumption is improved approximately 1 per cent. for every 7 to 13 deg. fahr. superheat; the better value holding good for about 50 deg. fahr. superheat, while the other value holds for about 200 deg. fahr. superheat. The advantage of superheat is greater with non-condensing than with condensing units, and is even more marked with low-pressure units. A change of 35 deg. fahr. superheat causes a change of 1 per cent. of thermodynamic efficiency in the average high-pressure condensing unit of moderate power. The saving in steam consumption due to superheat is not as marked as that due to increase of vacuum. Fig. 2 shows the influence of superheat on steam consumption for two types of steam turbines.

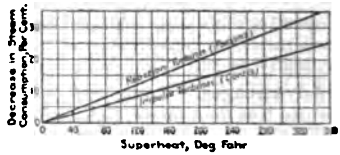

Fig. 2.—Influence of Superheat on Steam Consumption of Turbines.

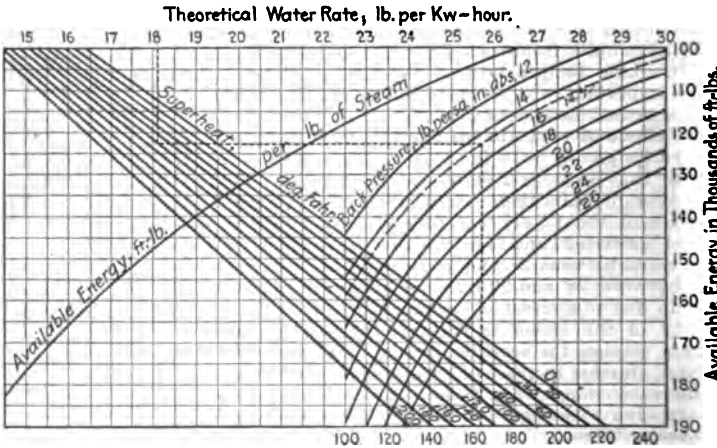

Fig. 3.—Theoretical Water Rates of High-pressure Non-condensing Steam Turbines.

Steam Consumption. The water rate of the steam turbine varies considerably. Other conditions being equal, the larger the power of the unit and the higher the speed the better the water rate. The theoretical water rates of steam turbines in lb. per kw-hour are given in Figs. 3, 4 and 5. To

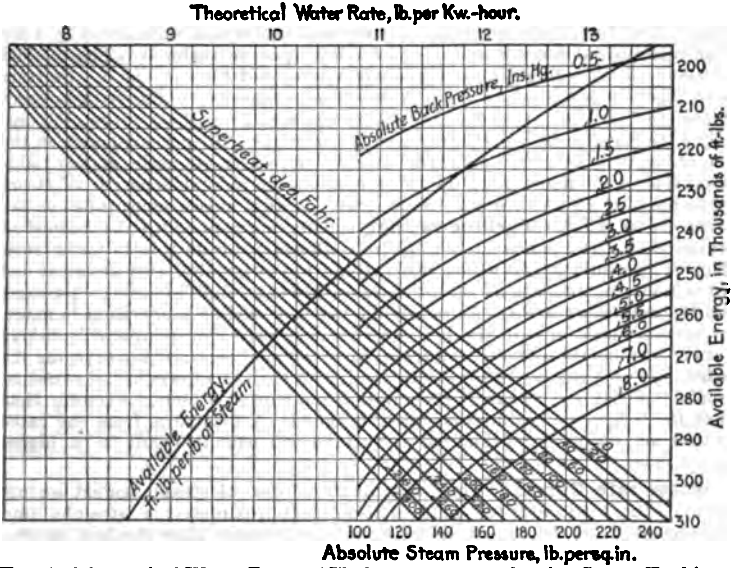

FIG. 4.—Theoretical Water Rates of High-pressure Condensing Steam Turbines.

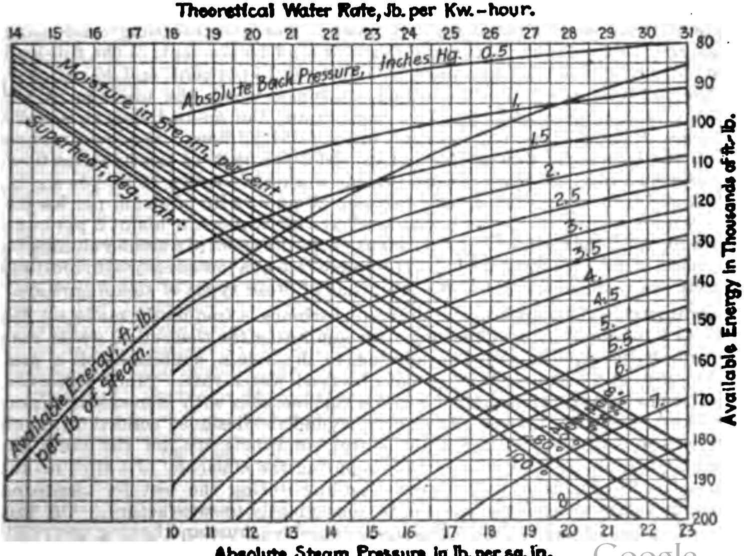

FIG. 5.—Theoretical Water Rates of Low-pressure Steam Turbines.

convert to lb. per h.p.-hour, take three-fourths of the water rate per kw.-hour. Fig. 3 gives the values for high-pressure non-condensing turbines; Fig. 4 for high-pressure condensing, and Fig. 5 for low-pressure turbines. The method of use of all three figures is indicated by the dotted lines in Fig. 3. Starting with the steam pressure (165 lb. abs.), go vertically to the back-pressure curve (14.7 lb. abs.), then horizontally to the initial superheat curve (100 deg. fahr.), and vertically to the water-rate scale (18.1 lb. per kw-hour) at the top of the diagram. The available-energy curve with its scale at the right-hand side of the figure gives the theoretical energy available per lb. of steam corresponding to the various water rates. Actual steam consumptions are given on p. 1006. **Turbine ratings** usually correspond to the output at which each turbine has its best overall efficiency, or its lowest water rate. This is the output for which the turbine has originally been designed and for which the dimensions of the nozzles, buckets, and interstage passages are theoretically correct. In nearly all types of turbines, provision is made, by excess nozzle area in the first stage or otherwise, for temporarily taking care of large overloads ranging from 25 to 50 per cent., or for carrying the rated load under unfavorable steam conditions such as a lower initial pressure, smaller initial superheat, higher initial moisture, or poorer vacuum than that for which the turbine has been designed. A departure from the rated output or steam conditions of a turbine will usually result in a higher water rate.

Water-rate Curves. The curve of total flow of steam against output between no load and full load is usually approximately a straight line. Beyond full load the total flow increases more rapidly than the load so that the flow line curves somewhat. If the water rates for two outputs not above rated load are given, an approximate flow line and water-rate curve of the turbine can be drawn. If only the water rate at full load is given, an estimate of the flow at no load must be made. For non-throttling condensing machines, this will vary between 5 per cent. and 15 per cent. of the full-load flow; for non-condensing machines, it is between 15 per cent. and 25 per cent. of the full-load flow. For throttling machines, where the pressure at the turbine nozzles rises and falls with the output, the no-load flow is usually between 25 per cent. and 35 per cent. of the full-load flow. For low-pressure turbines, the no-load flow should not exceed 5 per cent. of the full-load flow.

The water rate of a low-pressure turbine working between 16 lb. per sq. in. abs. and 28-in. vacuum is usually between 27 and 32 lb. of steam per kw-hr. Every pound change in initial pressure affects the water rate about 2 per cent. The effect of a change in vacuum is about twice the effect of a similar change on a high-pressure turbine (Fig. 1). The water rate of a low-pressure turbine will usually rise with overloads faster than that of other types of steam turbine.

Economy. A comparison of different turbines is frequently made on the basis of "thermodynamic efficiency," by computing the theoretical water rate (for adiabatic expansion) corresponding to the steam conditions of a particular test, and dividing this by the observed water rate. Since, however, the thermodynamic efficiency of a given turbine rises with increase of superheat and falls with increase of vacuum beyond the designed conditions, such comparison is misleading when the steam conditions are not the same for different turbines. The practice of computing the efficiency of a turbine for steam conditions other than those obtaining during the test by assuming constant thermodynamic efficiency, is consequently unsatisfactory. On this basis, turbines of large output, designed for high vacuum and having unavoidably high steam exit velocities from the last buckets on account of the enormous volume of steam handled, show, in general, a poorer thermodynamic efficiency than turbines designed for a poorer vacuum.

STEAM FLOW THROUGH NOZZLES AND BUCKETS IN IMPULSE TURBINES

(For general treatment of flow of steam, see p. 352)

Nozzles. The flow of **saturated steam**, dry or moist, through a nozzle when the back pressure is less than the critical pressure, can be computed approximately by Grashof's formula

$$W = 60 A_t p_1^{0.97} / \sqrt{x_1} \qquad (1)$$

in which W = flow of steam, lb. per hour; A_t = cross-sectional area of nozzle throat, sq. in.; p_1 = initial pressure, lb. per sq. in. absolute; x_1 = quality of steam corresponding to p_1. The results given by this formula are accurate to 1 to 2 per cent. within the range of the usual steam pressures encountered. Values of $p_1^{0.97}$ are given on p. 355. Within the range of $p_1 = 40$ to $p_1 = 300$ the above equation may be put in the form

$$\frac{W}{A_t} = \frac{50.5 p_1 + 150}{\sqrt{x_1}} \qquad (2)$$

with an error not exceeding 1 per cent.

For **superheated steam** the steam flow W as given by equation (1) is diminished, and when the discharge pressure p_2 is less than $0.58 p_1$,

$$W_s = \frac{W}{1 + 0.00065 T_s} = \frac{60 A_t p_1^{0.97}}{1 + 0.00065 T_s} \qquad (3)$$

in which W_s = flow of superheated steam, lb. per hour; and T_s = amount of superheat in deg. fahr.

When $p_2 > 0.58 p_1$, the flow of steam as given by (1) and (3) must be multiplied by a factor K.

$$K = 2.182 \sqrt{n(1 - 1.19n)} \qquad (4)$$

in which $n = 1 - (p_2/p_1)$. Table 1 gives values of K for pressure ratios p_2/p_1 down to 0.60.

Table 1

p_2/p_1	0.98	0.96	0.94	0.92	0.90	0.88	0.86	0.84	0.82	0.80
K	0.321	0.428	0.512	0.585	0.646	0.698	0.744	0.784	0.818	0.850
p_2/p_1	0.78	0.76	0.74	0.72	0.70	0.68	0.66	0.64	0.62	0.60
K	0.877	0.901	0.922	0.940	0.956	0.970	0.981	0.988	0.995	0.998

Nozzles designed to convert the pressure energy into velocity energy when the final pressure is less than 0.58 of the initial pressure (unaffected region), must have a diverging nozzle beyond the throat or orifice (section of minimum area). The divergence should not exceed 20 deg. included angle and should preferably be made about 15 deg. The ratio R of the mouth area to the throat area for various values of p_1/p_2, both for steam initially dry and saturated and for superheated steam, is given in Table 2.

Table 2. Ratio of Mouth Area to Throat Area of Nozzles for Various Pressure Ratios

p_1/p_2	100	80	70	60	50	20	10	8	6	4	2
Saturated steam: R =	13.802	11.555	10.395	9.163	7.980	3.966	2.436	2.069	1.716	1.349	1.015
Superheated steam: R =	9.681	8.271	7.529	6.761	5.959	3.214	2.075	1.818	1.545	1.258	1.005

When a nozzle having an actual expansion ratio r is used for steam pressures having a ratio p_2/p_1 which calls for an expansion ratio R, a percentage nozzle mouth error is introduced of a value $d = 100\ (r - R)/r$, which may be positive or negative, and the nozzle efficiency is reduced.

Table 3 gives values of the velocity coefficient C_v, by which the theoretical spouting velocity must be multiplied to obtain the actual spouting velocity for various values of the nozzle mouth error d. When the actual expansion ratio of the nozzle is greater than required, the nozzle is said to be overexpanded; when smaller, underexpanded. From Table 3 it appears that it is preferable to have a nozzle underexpanded than overexpanded. Thus, when the nozzle is overexpanded by 20 per cent. (a positive nozzle mouth error of 20 per cent.) the loss in nozzle efficiency is $1 - (0.953/0.970)^2$, or 3.5 per cent., while when the nozzle is underexpanded 20 per cent. the loss in nozzle efficiency is only $1 - (0.959/0.970)^2$, or 2.3 per cent.

Table 3

Nozzle mouth error, per cent.	−40	−30	−20	−10	0	10	15	20	25	30
Velocity coefficient, C_v	0.935	0.948	0.959	0.967	0.97	0.967	0.963	0.953	0.936	0.906

Bucket Velocity Coefficients. Theoretically, the velocity of the steam through the bucket in an impulse turbine wheel, *relatively to the bucket*, remains constant. Actually, however, as explained below, the relative exit velocity from the bucket is less than the relative inlet velocity by an amount depending on the magnitude of the inlet relative velocity. The ratio of exit velocity to inlet velocity is called the bucket velocity coefficient. Table 4 gives values of bucket velocity coefficients for the usual shapes of impulse turbine buckets. These coefficients are derived from tests and include not only the friction loss in the moving buckets but also the total losses from the nozzle mouth to the entrance of the succeeding intermediates or stationary reversing buckets, if any. These losses are the loss in the clearance space between the nozzles and the moving buckets, the loss due to the bluntness of the buckets at inlet, steam friction loss in passing through the moving buckets, and finally the loss in the clearance space between the moving buckets and the succeeding intermediates.

Table 4

Velocity relative to buckets, ft. per sec.	200	400	600	800	1000	1500	2000	2500	3000	4000
Bucket velocity coefficient	0.953	0.918	0.888	0.863	0.841	0.801	0.774	0.754	0.737	0.716

Bucket Velocity Diagram. Fig. 13 shows diagrammatically the usual arrangement of a nozzle with impulse turbine buckets having two velocity stages. Fig. 6 shows the corresponding bucket velocity diagram, giving the relative magnitudes and directions of the steam velocities in the nozzles and in the buckets. V_0 represents in magnitude and direction the theoretical spouting velocity of the steam from the nozzle, corresponding to the pressure drop in the nozzle. V_1 is the actual spouting velocity ($= 0.97V_0$, approx.) when there is no nozzle mouth error. The wheel speed at the pitch diameter of the buckets is U. The relative inlet velocity to the first row of buckets V_2 is obtained from the triangle of veloc-

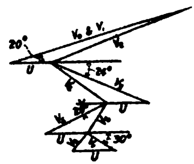

FIG. 6.—Bucket Velocity Diagram (Impulse Turbine).

ties. Multiplying V_2 by the proper velocity coefficient from Table 4 gives V_3, the relative exit velocity from the first row of buckets. Combining V_3 with U gives V_4, the *absolute* exit velocity from the first row of moving buckets, and the inlet velocity to the succeeding intermediates or stationary buckets. The exit velocity from the intermediates V_5 is equal to $0.95V_4$ regardless of the numerical value of V_4 (the difference between V_4 and V_5 representing only a friction loss, all other losses being taken care of by the velocity coefficients of the moving buckets). The relative inlet velocity to the second row of moving buckets V_6 is found by combining V_5 and U. Multiplying V_6 by the proper velocity coefficient from Table 4 gives V_7, the relative exit velocity from the second row of moving buckets. Finally, combining V_7 with U gives V_8, or the absolute velocity with which the steam is discarded from the turbine wheel.

Nozzle and Bucket Efficiency is the ratio of the energy utilized by the buckets to the energy represented by the pressure drop in the nozzle on the basis of adiabatic expansion.

Example 1. Let p_1 the initial pressure of the steam be 115 lb. per sq. in. absolute, and p_2 the final pressure be 15 lb. per sq. in. abs. An adiabatic expansion from p_1 to p_2, as read from a Mollier diagram, gives 148 B.t.u. per lb. of steam. Let the exit angle of the nozzle be 20 deg., and the exit angles of the first row of buckets, intermediates, and second row of buckets, be 24 deg., 26 deg., and 30 deg., respectively. (The best values for these exit angles are determined by experience). Let the wheel speed at the pitch diameter of the buckets be 620 ft. per sec.

From p. 355, $V_0 = 223.7\sqrt{148} = 2720$ ft. per sec., and $V_1 = 0.97V_0 = 2638$ ft. per sec. The wheel speed $U = 620$ ft. per sec. From the velocity diagram V_2 equals 2068 ft. per sec. (Fig. 6). From Table 4, the bucket velocity coefficient for 2068 ft. per sec. is 0.773. Then $V_3 = 0.773V_2 = 1597$ ft. per sec. Drawing V_3 at an angle of 24 deg. with U gives V_4 as 1061 ft. per sec. Then $V_5 = 0.95V_4 = 1007$ ft. per sec. and is drawn at an angle of 26 deg. with U. From the velocity diagram V_6 is 526 ft. per sec. Table 4 gives 0.900 for the velocity coefficient corresponding to 526 ft. per sec., so that $V_7 = 0.900V_6 = 473$ ft. per sec. Finally V_7 drawn at an angle of 30 deg. with U gives V_8 as 317 ft. per sec. Tabulating the above results, and converting velocity into equivalent B.t.u. [B.t.u. = $(\text{velocity}/223.7)^2$] the following is obtained:

	Ft. per sec.	Equivalent B.t.u.
Theoretical spouting velocity from nozzle	2720	148.0
Actual spouting velocity from nozzle	2638	139.0
First row buckets, relative inlet velocity	2068	85.5
First row buckets, relative exit velocity	1597	51.0
First row buckets, absolute exit velocity	1061	22.5
Intermediates, absolute exit velocity	1007	20.2
Second row buckets, relative inlet velocity	526	5.5
Second row buckets, relative exit velocity	473	4.5
Second row buckets, absolute exit velocity	317	2.0

The nozzle and bucket losses in B.t.u. are then as follows: Nozzle loss, $148.0 - 139.0 = 9.0$; first row buckets loss, $85.5 - 51.0 = 34.5$; intermediates loss, $22.5 - 20.2 = 2.3$; second row buckets loss, $5.5 - 4.5 = 1.0$; discarded velocity loss $= 2.0$. The total losses $= 48.8$ B.t.u. and the energy utilized is $148.0 - 48.8 = 99.2$ B.t.u. The nozzle and bucket efficiency is then $99.2/148 = 0.671$. If there had been only one row of moving buckets, the losses would have been $9.0 + 34.5 + 22.5$, a total of 66.0 B.t.u., and the nozzle and bucket efficiency only $82/148 = 0.554$. The addition of the second row of buckets in this particular example increases the nozzle and bucket efficiency by over 21 per cent.; although, if the wheel were originally designed for a single row of buckets, the efficiency could have been improved by the use of a smaller exit angle for the first row of buckets.

Rotation Loss. Of the many different formulæ proposed by various experimenters for the rotation loss of a bucket wheel in steam, the following have been found to give consistent results for the usual design and construction of turbine rotors:

$$L_d = 0.042D^2w \times (U/100)^{2.9} \quad (5)$$

$$L_b = 0.187Dwh^{1.25} \times (U/100)^{2.9} \quad (6)$$

in which L_d = rotation loss of the disk carrying the buckets, kilowatts; L_b = rotation loss of one row of buckets, kilowatts; U = wheel speed at pitch diam., ft. per sec.; D = pitch diam. (at center line of nozzle), ft. w = specific weight of steam, lb. per cu. ft.; h = mean bucket height, in. L_b must be figured for each row of buckets. L_d plus the sum of the values of L_b gives the total rotation loss in kilowatts for dry saturated steam. For wheels of pitch diameter greater than 36 in., the rotation loss computed from the above formulæ should be increased by 4 per cent. If the wheel rotates in moist or in superheated steam, the rotation loss computed from the above formulæ must be multiplied by an experimentally found factor such as given in Table 5.

Table 5

Superheat deg. fahr., or moisture, per cent.	100	50	0	2	4	6	8	10	12
Rotation loss factor	0.82	0.91	1.0	1.04	1.09	1.19	1.33	1.55	1.81

According to Buckingham (*Bull. Bureau of Standards*, vol. 10), a safe maximum value of the windage loss of wheels of ordinary shapes with one row of shrouded blades, running in the open or in casings which leave large clearances, in air or dry steam, may probably be computed from the following equation deduced from Stodola's results: Loss in horse power = $wn^3D^5[1 + 590(h/D)^2]/10^{16}$, where D = diam. of wheel at root of buckets, in., and n = r.p.m., other notation as above. Reducing the clearance around the buckets reduces the windage loss. With small clearance the resistance running backward is but little greater than when running forward. Wet steam offers more resistance than dry steam or air of the same density. The foregoing equation is for a wheel when driven through its shaft; if working in the usual manner the coefficient 590 may be reduced in the ratio of the idle buckets to the whole number. No formula, however, based on data now available can be trusted to give accurate results. For conditions similar to the above, Stodola gives the following formulæ for wheel friction, the second being derived from results of experiments carried out by the Allgemeine Elektricitäts-Gesellschaft: h.p. = $(0.061D^2 + 0.454Dh^{1.5})U^3w/10^6$; h.p. = $aD^4hn^3w/10^{10}$, where a = 0.78, 0.93, 1.25 and 1.89 respectively for 1, 2, 3 and 4 rows of buckets.

The friction loss in the buckets L_b may be approximately calculated from the formula $L_b = (1/3087)kL(C/4A)(v^2/2g)$ in B.t.u. per lb. of steam, where C = circumference of passage through which the steam flows, ft., A = sectional area of passage, sq. ft., v = relative entrance velocity of steam into buckets, ft. per sec., L = length of passage, ft., g = 32.2, and k = 0.06 to 0.10.

Bearing Loss. The friction losses of the bearings together with the usual friction losses of the shaft packings amount to not over 1 per cent. of the rating of the turbine.

Water Rate. The water rate of a turbine driving a generator is usually expressed in pounds of steam per hour per kilowatt of output at the terminals of the generator. If the turbine is connected to a centrifugal compressor the water rate is usually expressed in pounds of steam per 100 cu. ft. of air or gas delivered against a certain pressure, or if connected to a centrifugal pump or other mechanical drive the water rate is usually expressed in pounds of steam per shaft horse power delivered. In turbine design the water rate per bucket kilowatt or horse power is also used.

In the example given under nozzle and bucket efficiency, the available energy in the steam is 148 B.t.u. per lb. of steam. The nozzle and bucket efficiency is 0.671, hence the water rate per bucket kw. is 3412/(148 × 0.671) = 34.35 lb. of steam per hour. (1 kw-hr. is equivalent to 3412 B.t.u.). If 20,100 lb. of steam per hour are actually used in the turbine, the actual bucket kilowatts generated = 20,100/34.35 = 584. Assuming the rotation loss plus bearing losses to be 40 kw. the shaft output would be 584 − 40 = 544 kw.; and the water rate per shaft kw. would be 20,100/544 = 37 lb. per hour. If the turbine is direct-connected to a generator having an overall efficiency of 0.92 the power delivered to the switchboard is 544 × 0.92 = 500 kw. The water rate per kw. at the switchboard (terminals of the generator) is then 20,100/500 = 40.2 lb. of steam per hour.

IMPULSE TURBINES

Single-Stage (De Laval)

The total available pressure drop takes place in a single nozzle or set of nozzles, and the resulting kinetic energy is converted into mechanical work by a single turbine wheel carrying one or more rows of rotating buckets.

The **details of design** of a single-stage turbine are best explained by employing a numerical example. Let the initial pressure of the dry saturated steam used be 115 lb. per sq. in. absolute, and the exhaust pressure 15 lb. per sq. in. abs. It is desired to drive a 100-kw. generator at 3600 r.p.m. A water rate of 45 lb. per electrical kw-hour delivered is considered satisfactory. (Within reasonable limits a low water rate means a turbine with a rotor of large pitch diameter, hence large dimensions and high cost; a high water rate means a correspondingly cheaper turbine; therefore, either cost of unit or reasonable water rate must be determined upon.)

Nozzle. The necessary steam flow is 100 × 45 = 4500 lb. per hour. The theoretically required throat area [from (1)] is 4500/5980 = 0.752 sq. in. This area should be increased to allow the turbine to deliver full output when the initial steam pressure decreases or the exhaust pressure increases. Let the nozzle throat area be increased 25 per cent. or be 0.940 sq. in. The corresponding expansion ratio of the nozzle from Table 2 (by interpolation) is 1.99; hence the area of the nozzle at the exit is 0.940 × 1.99 = 1.870 sq. in. If the axis of the nozzle makes an angle of 20 deg. with the face of the nozzle plate or turbine rotor, the nozzle area on this plate is 1.870/sin 20 deg. = 5.47 sq. in. If the nozzles extended around the entire circumference of the rotating wheel, the nozzle height corresponding to this area would be very small. In an impulse turbine it is not necessary for the nozzles to extend around the entire circumference as is the case with reaction turbines. A reasonable nozzle height can therefore be assumed, in this case, 0.50 in. The necessary length of nozzle arc is 5.47/0.50 = 10.94 in. It is preferable to divide the necessary nozzle area into a number of small nozzles of the same total equivalent area, and to space them as close together as possible in order to deliver a practically continuous steam jet.

Rotor. Assuming that a peripheral speed of 620 ft. per sec. is satisfactory, the pitch diameter of the rotating buckets when running at 3600 r.p.m. must be $(620 \times 12 \times 60)/(\pi \times 3600) = 39.5$ in. The bucket angles and heights (bucket diagram) are usually determined by assuming certain bucket exit angles based on the results of experience, and calculating the corresponding correct inlet angles and bucket heights. Small values of exit angles give greater extraction of energy than larger exit angles but require correspondingly higher buckets at exit, which increases the rotation losses and mechanical difficulties of construction. Increase of bucket exit height (due to smaller exit angles) is practical only within certain limits because the steam jet in passing through the buckets will not diverge sufficiently to fill them. The angle of divergence should not exceed 20 deg.

Bucket Diagram. The steam velocities, bucket angles, and the nozzle and bucket efficiency are calculated in the examples under Nozzle and Bucket

Efficiency. The volume of steam remains constant as it passes through the turbine buckets and intermediates, but the steam velocity is decreasing; therefore, the heights of the buckets and intermediates must increase. The **exit heights** are as follows (for a nozzle height equal to 0.50 in.):

Buckets, 1st row: (2638 sin 20 deg./1597 sin 24 deg.) × 0.50 = 0.69 in.
Intermediates: (2638 sin 20 deg./1007 sin 26 deg.) × 0.50 = 1.02 in.
Buckets, 2d row: (2638 sin 20 deg./473 sin 30 deg.) × 0.50 = 1.91 in.

The **inlet height** of any bucket or intermediate is theoretically the same as the exit height of the nozzle or preceding bucket, but for mechanical reasons and also to allow for the slight spreading of the steam in the axial clearance between the nozzles and the buckets, and between the successive rows of buckets, the inlet height of each row of buckets is made somewhat larger than the exit height of the nozzle or of the preceding bucket. In the present example, the inlet height of the first row of buckets may be 0.56 in.; of the intermediates, 0.76 in.; and of the second row of buckets, 1.09 in.

The **rotation loss** may be computed by the use of equations (5) and (6) *ante*. In the present example, $U = 620$; $D = 39.5/12 = 3.291$; h, for first row of buckets $= (0.56 + 0.69)/2 = 0.625$; h, for second row of buckets $= (1.09 + 1.91)/2 = 1.50$; and w, for steam of 15 lb. per sq. in. abs., is 0.0381. The rotation loss uncorrected for moisture is then

$$L_d = 0.042 \times (620/100)^{2.9} \times (3.291)^2 \times 0.0381 = 3.44 \text{ kw.}$$
$$L_b = 0.187 \times (620/100)^{2.9} \times 3.291 \times 0.0381 \times [(0.625)^{1.25} + (1.50)^{1.25}] = 10.32 \text{ kw.}$$

As the pitch diameter of the buckets in the present case is greater than 36 in., the rotation loss as just computed must be increased by 4 per cent., giving a total uncorrected rotation loss of (3.44 + 10.32) × 1.04 = 14.30 kw.

The steam in expanding adiabatically from 115 lb. per sq. in. abs. to 15 lb. per sq. in. liberates 148 B.t.u., and has a final total heat of 1041 B.t.u. and a final moisture of 11.3 per cent. Assuming a shaft efficiency of 57 per cent. (to be checked presently), the 43 per cent. losses of energy in the steam due to steam friction, rotation loss, etc., appear in the exhaust steam in the form of heat, or 0.43 × 148 = 64 B.t.u. go back into the steam by reheating it. The total heat of the steam after it has passed through both rows of buckets is therefore 1041 + 64 = 1105 B.t.u. At a pressure of 15 lb. per sq. in. this corresponds to a moisture of about 4.7 per cent. The average moisture of the steam is then (11.3 + 4.7)/2, or 8 per cent. From Table 5 the rotation loss correction factor is 1.33, so that the corrected rotation loss is 14.30 × 1.33 = 19 kw.

Water Rate. Referring to Fig. 3, the theoretical water rate for the steam conditions of the present problem is 3412/148 = 23.0 lb. of steam per kw.-hour. With a nozzle and bucket efficiency of 0.671, the water rate per bucket-kw. is 23.0/0.671 = 34.4 lb. per hour. The bucket-kw. therefore from the assumed flow of 4500 lb. of steam per hour is 4500/34.4 = 131. The rotation loss, as found above, is 19 kw. Allowing about 1 kw. for bearing losses, the total loss is about 20 kw. The net shaft output of the turbine is therefore 131 − 20 = 111 kw.; and the water rate per shaft kw. is 4500/111 = 40.6 lb. per hour. The shaft efficiency is then 23.0/40.6 = 0.568. If the overall efficiency of the generator is 90 per cent., the generator output is 111 × 0.90 = 100 kw.; and the water rate per electrical kw. is 4500/100 = 45 lb. per hour.

Multi-stage (Rateau, Curtis, Zoelly)

The total available pressure drop is subdivided between two or more stages, each stage consisting of a set of nozzles and of a turbine wheel or rotor carrying one or more bucket rows. As the energy to be utilized in each stage is comparatively small, a good efficiency may be attained with a moderate wheel speed.

Details. The number of stages in an impulse turbine varies considerably, but it is always small in comparison with the number of stages in a reaction turbine for the same steam conditions and output. The pressure drop can be subdivided between the various stages so that each stage has the same available B.t.u. All wheels can be then of the same pitch diameter and have the same number of velocity stages.

Frequently, the first stage is allowed to take more than its equal share of the available pressure drop, in order to reduce the steam pressure in the first stage. This lowers the maximum pressure to which the casing is subjected, reduces the mechanical difficulties in the design of a packing to prevent leakage of steam from the first stage to the atmosphere, and, by lowering the density of the steam in the first stage, reduces the rotation loss of the first-stage wheel which is generally the greatest. In this case, the first-stage wheel usually has two or more velocity stages; while the following wheels, with a comparatively smaller B.t.u. per stage, have only one velocity stage each. The pitch diameters of the last wheels are frequently made larger so as to increase their nozzle and bucket efficiency, while their rotation loss remains fairly low on account of the low density of the steam in which these last wheels revolve. The nozzles of the first stage usually take up only a small part of the pitch circumference. As the pressure drops and the volume of the steam increases, the arc of admission increases from stage to stage till it reaches 360 deg. in the last stages, giving full peripheral admission.

Labyrinth Packings are designed to reduce the leakage between stages along the shaft to a minimum. This leakage may be computed by the following formulæ (see also p. 770).

$$W = 5.67A\sqrt{\frac{p_1^2 - p_2^2}{zp_1v_1}} \quad \text{when } p_2 > p_1 \times \frac{0.85}{\sqrt{z + 1.5}} \tag{7}$$

and

$$W = 5.67A\sqrt{\frac{1}{z + 1.5} \times \frac{p_1}{v_1}} \quad \text{when } p_2 \leq p_1 \times \frac{0.85}{\sqrt{z + 1.5}} \tag{8}$$

in which W = leakage, lb. per sec.; A = leakage area, sq. ft. (= circumference of shaft times the radial clearance, in ft.); p_1 = pressure before packing, lb. per sq. in. abs.; p_2 = pressure after packing, lb. per sq. in. abs.; v_1 = specific volume corresponding to p_1, cu. ft. per lb.; z = number of steps or subdivisions in packing. In practice, the loss due to leakage through the packings is usually from 2 to 4 per cent. of the rated output of the turbine.

Example. It is desired to design a turbine to drive a 1000-kw. generator at 3600 r.p.m.; initial pressure of the saturated steam to be used, 165 lb. per sq. in. abs., exhaust, 1 lb. per sq. in. abs. A water rate of 15.7 lb. per electrical kw. is assumed as satisfactory, and experience indicates a five-stage turbine should give this water rate. The first stage is assigned a pitch diameter of 36 in. and the other four stages one of 48 in. each. The first-stage pressure is chosen as 50 lb. per sq. in. abs. in order to keep down the maximum pressure existing in the turbine wheel, thereby reducing also the difficulty of designing the high-pressure packing to withstand the steam pressure of the first stage, and lowering the rotation losses of that stage. The available energy in the last four stages is usually equally divided, but the amount available in any stage depends upon the amount of reheating occurring in the previous stage. The reheating in any stage is equal to unity minus its shaft efficiency. A shaft efficiency is assumed and the output and amount of reheating of each stage are calculated and by trial and error the final distribution of energy and shaft efficiency determined. The following results are those obtained after several trial calculations.

Nozzle and Bucket Diagram, First Stage. The necessary steam flow from the assumed water rate is 1000 × 15.7 = 15,700 lb. per hour. The theoretical throat area, from equation (2) is therefore 1.85 sq. in., and should be increased 50 per cent. to allow the turbine to deliver full output with lower steam pressures and also full output when running non-condensing. This increase of area will not affect the efficiency or the design of the machine, because multi-stage impulse turbines are designed with governing mechanisms which admit the steam through a considerable number of valves opened or closed successively by the governor, each valve admitting steam only to a few nozzles of the first stage.

Pressure ratio for nozzles = 165/50 = 3.3; expansion ratio, from Table 2, = 1.23. Taking nozzle height = 0.5 in. and nozzle axis at angle of 20° with nozzle plate, area of nozzle mouth = 1.85 × 1.50 × 1.23/sin 20° = 10 sq. in., or net length = 10/0.5 = 20 in. Assuming exit angles of 24° and 30° for first and second rows of buckets and of 26° for intermediates, and drawing velocity diagram, Fig. 6, the steam velocities and equivalent B.t.u. are

	V_0	V_1	V_2	V_3	V_4	V_5	V_6	V_7	V_8
Ft. per sec.	2157	2092	1574	1253	774	735	336	313	332
B.t.u.	93	87.5	49.5	31.4	12	10.8	2.3	2.0	2.2

and the exit heights (as per p. 988) are 0.7 in., 2.28 in., and 1.11 in., respectively, for the first and second bucket rows and the intermediates. Nozzle and bucket efficiency (as per Example 1) = 0.706. With assumed shaft efficiency of 0.60, reheating = 0.40 × 93 = 37.2 B.t.u. Moisture after adiabatic expansion through nozzle = 7.7 per cent. (from Mollier diagram, Fig. 7) and total heat = 1102 B.t.u. ∴ total heat after reheating in first stage = 1102 + 37.2 = 1139.2 B.t.u.; corresponding moisture = 3.6 per cent., hence average moisture in stage = 5.7 per cent. The corrected rotation loss, taking inlet heights of first and second rows of buckets as 0.56 and 1.78 in., respectively, is 44 kw. (using method on p. 988). Bucket output per lb. steam = 93 × 0.706 = 65.7 B.t.u.; total bucket output = 15,700 × 65.7/3412 = 302 kw. Shaft output for first stage = 302 − 44 = 258 kw., and theoretical water rate = 3412/93 = 36.7 lb. steam per kw.-hr. Actual water rate = 15,700/258 = 60.8, making shaft effy. = 36.7/60.8 = 0.603.

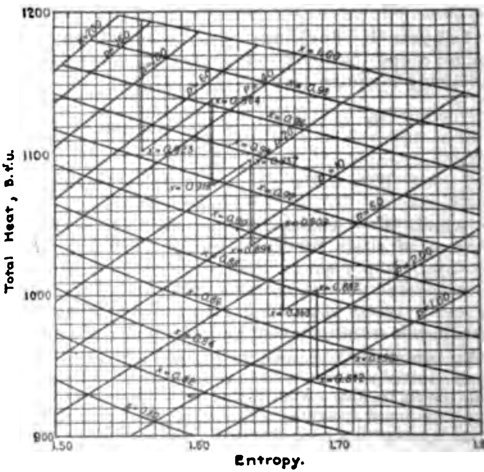

Fig. 7.—Mollier Diagram for Steam.

Nozzle and Bucket Diagrams, Second to Fifth Stages. Assume shaft efficiencies of 0.70, 0.75, 0.77 and 0.77, respectively, for these stages (higher for latter stages because of decreased rotation losses), and an available energy of 61.5 B.t.u. per stage. The second-stage nozzles expand from a pressure of 50 lb. and total heat of 1139.2 B.t.u. to a total heat of (1139.2 − 61.5 =) 1077.7 B.t.u. and a pressure (from Mollier diagram) of 21.3 lb. Reheating = entire loss of stage = (1 − 0.70) × 61.5 = 18.4 B.t.u., so that total heat of steam entering third stage = 1096.1 B.t.u. The third-stage nozzles expand the steam from 21.3 lb. through a B.t.u. drop of 61.5 to 8.5 lb. and 1034.6 B.t.u. Reheating = (1 − 0.75) × 61.5 = 15.4 B.t.u., making total heat of steam entering fourth stage = 1050 B.t.u. Similarly for fourth and fifth stages, the fifth-stage nozzles expanding from 3.1 lb. to 1 lb. (abs.).

Fig. 7 shows on a Mollier entropy-total heat diagram the expansion of the steam in this turbine from its initial to its final pressure (165 lb. abs. to 1 lb. abs.). It first expands to a pressure of 50 lb. and at the end of expansion has $(1 - x = 1 - 0.923 =)$ 7.7 per cent. of moisture. In passing through the buckets of the first stage the steam was reheated at constant pressure and finally had a moisture content of only $(1 - 0.964 =)$ 3.6 per cent. Similarly for the remaining stages.

Taking minimum nozzle height = 0.50 in., the nozzles of the first, second and third stages will extend only partially around the circumference. In the fourth and fifth stages they must extend entirely around and have respective heights of 0.76 in. and 2.10 in., allowing 10 per cent. for spaces between nozzles. As the available energy in each of the last four stages is 61.5 B.t.u., the nozzle and bucket angles are the same. Taking nozzle and bucket-exit angles each as 20°, the inlet angle (Fig. 8) is found to be 35°, and the steam velocities and equivalent B.t.u. are:

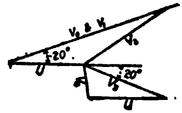

FIG. 8.

	V_0	V_1	V_2	V_3	V_4
Ft. per sec....................	1754	1701	1027	860	299
B.t.u..........................	61.5	57.8	21.1	14.8	1.8

By methods previously described, the nozzle and bucket efficiency of each stage is found to be 0.808, and the exit heights from the second-, third-, fourth- and fifth-stage buckets 0.99 in., 0.99 in., 1.5 in. and 4.16 in., respectively. The mean bucket heights are 0.80 in., 0.80 in., 1.22 in. and 3.58 in., taking 0.61 in., 0.61 in., 0.95 in., and 3 in. as the respective inlet heights. The corrected rotation losses are approximately 30 kw., 15 kw., 10 kw. and 10 kw., respectively, for the second, third, fourth and fifth stages. The bucket output per lb. of steam in each stage is $61.5 \times 0.808 = 49.7$ B.t.u., and the total bucket output per stage $= 15{,}700 \times 49.7/3412 = 229$ kw. The shaft outputs for the last four stages are then 199, 214, 219 and 219 kw., or a total for all five stages of 1109 kw. Allowing 4 per cent. for bearing losses and leakage, net shaft output = 1064 kw. Output at generator terminals (overall efficiency, 94 per cent.) $= 1064 \times 0.94 = 1000$ kw. Theoretical water rate for last four stages $= 3412/61.5 = 55.5$ lb. per kw.-hr. Actual shaft water rates for the four stages are $(15{,}700/199 =)$ 79, 73.4, 71.6 and 71.6 lb., respectively, and the shaft efficiencies $(55.5/79 =)$ 0.703, 0.755, 0.775 and 0.775.

The energy corresponding to a single adiabatic expansion from 165 lb. per sq. in. abs. to 1 lb. abs. is 322 B.t.u., and the theoretical water rate therefore $(3412/322 =)$ 10.6 lb. of steam per kw. per hour. In the turbine considered 15,700 lb. of steam develop 1064 kw. at the shaft, giving a shaft water rate of $15{,}700/1064 = 14.75$ lb. per kw. per hour, and making the overall shaft efficiency of the turbine $10.6/14.75 = 0.719$.

REACTION TURBINES (PARSONS)

The reaction turbine is always a multi-pressure-stage turbine with small pressure drop per stage. Each stage consists of a stationary set of blades or nozzles and a row of rotating buckets. As there is a continuous drop of pressure throughout each stage, partial peripheral admission of the steam (as in the impulse turbine) is impossible. Steam must be admitted around the entire circumference of the wheels, and therefore the stationary blades must extend around the entire circumference. The total available pressure drop for each stage is divided into two parts, one being converted into kinetic energy in the stationary blades, and the other in the moving blades. The residual velocity from one stage is utilized in the next stage.

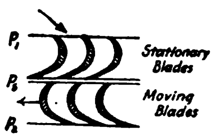

FIG. 9.—Reaction Turbine.

Details. The steam approaches each set of stationary blades (from the exit of the preceding stage) with a velocity of V_4 ft. per sec. and at an absolute pressure of p_1 lb. per sq. in. The steam expands adiabatically while passing through the stationary blades from pressure p_1 to p_s (see Fig. 9). The theoretical spouting velocity V_1 from the stationary blades is found from the available energy corresponding to the velocity of steam approach, V_4, plus the energy in the available pressure drop p_1 to p_s.

$$V_1 = 223.7\sqrt{(V_4/223.7)^2 + H_s} \qquad (9)$$

in which H_s is the available energy in B.t.u. per lb. of steam corresponding to adiabatic expansion from p_1 to p_s. This spouting velocity V_1 combined with the wheel speed U (see Fig. 10) gives the relative entrance velocity V_2 to the moving blades. The relative exit velocity from the moving blades is obtained from the available energy corresponding to the velocity V_2 plus the energy in the available pressure drop p_s to p_2. Or it can be expressed by the equation

$$V_3 = 223.7\sqrt{(V_2/223.7)^2 + H_2} \qquad (10)$$

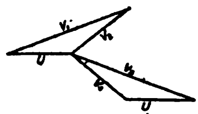

FIG. 10.—Bucket Velocity Diagram (Reaction Turbine).

in which H_2 is the available energy in B.t.u. per lb. of steam corresponding to adiabatic expansion from the absolute pressure p_s to the absolute pressure p_2. The absolute exit velocity V_4 from these moving buckets is found (Fig. 10) by combining V_3 with the wheel speed U. This absolute velocity V_4 is again available as the entrance velocity to the next stage.

Degree of Reaction. If H represents the B.t.u. corresponding to the total pressure drop p_1 to p_2 of any stage and H_2 the B.t.u. corresponding to the pressure drop p_s to p_2 in the moving blades alone, then H_2/H is the degree of reaction. Usually H_2/H is taken as 0.5; or the B.t.u. drop in the moving blades is equal to the B.t.u. drop in the stationary blades. This division of energy between the stationary and the moving blades is best obtained by having the entrance and exit angles of the stationary buckets equal respectively to those of the moving blades.

Grouping of Stages. As the pressure drop per stage is small, a reaction turbine has a large number of stages. It is usual to subdivide these stages into a number of main divisions, each with a different pitch diameter and usually called first, second, third, etc., drums. As the steam in passing through the turbine drops in pressure, its volume increases; and therefore the pitch diam. of the various drums increases from the first to the last. Experience has shown that three drums give a convenient arrangement for most reaction turbines; and for the usual ranges of steam pressures, the pitch diameters of the drums have usually a ratio of $1:\sqrt{2}:2$. The distribution of energy among the three drums in practice is approximately in the ratio of $1:1:1.5$.

Theoretically, each set of stationary and moving buckets on any one drum should either continually increase in height from one end of the drum to the other to accommodate the increasing volume of steam, or, with equal heights of blades, the various exit angles of the blades should gradually increase to accommodate the increase of steam volume. Practically, for constructive reasons, it is preferable to divide each drum into a number of groups, each group consisting of stationary and moving buckets of the same height and shape but so assembled that the exit angles of the buckets gradually grow larger as the steam volume increases. This is accomplished by "gaging" the buckets, that is, by turning the buckets in the successive rows after they are assembled on their respective drums, so that they have gradually increasing exit angles.

A convenient empirical formula for initial calculations of reaction turbines leading to the proper choice of the **number of stages per drum with three-drum construction**, is

$$z_1U_1^2 + z_2U_2^2 + z_3U_3^2 = \frac{25{,}000 \times H_0}{(k/K_a^2) - 1 + (2\cos a/K_a)} \quad (11)$$

in which z_1, z_2, and z_3 are the number of stages on the drums having respectively the wheel speeds U_1, U_2 and U_3 at their pitch diameters, H_0 is the total available B.t.u. for adiabatic expansion from the initial to the final steam pressures; k is a loss coefficient varying from 0.18 to 0.35, and generally assumed as 0.25 for the usual types of bucket construction; $K_a = U/V_1$ = wheel speed divided by steam velocity, and is usually assumed as 0.5; a is the mean exit angle of any group and usually assumed as 25 deg. Substituting the usual values in the above equation it can be expressed as

$$z_1U_1^2 + z_2U_2^2 + z_3U_3^2 = \frac{25{,}000H_0}{[0.25/(0.50)^2] - 1 + (2 \times 0.906/0.50)} = 6900H_0 \quad (12)$$

As the drum diameters are usually chosen in the ratio of $1:\sqrt{2}:2$, $U_2^2 = 2U_1^2$ and $U_3^2 = 4U_1^2$, so that equation (12) becomes

$$z_1 + 2z_2 + 4z_3 = 6900H_0/U_1^2 \quad (13)$$

The **wheel speed** U_1 can readily be obtained from the pitch diameter of the first drum (D_1) and the prescribed r.p.m. The pitch diameter of the first drum can be expressed by the equation

$$D_1 = \sqrt[3]{60G_1v_1KK_a/\pi^2e_1N \sin a} \quad (14)$$

in which G_1 = flow of steam through the buckets of the first drum, lb. per sec.; v_1 = initial specific volume of the steam, K = ratio of pitch diam. to bucket height; K_a = ratio of wheel speed to steam speed; e_1 = ratio of net or clear exit area from the buckets to the exit area if the buckets were infinitely thin; N = r.p.m.; and a = exit angle from the buckets of the first stage on the drum.

Leakage Losses. As there is a continuous drop of pressure from one end of a reaction turbine to the other, the radial mechanical clearances between the rotating buckets and the casing, and between the stationary buckets and the drums, are of considerable importance, because these clearance areas form a means for considerable leakage losses. The radial clearances are made as small as good mechanical operation permits, small clearances being of more importance in the first drum than in the succeeding drums on account of the small bucket heights and greater steam density. The mechanical clearance must be sufficient to allow for the stretch of the buckets and drum when subjected to centrifugal forces at running speeds, and also for expansions due to temperature changes of the revolving and the stationary parts. The leakage losses in the first drum are usually from 5 to 8 per cent.; in the second drum, from 3 to 6 per cent.; and in the third drum from 1 to 2½ per cent.; the lower values calling for very close clearances.

As all reaction turbines are subject to an axial **end thrust** of the rotating parts due to the difference of steam pressures at the ends of each drum, this thrust is usually balanced by **balancing pistons** mounted on the rotor running with close clearance to the casing and of the same diameter as the overall diameter of each drum. Each balancing piston is then subjected to the same difference of pressure as the rotating drums by means of steam-pipe connections, but so that the thrust is in the opposite direction from that of the rotating drums. In large turbines the drums are sometimes divided into two groups with steam flow in opposite directions to balance axial thrust without the use of a balancing piston. The leakage between the balancing piston and the casing is usually from 5 to 8 per cent. for the first piston; from 4 to 7 per cent. for the second piston; and from 2 to 3½ per cent. for the third piston.

Energy and Efficiency. The **B.t.u. drop** in the first stage of each drum can be obtained from the equation

$$H_1^{*} = [2(1 + k)V_1^2 - V_4^2]/50{,}040 \tag{15}$$

The B.t.u. drop for any other stage on a drum includes the energy in the steam velocity approaching the stage (exit velocity from preceding stage) and can be expressed by the equation

$$H_1 = 2[(1 + k)V_1^2 - V_4^2]/50{,}040 \tag{16}$$

The B.t.u. drop for the first group of $z_1{}^1$ stages on any drum is

$$H_s = [2z_1{}^1(1 + k)V_1^2 - (2z_1{}^1 - 1)V_4^2]/50{,}040 \tag{17}$$

The B.t.u. drop for any other group of (z^1) stages on any drum is

$$H_s = 2z^1[(1 + k)V_1^2 - V_4^2]/50{,}040 \tag{18}$$

The **efficiency** E **of any stage** is obtained from the equation

$$E = \frac{2(U/V_{1s})\cos a_s - (U/V_{1s})^2}{k + 2(U/V_{1s})\cos a_s - (U/V_{1s})^2} \tag{19}$$

The angle a_s being the exit angle of the rotating bucket of the stage in question, it is necessary to know this angle for any certain stage. As the B.t.u. drop per stage is known, the absolute pressure, quality and specific volume of the steam for any stage can be determined. Therefore the exit angle for the z stage can be found from the following relations:

$$V_{1s} \sin a_s = V_1 \sin a_1(v_s/v_1) \tag{20}$$

and

$$V_{1s} \cos a_s = V_1 \cos a_1 \tag{21}$$

in which V_{1s} is the absolute exit velocity from the stationary bucket of the z stage in question, which is also equal to the relative exit velocity from the moving bucket of the z stage (only in case the degree of reaction equals 0.5); a_s is exit angle of the rotating bucket of the z stage; v_s is the specific volume of the steam after the z stage; and V_1, a_1 and v_1 are the respective values for the first stage.

Equation (20) is a strictly rational formula, whereas (21) is an approximation based on general experience and used for all stages except where the steam volumes (and therefore the bucket heights) increase very rapidly, as in the last few stages of a reaction turbine. Combining equations (20) and (21), the **exit angle** can be solved by the relation

$$\tan a_s = \tan a_1(v_s/v_1) \tag{22}$$

and the value for V_{1s} can then be solved from equations (20) and (21).

Having angle a_s and the value of V_{1s}, the **efficiency** E in equation (19) can be solved. As equation (21) is only approximate, the final exit angle is sometimes revised, as will be explained in the numerical example following. The mean of the efficiencies of the first and the last stage in a group gives the mean efficiency E_{mean} of the group. Finally, the **losses** in the group are given by the equation

$$L = (1 - E_{\text{mean}}) \times \frac{2z_1{}^1(1 + k)V_1^2 - V_4^2}{50{,}040} \tag{23}$$

where L is the loss in B.t.u. in the group, this loss being returned to the steam as heat, thus increasing both the total heat and the quality of the steam at the end of the group.

Example. It is desired to design a reaction turbine to drive a 2000-kw. generator at 3600 r.p.m., using dry saturated steam with an initial pressure of 165 lb. per sq. in. abs., and exhausting at 1 lb. per sq. in. abs. A water rate of 16.5 lb. per electrical kw. per hour is considered satisfactory.

Three drums will be used with their pitch diameters in the ratio of $1 : \sqrt{2} : 2$. The total flow of steam $G = 16.5 \times 2000 = 33{,}000$ lb. per hour or 9.17 lb. per sec. In the first drum, the leakage in the clearance between the blades and opposing surfaces is from experience about 6 per cent., as is also that past the balancing pistons, so that steam flow through blades of first drum $= G_1 = 0.88G$. For second drum (blade leakage, 4 per cent.; piston leakage, 5 per cent.), $G_2 = 0.91G$, and for third drum (blade leakage, 1.5 per cent.; piston leakage when double steam-flow connection is not used, 2.5 per cent.), $G_3 = 0.96G$. From equation (14) the pitch diam. $D_1 = 1.125$ ft. $= 13.5$ in., assuming $K = 20$, $e_1 = 0.77$ and $a = 20$ deg., and the wheel speed $U_1 = 212$ ft. per sec., so that from equation (13), $z_1 + 2z_2 + 4z_3 = 49$, H_0 being taken as 322. If the total output is to be distributed among the three drums approximately in the ratio 1 : 1 : 1.5, $z_1 = 15$, $z_2 = 7$ and $z_3 = 5$ will be a satisfactory solution.

Design of First Drum. The fifteen stages on the first drum may best be divided into four groups, all the buckets in any one group being of equal height. In the first stage in each group the exit angle $= 20$ deg., $U = 212$, and $V_4^2 = U^2 + V_1^2 - 2UV_1 \cos a$. The B.t.u. developed in one stage (except in first stage of first group), from equation (17) $= 6.76$. The efficiency of the first stage in each group, from equation (19) $= 0.734$.

First Group (5 stages). Initial pressure $p_1 = 165$ lb. abs.; quality, 1.00; sp. vol., 2.753 cu. ft. per lb.; total heat, $H = 1195$ B.t.u. per lb. B.t.u. drop from equation (17) $= 34.9$; final total heat per lb. $= 1195 - 34.9 = 1160.1$ B.t.u., with corresponding pressure after adiabatic expansion of 108 lb., quality $= 0.969$, and sp. vol. $= 4.00$. Exit angle a_5 from fifth stage [equation (22)] $= 27° 55'$; this, however, gives too large a drop. Taking $a_5 = 28° 30'$, equation (20) gives $(V_1)_5 = 442$, whence $(V_4)_5^2 = 75{,}700$ and H_1, from (16) $= 6.74$ B.t.u. which is close enough to 6.76 B.t.u. before determined Angles of intermediate stages may be similarly calculated or interpolated between first and last stages. Velocity ratio of fifth stage $= 212/442 = 0.48$ and efficiency of stage, from (19) $= 0.71$. Mean efficiency of group $= (0.734 + 0.71)/2 = 0.722$. Losses, from (23) $= 9.4$ B.t.u. Neglecting losses due to radiation, these revert to the steam, making total heat per lb. at exit from first group $= 1160.1 + 9.4 = 1169.5$ B.t.u.

Steam flowing through blades of first drum $= 0.88 \times 9.17 = 8.07$ lb. per sec., sp. vol. $= 2.753$ amd $V_1 = V_3 = 424$, whence bucket exit area $= 8.07 \times 2.753/424 = 0.0524$ sq. ft. $= 7.54$ sq. in. With a 20° exit angle and $e_1 = 0.77$, annulus area between drum and outer ends of buckets $= 7.54/(\sin 20° \times 0.77) = 28.6$ sq. in.; height of all buckets in first group $= 28.6/13.5\pi = 0.675$ in. Before entering the second group of buckets the steam from the first group may be considered as mixing with the 6 per cent. of steam leaking through the clearance spaces. This leakage steam, having done no work, has a total heat of 1195 B.t.u. per lb., and the final total heat of mixture x as obtained from the equation $0.88G(x - 1169.5) = 0.06G(1195 - x)$, is 1171.1 B.t.u. per lb.

Second Group (4 stages). $p_1 = 108$ lb. abs.; $H = 1171.1$; quality, 0.981; sp. vol., 4.05. B.t.u. drop, from (18) $= 27$; final total heat $= 1171.1 - 27 = 1144.1$; corresponding pressure after adiabatic expansion $= 77$; quality, 0.959, sp. vol., 5.45. Exit angle a_4 from fourth stage, from (22) $= 26° 6'$, which is too small. Taking value of $26° 30'$, $(V_1)_4$ from (20) $= 437$ and $(U/V_1)_4 = 0.485$. Efficiency of fourth stage from (19) $= 0.717$. Efficiency of first stage of group is same as for first stage of first group, 0.734, hence mean effy., of group $= (0.717 + 0.734)/2 = 0.725$. Losses, from (23), $= 7.4$ B.t.u., which added to steam make total heat at exit $= 1151.5$ B.t.u. per lb. Bucket exit area $= 8.07 \times 4.05/424 = 0.0771$ sq. ft. $= 11.1$ sq. in., from which annulus area $= 42.1$ sq. in. and bucket height 0.994 in. Final total heat x after mixing with leakage steam, from $0.88G(x - 1151.5) = 0.06G(1171.1 - x)$, $= 1152.8$ B.t.u. per lb.

Third Group (3 stages). $p_1 = 77$ lb. abs.; $H = 1152.8$; quality, 0.969; sp. vol., 5.50. B.t.u. drop, from (18) $= 20.3$; final total heat $= 1152.8 - 20.3 = 1132.5$ B.t.u.; corresponding pressure after expansion $= 59$; quality, 0.952; sp. vol., 6.95. Exit angle a_3 from third stage, from (22) $= 24° 42'$. Taking a value of 25°, $(V_1)_3$ from (20) $= 433$, $(U/V_1)_3 = 0.489$, and efficiency of third stage, from (19) $= 0.722$. With efficiency of first stage of 0.734 as in previous groups, mean effy. $= (0.734 + 0.722)/2 =$

0.728, and losses by (24) = 5.5 B.t.u., which added to steam give total heat at exit of 1138 B.t.u. Bucket exit area of third group = 8.07 × 5.50/424 = 0.1047 sq. ft. = 15.08 sq. in., annulus area = 57.3 sq. in. and bucket height = 57.3/13.5π = 1.352 in. Final total heat x after main steam mixes with blade leakage, from $0.88G(x - 1138) = 0.06G \times (1152.8 - x)$, = 1138.9 B.t.u.

FOURTH GROUP (3 stages). p_1 = 59 lb. abs.; H = 1138.9; quality, 0.959; sp. vol., 7. The first stage of this group is similar to that in second and third groups, and B.t.u. drop = that in third group = 20.3. Final total heat per lb. = 1138.9 − 20.3 = 1118.6 B.t.u.; corresponding pressure after adiabatic expansion, 45; quality, 0.943; sp. vol., 8.8. Exit angle a_3 from third stage, from (22) = 24° 34′. Taking value of 24° 55′ $(V_1)_3$ from (20) = 433, and $(V_4)_3{}^2$ = 65,700. From (16), H_1 = 6.73 B.t.u., which agrees with value first determined (6.76 B.t.u.). Velocity ratio for stage = 212/433 = 0.49, and efficiency from (20) = 0.722. Mean efficiency = (0.734 + 0.722)/2 = 0.728. The losses in the fourth group are equal to those in the third, namely, 5.5 B.t.u. There is a residual velocity loss due to change in pitch diam. from first to second drum = $(V_4)_3{}^2$/50,040 = 1.3 B.t.u., making total loss = 6.8 B.t.u., and total heat per lb. of steam at exit = 1118.6 + 6.8 = 1125.4 B.t.u. Bucket exit area = 19.21 sq. in., annulus area, 73 sq. in. and bucket height, 1.72 in. Total heat after mixing with leakage = 1126.2 B.t.u. per lb. Before entering second drum 1 per cent. of the total steam that has traveled over balancing piston mixes with main steam entering second drum (leakage past balancing piston of first drum, 6 per cent., minus that past piston of second drum, 5 per cent.). As this (at 1195 B.t.u.) has done no work, the new total heat = x = 1126.9 B.t.u.

Design of Second Drum. Pitch diam. = 13.5 × $\sqrt{2}$ = 19.09 in., and wheel speed U = 300 ft. per sec. Because of larger B.t.u. drop per stage and the more rapid increase in sp. vol. and in required exit angle, the smaller number of stages allotted (7) is divided into three groups. In first stage of each group a = 20°, V_1 = 300/0.50 = 600, $V_4{}^2$ = 111,600. B.t.u. developed in one stage (except first stage of first group) from (17) = 13.54. Efficiency of first stage in each group, from (20), = 0.734. The method of design of the three groups follows the same processes as for the first drum.

Design of Third Drum. Pitch diam. = 13.5 × 2 = 27 in. Five stages will be used, each computed separately on account of the very rapid increase in sp. vol. In the first four stages exit angle a will be taken as 20 deg. and V_1 as 848 ft. per sec. Max. bucket height for mechanical reasons is taken as 5.4 in. As this is too small to accommodate the flow, a double-flow construction will be used, where the steam at exit from second drum will divide in parallel between two 27-in. drums at opposite ends of the turbine. The heights of buckets on each drum will then be only one-half of the values found in the computation of total bucket height.

For method of design of the five groups, follow the procedure as given for the first drum. The complete calculation yields the following results:

	First drum	Second drum	Third drum
Pitch diameter, in.	13.5	19.09	27.0
Initial pressure, lb. per sq. in. abs.	165.0	45.0	11.0
Quality of steam	1.0	0.952	0.919
Flow through buckets, lb. per hr., G*	29,040.	30,030.	32,550.
Total bucket B.t.u. developed per lb. of steam, P	74.4	69.8	102.1
Total bucket output (GP/3412), kw.	633.0	614.0	975.0

	Group No.	Number of stages	Available B.t.u.	Mean efficiency	Bucket B.t.u.	Total bucket height, in.
First drum	1	5	34.9	0.722	25.2	0.675
	2	4	27.0	0.725	19.6	0.994
	3	3	20.3	0.728	14.8	1.352
	4	3	20.3	0.728	14.8	1.720
Second drum	1	3	42.8	0.714	30.6	1.022
	2	2	27.1	0.724	19.6	1.767
	3	2	27.1	0.723	19.6	2.510

* 33,000 × 0.88, 0.91, and 0.985, respectively.

	Group No.	Number of stages	Available B.t.u.	Mean efficiency	Bucket B.t.u.	Total bucket height, in.
Third drum....	1	1	31.5	0.734	23.1	2.910
	2	1	27.0	0.734	19.8	4.310
	3	1	27.0	0.734	19.8	6.580
	4	1	27.0	0.734	19.8	10.400
	5	1	28.1	0.708	19.7	10.800

The total bucket output = 633 + 614 + 975 = 2222 kw. Allowing 5 per cent. of this output for radiation and for mechanical loss, shaft output = 2222 × 0.95 = 2111 kw. With a generator efficiency of 94.7 per cent. the electrical output is 2000 kw. and the water rate per electrical kw. is 33,000/2000 = 16.5 lb. per hour.

LOW-PRESSURE, MIXED-PRESSURE, AND EXTRACTION TURBINES

Low-pressure Turbines are those designed to utilize low-pressure steam, usually exhaust steam from other apparatus (at pressures ranging from atmospheric to 25 lb. gage), and should operate exhausting into high vacua. Installations having large reciprocating engines can greatly increase the overall steam economy and output by the addition of low-pressure turbines taking the steam from the engines at pressures slightly above atmosphere. The expansion of the steam in the cylinders of reciprocating engines is limited by mechanical difficulties, because cylinder and piston diameters become mechanically impracticable if expansion to a high vacuum is attempted, while on the other hand steam turbines can easily accommodate almost any volumes of steam by providing sufficient steam-flow area. Generally speaking, a plant having first-grade reciprocating condensing engines can be remodeled by the installation of low-pressure turbines so that the reciprocating units run non-condensing and exhaust into the turbines. The additional capacity thus secured varies with local conditions, but is usually about 100 per cent. That is, for each 1000 h.p. output of the condensing engines the remodeled plant will have approximately 2000 h.p. output, with a moderate increase in the steam output of the boilers. By resetting their valve motions the engines are made to give their former output running non-condensing, and the low-pressure turbines are designed to produce equal output with the available low-pressure steam from the reciprocating units. The methods used in the design of low-pressure turbines are exactly similar to those described for high-pressure turbines.

Governing of Low-pressure Turbines. If both the engine supplying the exhaust steam and the low-pressure turbine are driving electric generators, the two generators, after being brought up independently to their correct speeds, should be interlocked electrically by being connected to the same busbars; as the load varies, the engine automatically supplies the turbine with the necessary amount of steam to enable the latter to take its proper share of the load.

If the engine is under a mechanical load while the turbine has an electrical load, a synchronous motor connected to the busbars of the turbine generator and also belted to the countershaft driven by the engine serves as a convenient means for transferring power from the turbine to the engine and *vice versa*.

If the load on the engine is of an intermittent character, a regenerator or heat accumulator is frequently used, in which the excess steam from the engine is condensed in water, and from which steam is evaporated and sent to the turbine when the steam supply from the engine is cut off. Or, one or two stages may be added to the turbine to take high-pressure steam when the low-pressure steam fails, this stage or stages being automatically cut out when the low-pressure steam is again available. (See Mixed-pressure Turbines.)

Mixed-pressure Turbines are designed to operate with two sources of steam supply, a high-pressure source and a low-pressure source. They are usually low-pressure turbines which automatically utilize high-pressure steam when the low-pressure steam supply fails or is insufficient in amount to carry the load. They can be designed as a very highly efficient low-pressure turbine with a high-pressure end of poorer efficiency and merely considered as a reserve or protection against loss of power when the low-pressure steam is not available; or they can be designed as a highly efficient high-pressure turbine utilizing incidentally any available low-pressure steam. An ordinary straight high-pressure turbine operating at various loads does not have constant stage pressures, and in designing a mixed-pressure turbine this fact must be recognized. If an efficient low-pressure turbine is desired, some means of holding a constant pressure at the stage into which the low-pressure steam is introduced is desirable. If, however, high-pressure steam economy is more important, the stage pressure should be permitted to vary and the low-pressure steam introduced at a pressure equal to or greater than the pressure existing in that stage when the turbine is carrying full load with high-pressure steam only.

Extraction Turbines. High-pressure turbines which permit the extraction of some of the low-pressure steam from any of their stages are known as extraction turbines. These turbines are used where quantities of low-pressure steam are needed constantly or intermittently. If used constantly, the areas for steam flow in the latter stages of the turbine are designed for less steam than passes through the high-pressure stages. Should the low-pressure extraction cease and all the steam be required to pass through the final exhaust of the turbine, the stage pressures would increase and the turbine would operate less efficiently. If, however, the steam extraction is intermittent and the steam flow to the turbine exhaust is usually the full amount, the latter stages of the turbine are designed for full steam flow, which results in a somewhat lower efficiency when steam is being extracted.

It is possible to design a mixed-pressure turbine so that it can be an extraction machine when desired. Some installations require turbines which will utilize low-pressure steam from various sources when there is an excess of this low-pressure steam, and will automatically supply low-pressure steam when there is a deficiency. To accomplish this the turbine governor controls both the supply of low- and of high-pressure steam by means of suitable valves. An auxiliary governor responsive to the stage pressure in which the low-pressure steam is introduced influences the main governing so that constant stage pressure is held. If the stage pressure tends to drop due to a diminution of the low-pressure steam supply, the governor, in order to hold constant stage pressure, admits more high-pressure steam; and when more low-pressure steam again becomes available, the stage pressure tends to rise and the governor cuts off some of the high-pressure steam, and the turbine utilizes more low-pressure steam.

TURBINE TYPES

During the life of the fundamental turbine patents, turbine types were more distinctive than to-day. At present there is a gradual tendency toward a more uniform type, especially in the case of large units.

CURTIS TURBINE OF THE GENERAL ELECTRIC CO.

The Curtis turbine is the most extensively used type of turbine in the United States. It is built in sizes of from less than 1 kw. up to 40,000 kw. capacity. Although some of the large units have been built with a vertical shaft, the horizontal-shaft machine is now available in all sizes. The smaller units up to about 100 kw. are designed with a single pressure stage having two or three velocity stages and throttling governors. From about 100 kw. to 3000 kw. capacity the turbines are built with two to five pressure stages, the first stage having usually two bucket rows (two velocity stages) and the succeeding stages either one or two bucket rows. Fig. 11 gives a sectional view of a 2000-kw. four-stage turbine. The governor controls a series of double-seated valves which admit steam to successive groups of nozzles in the first stage. The turbine is primarily arranged for condensing operation, but is provided with an exhaust opening from the second stage if it is necessary to operate at times non-condensing. From 3000-kw. upward the number of pressure stages varies from five to twelve, the first stages usually having two bucket rows and the succeeding stages having one bucket row each. In the very large units, the last one or two stages are arranged for double steam flow; that is, the steam passes in parallel through two wheels instead of one. This is necessary on account of the large volumes of steam and the otherwise excessive heights of buckets.

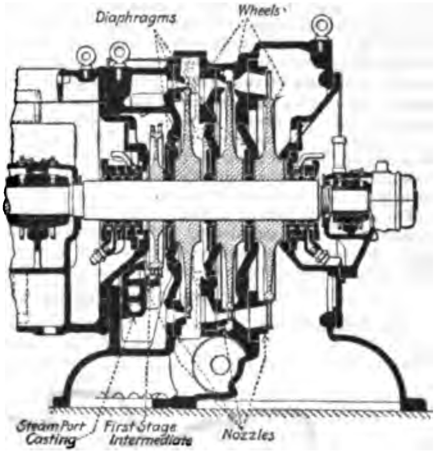

FIG. 11.—2000-kw. Four-stage Curtis Turbine.

The peripheral wheel speeds are generally between 400 and 850 ft. per sec. The buckets are inserted in the wheel rim by a dovetail construction as shown in Fig. 12, and are surrounded by a thin shroud mounted in sections and secured to each bucket. The buckets are made of a special non-corrosive copper alloy, nickel steel or chrome-vanadium steel according to the height of bucket and the peripheral speed employed. The buckets are equally spaced around the circumference of the wheel either by space blocks inserted in the dovetail of the wheel between the buckets, or by having these spacing blocks forged integral with the bucket. The nozzles are either expanding or non-expanding. In the first and earlier

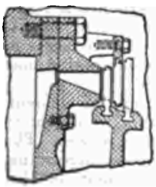

FIG. 12.—Mounting of Buckets in Curtis Turbine.

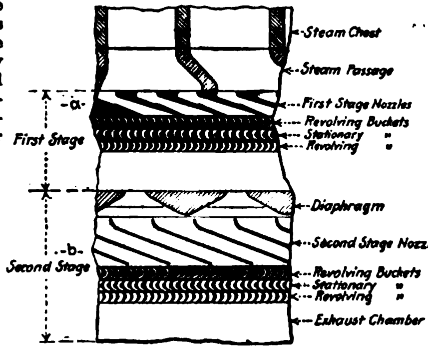

FIG. 13.—Arrangement of Nozzles and Buckets in a Two-stage Curtis Turbine.

stages where the steam temperatures are high the nozzles are machined out of bronze alloy, as shown at *a* in Fig. 13, while in the latter stages, the nozzles are made of plates of nickel steel cast into a nozzle ring of cast iron, as shown at *b* in Fig. 13, or cast directly into the diaphragms between stages.

To prevent steam leakage from stage to stage or to the atmosphere, either carbon packings or metallic labyrinth packings are employed. Carbon packings consist of one or more rings of pure carbon made in sections of 90 or 120 deg. and held toward the shaft with small clearances by means of springs. Metallic labyrinth packing is made of a light special alloy and is used similarly to the carbon packing. The labyrinth packing has the usual sawtooth arrangement where it comes in contact with the shaft, so that it will readily wear its own clearance when the shaft rotates. To prevent steam leakage from the high-pressure end to the atmosphere and air from the atmosphere to the vacuum end of the turbine, the packing is arranged in the form of three to five rings. On the high-pressure end the leakage of steam past the first few rings is carried to some of the low-pressure stages of the turbine, so that the outer rings need only prevent the leakage of this low-pressure steam to atmosphere. On the vacuum end, low-pressure steam is introduced between the packing rings in just sufficient quantity to supply the leakage toward the vacuum end of the turbine, and again the outer rings are employed to prevent the leakage of this low-pressure steam to atmosphere.

The turbine governor is connected by levers directly to a pilot valve which operates a steam- or oil-actuated piston. This piston controls directly or by means of a shaft and cams the successive opening or closing of a series of valves. Each valve controls the admission of high-pressure steam to a certain number of nozzles in the first stage.

WESTINGHOUSE TURBINES

The Westinghouse Machine Co. builds turbines ranging in size from 1 to 30,000 kw. The smaller machines up to 200 kw. capacity have a re-entry impulse wheel furnished with one row of buckets. The steam being expanded in a nozzle, passes the

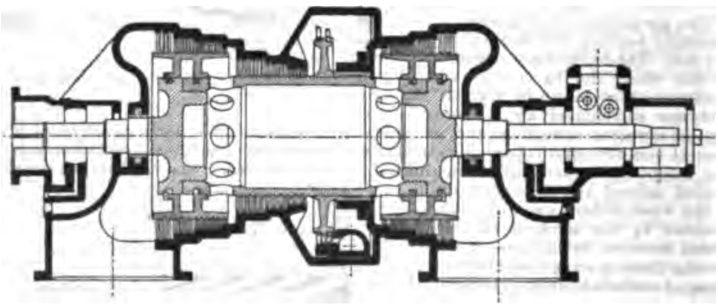

Fig. 14.—Westinghouse Turbine with Semi-double-flow Rotor.

wheel, and by means of suitably formed reversing chambers is re-directed into the same row of buckets. Depending upon the operating conditions, there may be two or more expansions, all operating on the same row of blades. In the larger machines a combination of impulse and reaction blading is used. The combination machines are built (1) single-flow, (2) semi-double-flow, and (3) double-flow.

In the single-flow unit, the steam after acting on the impulse element flows in one direction only, and the end thrust is compensated either wholly or in part by balance pistons provided with labyrinth packings on their outer edges. The reaction blading may be carried on drums of one or two different diameters, depending upon the size of the machine. This type is used for 60-cycle units up to about 1000 kw., and for 25-cycle up to about 1500 kw. capacity. Fig. 14 shows a semi-double-flow rotor such as is used for 1800-r.p.m., 60-cycle machines up to 6000 kw. capacity, and for 25-cycle 1500-r.p.m. machines up to about 7500 kw. normal rating. The intermediate reaction blading is made in a single section large enough to pass the entire quantity of steam. A balance piston similar to that used on the single-flow type (shown at the right of the impulse wheel) compels all of the steam to pass through the single intermediate section of the reaction blading and balance the end thrust due to this section. When the steam issues from the intermediate section the current is divided, one-half passing directly to the adjacent low-pressure section, while the other half passes through holes in the periphery of the hollow rotor and through the rotor itself, beyond the dummy ring, into the other low-pressure section at the right-hand end of the turbine.

In the double-flow rotor, the steam after acting on the impulse element divides, one-half going through the reaction blading at the left, the remainder passing over the top of the impulse wheel and through the reaction blading at the right. The double-flow construction is used for 60-cycle, 1800-r.p.m. units up to 15,000 kw., 60-cycle, 3600-r.p.m. units up to 5000 kw. and for 25-cycle, 1500-r.p.m. units up to 20,000 kw. capacity. The larger turbines may have their expansion carried out in two separate elements, and it is sometimes convenient to operate these at two different synchronous speeds, permitting the use of reaction blading in both elements.

Leakage along the turbine shaft at the ends of the casing is prevented by a water packing. This is virtually a single-stage centrifugal-pump impeller mounted on the shaft and supplied with water. Centrifugal force confines the water at the periphery of the impeller and between it and the surrounding packing casing. The impeller is made of sufficient diameter to seal against the pressure differences between casing and atmosphere. In the smaller turbines the governor acts directly on the steam admission valves, opening first the primary and then the secondary valve. Governors for the larger turbines employ an oil-relay mechanism for operating the steam valves. Non-condensing and low-pressure turbines are both built of reaction elements only, the latter generally being double-flow. Bleeder turbines are generally of the combined type.

DE LAVAL TURBINE

The original De Laval turbine was a single-pressure-stage impulse turbine with one revolving row of buckets, rotating at high speeds, usually from 10,000 to 30,000 r.p.m., and connected to generators or other apparatus by means of double helical reduction gears. The multi-stage turbine built by the De Laval Steam Turbine Company, Fig. 15, is of the impulse type and is a pure pressure-stage turbine, each stage consisting of a De Laval single-stage turbine; in some designs, however, the turbine is divided into a number of pressure stages, each stage contains several velocity stages. It is built in capacities from 50 h.p. to 15,000 h.p., with the turbine wheels mounted directly on a rigid shaft. The maximum peripheral bucket speed is not greater than 650 ft. per sec.; maximum rotative speed, 6000 r.p.m.

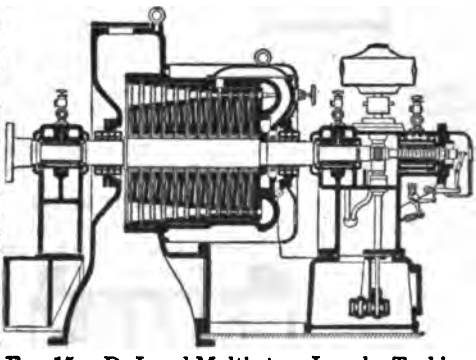

FIG. 15.—De Laval Multi-stage Impulse Turbine.

The De Laval single-stage turbine is built in capacities up to 600 b.h.p., peripheral speeds up to 1300 ft. per sec. being employed. The turbine wheel is made of chrome-nickel steel without any hole in the center, the shaft being joined to the disk by flange connections. On account of the high rotative speed and the mechanical impossibility of perfect rotative balance the shaft is made small in diameter, thus permitting the turbine rotor to revolve more nearly about its own true center of gravity. The buckets are of forged steel, with bulb shanks which fit into axial cylindrical grooves in the bucket wheel; on the outer end of the bucket the contributing section of the ring is forged as an integral part.

INGERSOLL-RAND TURBINES

The Ingersoll-Rand Co. turbines are primarily designed for driving turbo-compressors and turbo-blowers, and are generally of the mixed-pressure type. They are built in sizes up to 5000 kw., and designed for high-speed operation. High-pressure turbines are also built for driving electric generators through reduction gears.

Ingersoll-Rand turbines are of the impulse type and the high-pressure steam turbine has five to six wheels with single rows of buckets, the first wheel being of larger diameter than the following wheels. The first wheel works with partial, and the following low-pressure stages with nearly full, peripheral admission; peripheral velocity of wheels, 500 to 750 ft. per sec. Fig. 16 shows a typical high-pressure steam turbine used for turbo-compressors, having a capacity of 450 kw. at 6200 r.p.m.

The I.-R. mixed-pressure turbines are mostly designed on the double-flow principle and the steam admission to the low-pressure turbines is controlled by two separate inlet gears which open one after the other as the load increases. The discharge steam of the high-pressure stage passes to one of the low-pressure turbines only. The efficiency is practically constant from 40 per cent. load up to full load, when exhaust steam alone is used. Two kinds of steam control are used—steam throttling and nozzle regulation.

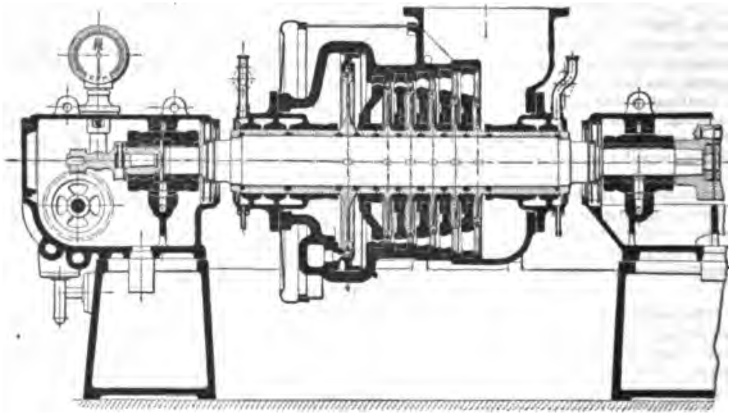

Fig. 16.—Ingersoll-Rand High-pressure Impulse Turbine.

KERR TURBINE

The Kerr turbine (Fig. 17) is of the multi-pressure-stage type with one bucket row per stage, and is built in sizes from 1 h.p. to 1500 h.p. The turbine is divided into stages

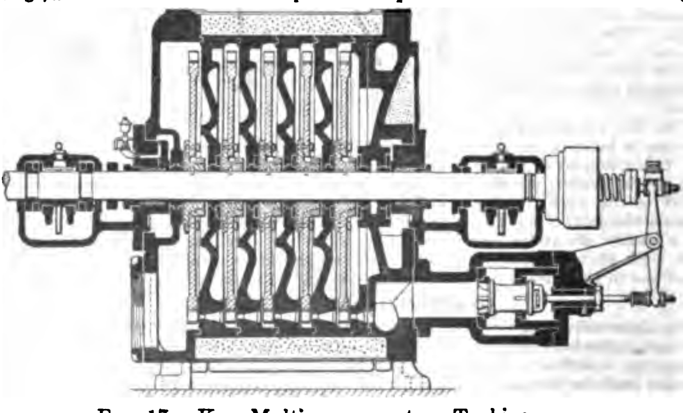

Fig. 17.—Kerr Multi-pressure-stage Turbine.

vertically, the wheels being mounted on the shaft by means of detachable hubs. In sizes from 300 to 1000 kw., the turbine casings are split horizontally, so that the upper half of the casing, frequently carrying the upper halves of the diaphragms with it, can be removed and the rotor taken out without breaking the steam and exhaust connections. The smaller turbines are built with from two to eight stages, and the larger machines up to thirteen stages, depending upon the power developed, steam pressure and vacuum. Governing is accomplished by throttling.

The buckets, made of 3.5 per cent. nickel steel, are set into dovetailed slots in the rim of the wheel and stiffened by a shroud ring. Peripheral speeds, from 300 to 600 ft. per sec. The nozzles are of the non-expanding type, except in the case of two- and four-stage turbines, or in mixed-pressure turbines. They are formed by casting in the diaphragms nickel-steel blades about 1/16 in. in thickness.

TERRY TURBINE

The Terry turbine is usually built as a single-pressure-stage turbine (with multi-velocity staging) having tangential admission of steam. The wheel has buckets or semi-circular recesses milled into its periphery, mounted around which are groups of nozzles with contiguous reversing chambers. The steam is expanded down to the exhaust pressure in a single nozzle, and, after striking one side of the wheel bucket, is reversed in direction, leaving the opposite side of the same wheel bucket. It then enters the first stationary bucket or reversing chamber, Fig. 18, which directs the steam back again into another bucket of the same wheel. This operation is repeated as many times as is necessary to reduce the kinetic energy in the discarded steam to a relatively low value. The turbine casing is split horizontally, the steam and exhaust connections being in the lower half, and is subjected to exhaust pressure only. Steam leakage between the shaft and the casing is prevented by bronze glands with an annular ball seat, no soft packing being used. Governing is by throttling. The single-wheel Terry turbine is used for non-condensing service and for condensing service in the smaller sizes. In the larger sizes, the condensing turbines are a combination of the above-described wheel for the high-pressure end with a series of single-velocity multi-pressure stages for the low-pressure end.

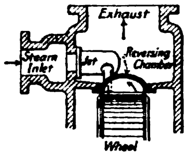

FIG. 18.—Terry Turbine.

THE MARINE TURBINE

Its smaller dimensions and weight for a given output, the rapidity with which it may be reversed, and its comparative freedom from vibration, have among other important reasons caused the steam turbine in recent years to be more and more frequently preferred for marine work, especially for torpedo boats and cruisers, and for fast passenger steamers. The main objection against its universal adoption on shipboard has been the fact that the steam turbine is essentially a high-speed machine, while ship propellers designed for very large powers must run at low relative speeds. Some of the methods by which this difficulty is overcome, are described in the following paragraphs.

Series Arrangement. In the Parsons marine turbine the expedient has been adopted of having the total steam expansion from boiler pressure to condenser pressure take place successively in several separate turbines, each turbine driving an independent propeller. Thus, in a 16,500-h.p., 290-r.p.m. turbine for an 18-knot steamer, the total power is distributed between three turbines, the high-pressure turbine driving the central shaft and exhausting into two low-pressure turbines located in the wings and taking the exhaust steam in parallel. The pitch diameter of the high-pressure turbine is over 6 ft., and that of the low-pressure turbines is nearly 9 ft. The reversing turbines are mounted on extensions of the low-pressure drums, their casings forming a continuation of the low-pressure casings.

Velocity Stages. In the Curtis marine turbine both the number of velocity stages per wheel and the number of pressure stages are much larger than in stationary turbines. On the U. S. Destroyer "Perkins," the two Curtis turbines (mounted on independent propeller shafts) developed a total of 12,000 h.p. at 600 r.p.m., attaining a speed of 30 knots. At 300 r.p.m. the combined output was 1550 h.p., and the speed 16.6 knots. Each turbine comprises six Curtis wheels, of which the first has four bucket rows and the others three rows each, and eight low-pressure stages arranged on a single drum. The common pitch diameter is 6 ft. The reversing turbine located in the same casing with the main turbine consists of two wheels, each having four bucket rows.

Gear Reduction. By the interposition of suitable gearing, the r.p.m. of the turbine and of the propeller become independent of each other, and each may therefore be designed for the r.p.m. at which it works most advantageously. On the U. S. S. "Neptune" a 4000-h.p. turbine running at 1250 r.p.m. drives a propeller shaft at 130 r.p.m. through a gear and pinion of the double-helical or herringbone type. The gearing in this case has been designed by Messrs. Melville and McAlpine, and is characterised by the elastic support of the pinion shaft in a floating frame carried on hydraulic rams. This support renders the gearing practically noiseless and insures automatically more nearly perfect alignment between gear and pinion under all conditions. With turbines of smaller output satisfactory operation with reduction gearing has been obtained without the use of a floating frame. The transmission efficiency of reduction gearing may exceed 98 per cent.

Hydraulic Transmission. In this method the shaft of the steam turbine carries two centrifugal pump impellers, each impeller being enclosed by a casing which contains suitable stationary passages and a water-turbine wheel. The two water-turbine wheels are mounted directly on the propeller shaft, which is entirely independent of the steam-turbine shaft. In operation, one of the casings is filled with water which circulates through the pump, stationary passages, and water wheel, driving the latter at the r.p.m. that the propeller was designed for. To reverse the direction of rotation, the first casing is emptied out and the water quickly transferred to the second casing, the water wheel of which is designed to drive the propeller in the opposite direction. In an hydraulic transmission gear designed by Prof. Föttinger for a 10,000-h.p., 850-r.p.m., steam turbine driving a propeller shaft at 170 r.p.m., a transmission efficiency of nearly 90 per cent. was attained.

Electrical Transmission. In this method the propeller may be driven by an electric motor mounted directly on its shaft, and supplied with current from a high-speed turbo-generator set located in any convenient part of the ship. On the U. S. Collier "Jupiter," a 5000-kw., nine-stage steam turbine driving a bipolar 2200-volt, 2000-r.p.m., 3-phase alternator, supplies current to two induction motors, each of which drives a propeller shaft at 110 r.p.m. The facility of starting, stopping, speed variation, and reversal, and the ability to tell at any time the r.p.m. and the power consumed by the propellers, are important advantages.

Reversing Turbines. Where the driving turbine is mounted directly on the propeller shaft, an additional reversing turbine must be supplied for use during maneuvering. As the usual output of the reversing or astern turbine is only from 25 to 50 per cent. of that of the ahead turbine, and as steam consumption during maneuvering is only of secondary importance, the astern turbine comprises comparatively few stages and the wheels are of a smaller diameter. This turbine is generally located close to the low-pressure part of the ahead turbine, and, when not in active operation, it runs in a vacuum with a low rotation loss. The reversing process requires very little skill and consists merely in closing the valve of the ahead turbine and opening that of the astern turbine.

Combination Drive. Steam turbines may be used to drive some of the propellers, the others being driven by steam or oil engines. On the French liner "Rochambeau," two reciprocating steam engines drive the two central shafts and each engine exhausts into a nearby low-pressure steam turbine driving a propeller in the wings. During maneuvering, the steam turbines are by-passed and the engines exhaust directly into the condensers, thus obviating the necessity for a reversing turbine. Similarly, English destroyers have been designed with oil engines driving the center shaft during slow-speed cruising, and with steam turbines driving the wing shaft during fast travel.

GENERAL TURBINE DATA

Foundations. Turbine foundations need not be as heavy as those used for reciprocating apparatus. On the other hand, high-speed apparatus produces vibrations which are sometimes not perceptible at the unit itself, but which may be transmitted to other parts of a building which vibrate in synchronism and become more marked than at the source. For this reason it is desirable not to tie turbine foundations to the structural ironwork of a building. Where this is necessary, the ironwork must be reinforced and the flooring or floor plates of the station must not be connected to the foundation.

Expansion Joints. If the foundations are satisfactory the only external means by which a turbine can be pulled out of alignment is by the steam and exhaust piping. The steam pipe should have large bends to allow for heat expansion. The steam-exhaust piping is of larger dimensions and should be installed with expansion joints, preferably of corrugated sheet copper of about one pipe diam. length between flanges. It is preferable to install the expansion joint directly to the exhaust flange of the turbine and so to anchor the succeeding piping that no movement or strains from the exhaust piping beyond the expansion joint can be transmitted to the turbine.

Efficiencies. An approximate idea of the water rate of the steam turbine may be obtained from the knowledge of the number of wheels, the number of bucket rows per wheel, the pitch diameters of the various wheels, and the r.p.m. For most commercial machines within the usual range of sizes, the shaft efficiency of the steam turbine is a function only of the summation of the squares of its wheel speeds, each bucket row counting as a distinctive wheel. Consequently, if a few sizes of a given type of turbine have been tested out and their shaft efficiencies have been plotted against the summation of the squares of the wheel speeds, the shaft efficiencies of any intermediate sizes operating under approximately the same steam conditions may safely be predicted. In Table 6 the efficiencies of a number of impulse and reaction turbines are given against a function $K = N(d/10)^2(\text{r.p.m.}/100)^2$, where N is the total number of rows and d the pitch diameter in in. of the various wheels. These efficiencies hold good only for the particular load for which the turbine is best suited.

Water Rates and Prices. On account of the decided differences in actual turbine design, and more so on account of the various uses to which turbines are applied, no general statement as to water rates for any given size can apply. Industrial turbines for driving centrifugal pumps or other plant auxiliaries usually run non-condensing and the water rate is of no moment on account of the availability of the exhaust steam for heating purposes. These machines are designed with a view of obtaining low costs, and the water rate is poor. Larger turbines for driving centrifugal pumps or centrifugal compressors are designed for high economy, and are more costly per horse power than the former class. They have not as yet been as fully standardized as the turbines for generator drive. Table 7 gives approximately the limitations of water rates that can be expected for turbo-generators. The better figure is probably the best that can be obtained in general practice.

Table 7. Water Rates and Prices of Turbo-generators*

(60-cycle, 2300-volt a-c. generators)

3,500	15.3 to 16.9	11.4	75,000	10.4 to 10.8	....	3,500	28.6 to 29	11.3

* Speeds: 50 to 3500 kw., inc., 3600 r.p.m.; 4000 to 20,000 kw., inc., 1800 r.p.m.; 25,000 kw. and over, 1200 r.p.m.

The **prices** given in the table can be used for general estimating purposes, but are subject to large fluctuations; higher-class turbo-generators cost more than the prices quoted, and turbo-generators of poorer water rate can probably be obtained at lower prices.

CONDENSATION

BY

G. A. ORROK

REFERENCES: Gebhardt, "Steam Power Plant Engineering," Wiley. Morrow, "Steam Turbine Design," Longmans Green. Hausbrand, "Evaporating, Condensing and Cooling Apparatus," Scott, Greenwood & Co. Dalby, "Heat Transmission," *Proc. Inst. M. E.*, 1909. Orrok, *Trans. A. S. M. E.*, vols. 32 and 34.

General. Condensation is either that by direct contact between steam and water, as in the case of the jet condenser; or surface condensation, where a film of metal prevents the mixing of the steam and the cooling medium, as in the case of the ordinary surface condenser type. The cooling medium is generally water. Direct-contact condensers may be divided into three classes: (*a*) jet (*b*) barometric, and (*c*) ejector condensers. Surface condensers may be classed as (*d*) water-cooled, (*e*) air-cooled, and (*f*) evaporative.

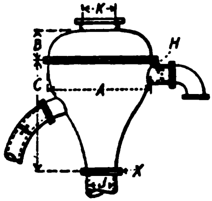
In a **jet condenser** the exhaust steam and the cooling water enter at or near the top of the condenser bell and the steam is condensed by the water falling in a fine spray, the resulting mixture of condensed steam, cooling water and air being removed by a tail pump; or an independent pump may be used to remove the air. For high vacuum, the independent air pump is necessary. The tail pump is replaced by the tail pipe in the **barometric condenser,** and the cooling water and condensed steam flow from the bottom of the tail pipe without the aid of a pump. An independent air pump is generally used, but is not necessary with some types. The **ejector condenser** acts on the same principle as a steam ejector; the exhaust steam enters the ejector through a series of orifices and is condensed by the cooling water, resulting in the water being given a velocity high enough to discharge it against atmospheric pressure. This type is not suitable for intermittent service or for a load which varies widely.

In a **water-cooled surface condenser** the water flows through tubes and the steam is condensed by being brought into contact with the outside of the tubes. The steam generally enters at the top of the condenser and the cold water first passes through the lower tubes and then through the upper tubes. This is known as the counter-flow type. If the condensing water enters at the top near the steam inlet, the condenser is of the parallel-flow type. In **air-cooled condensers** the heat is removed from the steam by the passage of cool air through the tubes or over plates. In **evaporative condensers,** steam is brought into contact with one side of a plate or tube and water is allowed to flow over the other side. The heat which is absorbed by the water is carried away by a stream of air passing over the surface of the water, part of the water being evaporated.

DIRECT-CONTACT CONDENSERS

Condensing Water Requirements. Let t_s = temperature of the steam to be condensed, t_0 that of the injection water, and t_1 that of the outlet or hot-well water, all in deg. fahr.; H = total heat in the steam at t_s, and q = heat in the liquid at t_1, both in B.t.u. per lb.; W = weight of steam per hour to be condensed, and Q = weight of water per hour needed for condensing, both in lb. Then $Q/W = R = (H - q)/(t_1 - t_0)$, and R is the ratio of water to steam required for condensation. $H - q$ may usually be taken as 1000 B.t.u. Theoretically, t_1 is equal to t_s, but in practice it is from 5 to 15 deg. lower than t_s, owing to the presence of air and to imperfect mixing.

In proportioning ordinary jet or barometric condensers, W is the normal amount of steam to be condensed; a 50 per cent. overload is common at some reduction of vacuum.



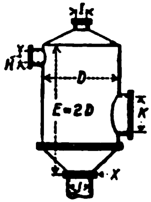


FIG. 1. FIG. 2.
Jet Condenser Bells.

Design of Condenser Bells. Good proportions are as follows (see Figs. 1 and 2): Cubical contents of cone $= G = 0.00143W + 8.25$ cu. ft. With an allowable velocity of 5 ft. per sec. in the tail pipe, $J = 0.0765\sqrt{W}$ in., $A = 15.7\sqrt[3]{G}$ in., $B = 0.3A$, and $C = 1.2A$. Diam. of injection pipe $H = J - 1$ in. ($J - 2$ in.) for small (large) sizes. Diam. of air pipe $I = J/3$ for 26- to 27-in. vacuum, to be increased slightly for 28-in. vacuum. The steam velocity in K is about 600 ft. per sec. K is equal approximately to $\sqrt{W/50}$. In the barometric type the height of the flange X above the level of the hot well should never be less than 35 ft., and may be greater with advantage. In the counter-current type, Fig. 2, D (inches) $= 20 + 0.125\sqrt{W}$.

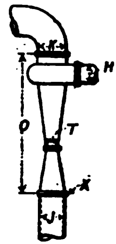

FIG. 3. Ejector Condenser.

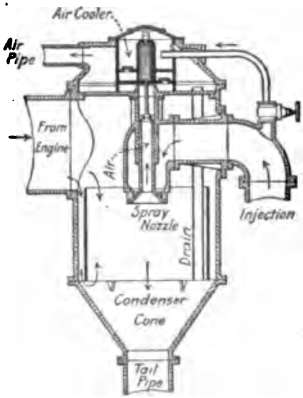
The condenser bell should be as near to the exhaust flange as possible, as friction and velocity head increase rapidly with increasing vacuum. In the ordinary jet condenser the bell is generally placed over the suction chamber of the pump. In all arrangements of this type, with a reciprocating pump, there must always be a sufficient head of water over the suction valves to insure their rising. Condenser bells of practically any shape may be used for the jet and barometric types, and are equally efficient if the water and steam are brought into contact and the air is collected and carried away. The latter may be done by a separate dry-air pump, or the air pipe may be lead into the throat of the tail pipe.

In ejector condensers with tail pipes (Fig. 3) the throat is usually figured for a velocity of 15 to 20 ft. per sec. Dimensions in inches are as follows: $K = \sqrt{W/50}$; $H = 0.0765\sqrt{W} - 1$; $T = 0.6H$; $J = 0.0765\sqrt{W}$; $O = 5K$, approx. The flange X should be about 40 ft. above the level of the tail water. If it must be placed near the level of the water in the discharge well, the velocity through throat T must be increased in order to discharge the water



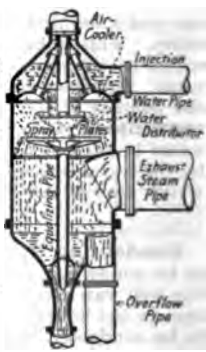


FIG. 4a.—Alberger. FIG. 4b.—Tomlinson.
Barometric Condensers.

and air against atmospheric pressure. Ejector condensers without the tail pipe are common, and when properly installed and operated, work very well.

Pumps Required by Direct-contact Condensers. Barometric condenser: circulating pump and sometimes a dry air pump; jet condenser: tail pump; ejector condenser: circulating pump; ejector condenser without tail pipe: circulating pump.

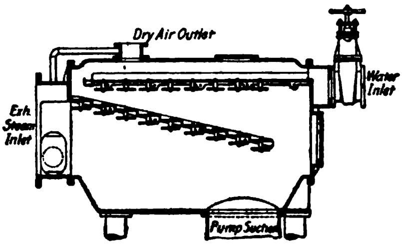

FIG. 4c.—Wheeler Jet Condenser.

SURFACE CONDENSERS

Surface Condensation. Let N = total heat to be transmitted per hour, B.t.u.; S = total outside surface of tubes, sq. ft.; W = steam condensed per hour, lb.; Q = condensing water required per hour, lb.; $R = Q/W$; k_0 = coefficient of heat transmission; t_m = mean temperature difference of water and steam, t_s = vacuum temperature, t_w = hot-well temperature, t_0 and t_1 = temperature of circulating water at inlet and outlet, respectively (all temperatures in deg. fahr.); H = total heat at t_s and q = heat in liquid at t_w. Then $N = k_0t_mS = W(H - q)$, $Q = W(H - q)/(t_1 - t_0)$, and $S = Q(t_1 - t_0)/k_0t_m = W(H - q)/k_0t_m$. For practical work k_0 may be taken as constant for any one condition; although it has been shown by experiment to be subject to small variations with t_m. The mean temperature difference for rough calculation with small rise in temperature of the circulating water may be taken as the arithmetical mean without serious error, but for most calculations the logarithmic mean should be used. See p. 306. The quantity of circulating water Q is a function of the number and size of the tubes, the number of water passes in the condenser and the velocity of the water in the tubes. The values of k_0 depend on the velocity of the water, as well as on the material of the tube, its cleanliness and the richness of the steam and air mixture in the condenser, see p. 307. The water velocity w in the tubes should be around 8 ft. per sec. The material coefficient may usually be taken at 0.95, and the cleanliness coefficient at about 0.9 for such waters as are found in New York or Chicago. The air richness ratio (p_s/p_t) is exceedingly difficult to measure experimentally, but for tight condensers with efficient air pumps it may be taken at from 0.95 to 0.97. Under these conditions k_0 = 782.

Design of Surface Condensers. In condenser design the given quantities usually are W, t_0, and the required vacuum. It is important that the place of measurement of the vacuum should be stated, and this is usually in the nozzle connecting the prime mover to the condenser. The highest vacuum will always be found at the air-pump suction, less in the body of the condenser, and the lowest vacuum in the nozzle. The vacuum inside the prime mover will be less by the velocity head necessary to give motion to the exhaust and by friction in the nozzle. The allowable velocity in a turbine nozzle is about 600 ft. per sec. The **loss** (or "drop") in a well-designed condenser should not exceed 0.2 in. of mercury, and t_s should be taken as the temperature corresponding to this reduced vacuum. For good practice, t_1 should be from 8 to 10 deg. fahr. lower than t_s. Q/W, or the **ratio of cooling water to condensed steam,** usually ranges from 50 to 100 for turbines and from 20 to 40 for engines; a large ratio requires more power in the circulating pumps.

Small **tubes** are best for the transmission of heat, but cannot be used with dirty water, so that the usual sizes are ⅝ in., ¾ in. and 1 in., and in some cases with very bad water 1¼ in., or even larger. Let a = internal cross-sectional area of tube, sq. in.; l = length of tube (sum of all passes), ft.; d = outside diam. of tube, in.; n = number of tubes in one pass; A = area of one pass, sq. ft.; f = number of passes. Then $n = 144A/a = Q/1560aw$, and $l = 3.82S/nd$. The length of a single tube is l/f, and the tube ratio l/d should be between 25 and 50. The best value of this ratio, however, has not been established by experiment.

Example. Design a condenser for turbine service, 30,000 lb. of steam to be condensed per hour, circulating water at 70 deg. fahr., with a vacuum in the nozzle of 28.4 in. referred to a 30-in. barometer. Clean salt water to be used for condensing and Admiralty tubes of 1 in. diam., No. 18 B. W. G. (internal diam. = 0.902 in.).

SOLUTION. $k_0 = 350 \times 0.9 \times 0.98 \times 0.92 \times \sqrt{8} = 804$ B.t.u. Vacuum (28.4 in. + 0.2 in. for drop) = 28.6 in. From the steam tables, t_s = 89.6 deg. fahr., whence $t_1 = 89.6 - 10 = 79.6$ deg. fahr. Also q = 47.6 B.t.u. and H = 1099 B.t.u., making $R = (1099 - 47.6)/(79.6 - 70) = 109.5$, from which $Q = 30{,}000 \times 109.5 = 3{,}285{,}000$ lb. per hour. $t_m = 9.6/\log_e(19.6/10) = 9.60/0.6729 = 14.3$ deg., and $S = 30{,}000 \times 1051.4/(804 \times 14.3) = 2743$ sq. ft. Tube area $= \pi \times 0.902^2/4 = 0.64$ sq. in.; number of tubes $n = 3{,}285{,}000/(1560 \times 0.64 \times 8) = 411$; total length of tube $l = 3.82 \times 2743/411 \times 1 = 25.5$ ft., or say, a two-pass condenser with tubes 13 ft. long.

Condensing Surface Requirements. Table 1 gives the **amount of cooling surface** for various values of temperature rise in the water and ratios of cooling water to condensed steam. This table is based on a value of $k_0 = 350$, which is an average value taken from a large number of installations. For other values of k_0 multiply the figure taken from the table by 350 and divide by the new value of k_0 to obtain the surface necessary. Surface condensers for large turbine installations have generally from 1¼ to 2 sq. ft. of **condensing surface per kw.**, or approximately 1/12 to ⅛ sq. ft. per lb. of steam condensed. Small turbo-generators require from 2 to 4 sq. ft. per kw., or from 1/10 to ⅙ sq. ft. per lb. of steam.

For **dry-air condensers** the coefficient of conductivity in B.t.u. per hour per sq ft. of surface per deg. fahr. difference of temperature, varies from 3 in still air, to 14 with air moving at a velocity of 1500 ft. per min.

Materials of Construction. The materials generally used for **tubes** are brass, copper, aluminum bronze, and Muntz metal. Any of these will give satisfactory service with fresh water, but with salt water considerable trouble may be experienced. Admiralty mixture (70Cu, 29Zn, 1Sn) is generally used for salt water. Tubes are made of No. 20, No. 18 and sometimes No. 16 B. W. G. The variation in heat transfer due to the thickness may be neglected. **Tube spacing** is important, as there must be room for the glands and sufficient metal between them for strength. The minimum allowable spacing or pitch of tubes is as follows (number of tubes per sq. ft. $= 166/s^2$, approx., s being the pitch in inches):

Diam. of tube, in.	⅝	¾	⅞	1	1¼
Pitch of tubes, in.	15/16	1 1/16	1¼	1⅜	1⅝
Number of tubes per sq. ft.	189	147	106	88	63

The **tube sheets** should be of Muntz metal or brass. A rolled sheet will give the best service, although cast sheets are used. Thickness should be at least ⅛-in. greater than the tube diameter. **Glands** should be of the same metal as the tubes and be provided with an inside lip to prevent creeping of tubes. The entrance of the gland should be rounded. **Rubber rings** are

* $H - q$ assumed to be 1000 in calculating this table.

much used for **packing** on European condensers with fresh condensing water, but the screw gland with corset-lace packing put in with an automatic gun is probably best. Tube packings may be of fiber, woven hose or corset lacing. No animal or vegetable fats should be used on the packing, as they form soluble compounds with copper; paraffin is the best wax to use with woven packings.

Condenser **shells** are usually cast iron, ribbed outside against collapsing pressure, but may be of steel plate or sheet brass (navy practice) stiffened with angles. Tubes should be supported at distances of 60 to 70 diameters by supporting plates (usually of cast iron) drilled with 1/16-in. clearance around tube. **Water boxes** should be large and designed to offer little friction to the passing of the water. A hole 1/8-in. in diameter in the partition will allow the upper box to drain when not in use, and the condenser is usually set on a slope of 1 in. in 15 ft., so that the tubes may drain. Where possible, the steam should enter from the top and water at the bottom (counter-current principle), but this is not essential, as parallel-flow condensers give good results. The bottom of the circulating-water outlet should be above the highest point of the tube bank. If this cannot be done at the water box the discharge pipe should be carried up to the same height away from the condenser.

The steam passage should be direct to the tube bank, and, if possible, the nozzle should be spread so that no dead pockets may be left away from the path of the steam. Baffle plates and guide plates are also used for the same purpose but are not as efficient. The upper bank of tubes may have a wider spacing than the lower, or channels may be made in the tube bank to afford a free passage for the steam. The **steam flow** should be directed to the coldest part of the condenser and here the dry-air suction should be taken out. The suction should be baffled to prevent water being carried into it. **Water connections** should be figured for a velocity of 8 ft. per sec. and the air-pump connection should be at least twice that of the hot-well pump suction, which should be figured for about 4 ft. per sec.

AIR PUMPS

The amount of air in feed water varies from 0.75 to 5 per cent. by volume at atmospheric temperature and pressure. If closed heaters are used, all of the air passes through the boilers and prime movers into the condenser. If open heaters are used, the air in the feed water (at 200 deg. fahr.) should not be over 1 per cent. The **leakage in surface condensers** is an extremely variable quantity, ranging from 1 per cent. in tight condensers to 25 per cent. or more in condensers in poor condition. The average leakage is from 5 to 10 per cent. of the volume of the feed water. The **volume of air passing into the air pump** may be calculated as follows, if the volume of free air is known: $V = V_aP_a(t_s + 460)/(P_c - P_s)(t_a + 460)$, where V = volume of the air in vacuum, cu. ft.; V_a = volume of the air at atmospheric pressure and temperature entering the condenser, cu. ft.; P_a = atmospheric pressure, P_c = total pressure at pump suction, and P_s = pressure of vapor at t_s, all in in. of mercury, absolute; t_s = temperature at pump suction, and t_a = atmospheric temperature, both in deg. fahr. As there is always leakage through glands, pipes or joints, the air pump must have a displacement greater than that given by the above formula. In practice the dry-air pump has a displacement of from 10 to 60 times the volume of the condensed steam. The average ratio for engines is about 20, and for steam turbines 25 at low vacua and 35 to 45 at high vacua. If the air pump must remove the condensed steam, allowance is made therefor. Fig. 5 shows the relation between the temperature in the air-pump suction pipe and the volume of saturated air in cu. ft. per lb. of dry air.

The circulating water may contain as much as 5 per cent. air (by volume), but an extra allowance of from 3 to 5 per cent. should be made for leakage. The combined circulating and air pump generally has a displacement approximately three times the volume of the cooling water. If an independent air pump is used, its displacement should be only twice the volume of the cooling water. The **effect of air leakage on vacuum** in surface condensers is shown by Fig. 6, from a paper by G. A. Orrok, in *Jour. A. S. M. E.*, Nov., 1912, which describes the method of determining the amount of air handled by the air pump and also the method of determining the quantity of air in the feed water.

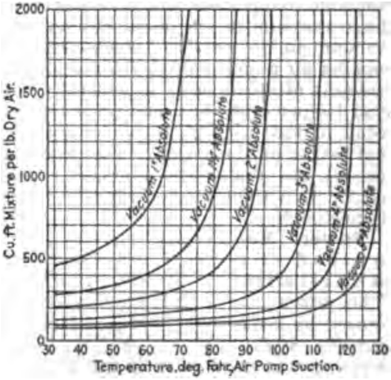

FIG. 5.—Relation Between Temperature in Air-pump Suction Pipe and Volume of Saturated Air.

Fig. 7 shows three of the centrifugal hydraulic or **rotary air pumps** now on the market. In Fig. 7*a* the centrifugal force imparted to the water forces it out through the discharge, in the meantime creating a vacuum which draws in more water which is hurled in thin sheets at a high speed into the diffuser, each sheet of water carrying with it a layer of air drawn in through the air inlet. In Fig. 7*b* the action is similar but the arrangement is different. Fig. 7*c* shows a design of pump in which the impeller is entirely removed from the air-pump casing. An ordinary centrifugal pump may be used to supply the hurling water to the revolving jet wheel shown. The jets of water form a large number of pistons which discharge the air through the tail pipe. This type of pump is now in common use and is rapidly eliminating the reciprocating pump in the large central stations. It is driven by a motor or turbine, is very compact, and, owing to the absence of valves and reciprocating parts, requires very little attention. The efficiency of

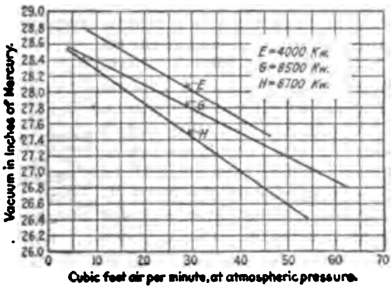

FIG. 6.—Effect of Air Leakage on Vacuum in Surface Condensers.

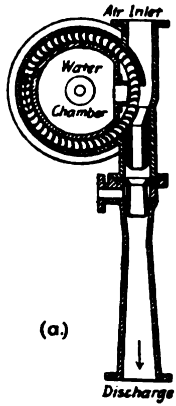

FIG. 7*a*.—Westinghouse-Leblanc Rotary Air Pump.

the hydraulic pump is low, the power required being from three to eight times that for a reciprocating pump.

In the **Parsons vacuum augmenter** (Fig. 8) the air is exhausted from the condenser by means of a steam jet into an auxiliary condenser. The dry vacuum pump does not have to maintain the high vacuum in the main condenser, as the vacuum in the auxiliary condenser is lower; a smaller air pump may therefore be used. The amount of steam used is generally between 1 and 1.5 per cent., but may be as low as 0.6 per cent. of that used by the main turbine. The net saving on the average condenser due to the use of the augmenter averages about 5 per cent.; with tight condensers the saving made is negligible.

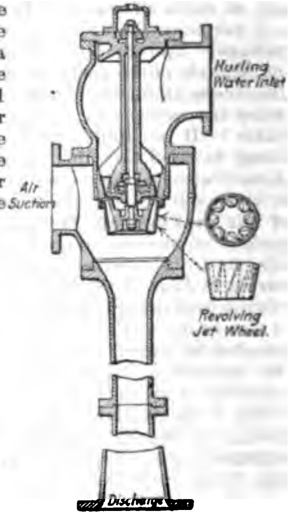

FIG. 7c.—Worthington Air Pump.

Power Required by Auxiliaries. The power required by large turbine auxiliaries varies from 1 to 3 per cent., generally between 1 and 2 per cent. of the power of the main unit. In small installations the power consumed varies from 2 to 10 per cent. Centrifugal hot-well pumps for surface condensers generally require from 0.05 to 0.10 h.p. for each 1000 lb. steam condensed per hour. Reciprocating air pumps require from 0.10 to 0.3 h.p. per 1000 lb. steam per hour. Centrifugal air pumps require 0.25 to 0.5 h.p. per 1000 lb. steam per hour. The power required by circulating pumps varies with the design of the condensers, quantity of water pumped, and the efficiency of the pump. The pumping head may be as low as 10 ft. in some condensers and as high as 35 ft. or more in others, the average being about 20 ft. Pump efficiencies range from 60 to 80 per cent. for this service. Assuming a ratio of cooling water to steam of 50, a pumping head of 20 and an efficiency of 70 per cent., the brake horse power per 1000 lb. steam per hour would be approximately 0.75 h.p. The **steam required** for auxiliaries in lb. **per brake horse power per hour** is as follows:

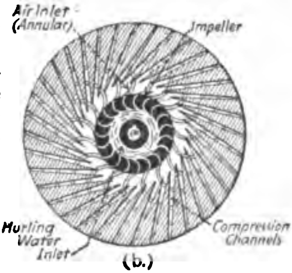

FIG. 7b.—A. E. G. Air Pump.

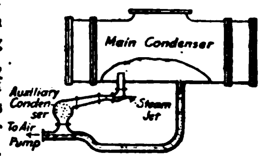

FIG. 8.—Parsons Vacuum Augmenter.

Circulating pumps, slow-speed, engine-driven	25 to 75
Circulating pumps, high-speed, engine-driven	40 to 100
Circulating pumps, turbine-driven, geared	25 to 30
Circulating pumps, turbine-driven, direct-connected	30 to 60
Air pumps, reciprocating	40 to 100

Hydraulic air pumps	40 to 55
Hot-well pumps, reciprocating	50 to 100
Hot-well pumps, centrifugal	40 to 60

The **power required by jet condensers** varies from 1 h.p. per 1000 lb. steam used per hour by the main turbine engine in the case of large units, to 3 h.p. per 1000 lb. steam for small units. Barometric condensers require from 0.5 h.p. to 1.5 h.p. per 1000 lb. steam per hour.

Most Economical Vacuum. No definite rule can be laid down for the most economical vacuum to be used. Each case must be considered separately on account of such factors as the cost of condensers, auxiliaries and piping (all of which vary with temperature of inlet water), foundations, space, cost of coal, load factor, and fixed charges on main unit. For steam turbines a vacuum of 28 in. is generally considered the most economical with inlet water at 70 deg. fahr. For engines a vacuum of 26 in. is the most economical with water of ordinary temperatures. A higher vacuum will not increase engine economy.

Salt-water Leakage. Where salt water must be used for circulating water in surface condensers it is important that there should not be an excessive leakage into the condensed steam which is to be used for boiler feed. If the hot-well water contains more than 1 per cent. of salt, it should not be supplied to the boilers. The method of determining this percentage is as follows:

Ten cu. cm. of the condenser water are measured out by a pipette, placed in a beaker, and two or three drops of potassium chromate solution added. A standard solution of silver nitrate is then added drop by drop from a burette, but only until the liquid in the beaker maintains a faint pink color on agitating. The volume of silver nitrate solution used is then recorded. Ten cu. cm. of the sample of circulating sea water are now measured out, 90 cu. cm. distilled water added, mixed, and 10 cu. cm. of the mixture taken. A few drops of the chromate solution are now added, and the silver nitrate added as before, the amount of the latter used being recorded. The amount of silver nitrate used for the circulating water multiplied by ten and divided into the amount used for the condenser water and the quotient multiplied by 100, gives the percentage of sea-water leakage in the condenser water. The silver nitrate solution usually used is made up by dissolving 9.6 gm. silver nitrate in 2 liters of water. This is of such strength that 1 cu. cm. is equivalent to one milligram of chlorine.

COOLING EQUIPMENT

Cooling Ponds. Where an inexpensive and sufficient supply of circulating water is not available, a **cooling pond** may be provided for reducing the temperature of the discharge water so that it may be recirculated again and again. The weight of water evaporated per sq. ft. of water surface per hour in still air (Box, p. 152) $= E(\text{lb.}) = (243 + 3.7t)(V - v)/7000$, where t = temperature of water, deg. fahr., V = maximum vapor tension at temperature t, and v = actual vapor tension of air, both in in. of mercury. The evaporation is increased considerably by wind and may be as much as ten times that given by the above formula. Approximately 35 lb. of water will be cooled 30 deg. by the evaporation of 1 lb. from the surface of a pond. Under average conditions 1 sq. ft. will be sufficient to cool from 4 to 6 lb. of water per hour from 100 deg. fahr. to 70 deg. fahr. Ruggles (*Jour. A. S. M. E.*, April, 1912) states that under ordinary conditions in the northern part of the United States with engines using 15 lb. of water per h.p.-hour and a vacuum of 26 in., a reservoir having a surface of 120 sq. ft. per h.p. is ample for cooling and condensing water.

As cooling ponds require considerable space, their use is often impracticable, and **cooling sprays** are used to accomplish the same object. The nozzle used must be of such design that the water jet emerging will be broken up into fine spray, under pressures ranging from 3 to 15 lb. Approximately 3 per cent. of the water is lost by evaporation. The power consumed ranges from 0.75 per cent. for the low heads to 2 per cent. at the high heads. The area required for the pond is approximately 1 sq. ft. for every 150 lb. water per hour for plants of 500 h.p. and 1 sq. ft. for every 250 lb. for plants of 5000 h.p.; the depth need not be more than 3 ft. A spray system for cooling 4800 gal. per min. could be laid out with three rows of eight nozzles (or sets of nozzles), each nozzle (or set) having a capacity of 200 gal. per min. The rows should be spaced 20 ft. apart in this case and the nozzles 13 ft. c. to c. in each row. In order to prevent spray from being carried away from the pond, there should be 24 ft. between the outer nozzles and the borders of the pond, but if all of this space is not available, a fence should be erected with sufficient openings for the passage of air. A spray system of this capacity would require a pond 139 ft. long by 88 ft. wide. Test made on nozzles have shown the following results:

Temp. of air, deg. fahr.	80	87	78	72	30	74
Humidity, per cent.	65	48	65	84	50	84
Temp. of water before spraying, deg. fahr.	120	122	117	112	79	114
Temp. of water after spraying, deg. fahr.	85	88	82	88	58	89
Drop in temp., deg. fahr.	35	34	35	24	21	25

Cooling Towers. A cooling tower consists of an iron or wooden casing surrounding a network of wooden partitions, sheet-iron trays or iron-wire mats, or layers of short, staggered cylindrical earthen or metallic tiles. The water to be cooled is distributed at the top of the tower and falls down over the boards or mats in such a manner that a large surface of the water is exposed to the current of air passing upward. The water is cooled partly by the evaporation of a portion of its volume, and partly by conduction of some of the heat to the air. If the tower is of sufficient height, the air can be circulated without the use of a fan (natural-draft tower). If the air must be forced or induced through the tower, it is known as a forced-draft tower. The **volume of air necessary per pound of steam** condensed may be determined with sufficient accuracy for practical purposes from the formula $W(q_t - q_b) = 0.238(T_t - T_b)V_bW_a[(p - p_bh_b)/29.92] + r(V_tW_th_t - V_bW_bh_b)$, where W = weight of cooling water per lb. steam condensed per hour, W_a = weight of 1 cu. ft. dry air at temperature T_b and 29.92-in. barometer, $W_t(W_b)$ = weight of 1 cu. ft. of water vapor at temperature $T_t(T_b)$, all in lb.; $h_b(h_t)$ = relative humidity of air entering (leaving) tower; p = atmospheric pressure, and $p_t(p_b)$ = pressure of vapor corresponding to $T_t(T_b)$, all in in. of mercury; $q_t(q_b)$ = heat of liquid in water entering (leaving) tower, B.t.u.; $T_b(T_t)$ = temperature of air entering (leaving) tower, deg. fahr. abs.; V_b = volume of air entering tower at atmospheric temperature and pressure, cu. ft.; V_t = volume of air leaving tower at T_t, cu. ft., = $[V_b(p - p_bh_b)/(p - p_th_t)](T_t/T_b)$; r = heat of vaporization at T_t.

Example. An engine consumes 20,000 lb. steam per hour; temperature of the injection water, 90 deg. fahr., of the discharge water, 120 deg., of the outside air, 70 deg.; barometer, 30 in.; relative humidity of air entering tower, 70 per cent., of discharge air, 95 per cent. Determine the amount of air per hour necessary to cool the water.

Solution. $W = (H - q)/(t_1 - t_0) = 1000$ (approx.)$/(120 - 90) = 33.3$ lb. $W_a = 0.0749$; $W_t = 0.00377$; $W_b = 0.00115$; $h_t = 95$; $h_b = 70$; $p = 30$; $p_t = 2.59$; $p_b = 0.74$; $q_t = 88$; $q_b = 58$; $T_t = 110 + 460 = 570$; $T_b = 70 + 460 = 530$; $r = 1030$. T_t is generally from 5 to 10 deg. below the temperature of the water entering the tower; h_t generally ranges from 90 to 100. Substituting the foregoing values in formula and solving for V_b, $V_b = 243$ cu. ft. of air per lb. steam condensed = 4,860,000 cu. ft. per hour for 20,000 lb. of steam condensed.

For cooling towers 60 to 80 ft. high, filled with layers of staggered 4- to 5-in. sheet-metal cylinders (8 to 12 in. long) to a depth of 15 to 20 ft., over the surface of which water trickles from a revolving cross-arm spray, 1 sq. ft. of ground area is required for each 80 lb. of steam condensed per hour; cooling surface (of cylinders), about 3.5 sq. ft. per lb. steam condensed per hour. For towers enclosing lattice-work systems of cooling surface, ground area required ranges from 1 sq. ft. for each 16 lb. steam condensed per hour (in a size to handle the circulating water needed to condense 16,000 lb. steam per hour) to 1 sq. ft. for 26 lb. steam in the largest sizes.

POWER FROM SOLAR HEAT*

The heat received per minute from the sun on 1 sq. ft. of surface normal to the sun's rays above the atmosphere of the earth amounts to 7.12 B.t.u. (0.168 h.p. per sq. ft.), but, before reaching the earth where it can be utilized, part of this heat is absorbed by water vapor and dust suspended in the atmosphere. In vast areas in the tropics and in certain semi-tropical and arid sections (*e.g.*, Arizona, Egypt), however, the air is dry and clear, this loss is small, and sun power can be profitably produced provided coal is very expensive and the cost of the considerable land area required for a plant is low.

A. S. E. Ackermann (*Jour. Roy. Soc. Arts*, Apr. 30, 1915) states the theoretical thermal efficiency of a solar heat absorber to be $e = [Dsa - pk \times (T^4 - \frac{2}{3}A^4) - (1 - r)Dsa]/Dsa$, where D = width of reflector, ft.; s = solar constant = 7.12 B.t.u. per sq. ft. per min.; a = coefficient of atmospheric transmission = 0.7; p = perimeter of boiler, ft.; k = boiler radiation constant = $10^{-10} \times 0.36$ B.t.u. per sq. ft. per min.; T = boiler temperature, deg. fahr. abs.; A = temperature of reflectors, deg. fahr. abs. (= atmos. temp. + 9 deg.); r = efficiency of silvered glass as a reflector of heat—taken as 0.6. Also, theoretical overall thermal efficiency of a sun-power plant $= e_1 = e \times (T - 568)/T$, where 568 is the absolute temperature of the condenser, deg. fahr. (assumed constant). In the Cairo plant, D = 12.67 ft. and p = 2.92 ft. Assuming A = 561 deg. and solving equation for e_1 for various values of T and plotting the results, it is found that the maximum value for e_1 (5.9 per cent.) is obtained when T = 231 deg. (= 692 deg. abs.) or the temperature for a steam pressure of 21 lb. abs. The actual maximum overall efficiency of the plant was found to be 4.32 per cent., showing that about 75 per cent. of the boiler h.p. theoretically possible was obtained.

In a 50-b.h.p. plant installed in 1913 at Cairo, Egypt, by Frank Shumann (Manchester Assn. of Engrs., March 14, 1914), the sun's rays are concentrated on the flat bottom of a cast-iron boiler by silvered panes of ordinary window glass arranged in frames so as to form approximate parabolic reflectors, which frames are so geared that the engine (working through a friction clutch governed by a thermostatic device) intermittently turns them and keeps them facing the sun throughout its course during the entire day. This boiler generates steam at atmospheric pressure (14.7 lb. per sq. in.) which is utilised in a specially designed condensing engine that yields 1 b.h.p. on a consumption of 22 lb. of steam. (For larger plants the use of low-pressure turbines is proposed.) When the sun is obscured by clouds the engine will continue to generate power economically until the pressure drops to about 4 lb. abs. To provide power over rainy spells of 2 or 3 days, additional plant must be provided to heat water to 212 deg. for storage in insulated tanks. The latitude of Cairo is 30 deg. N.; at a location 1000 miles nearer the equator the Cairo plant would yield 65 b.h.p.

The steam-producing part of the Cairo plant cost $7600. With interest and depreciation at 10 per cent., the annual charge would be $760. An equivalent coal-burning plant with stack, boiler and buildings would cost $3750, and the annual charge at the same rate would be $375, or $385 less than for the sun-power plant. Assuming a coal consumption of 2 lb. per b.h.p.-hour, the fuel annually required for 365 ten-hour days would amount to 163 long tons. That is, the sun-power plant will compete on an even basis with a coal-burning plant using coal costing but ($385/163 =) $2.36 per long ton. For particulars regarding sun-power plants using less efficient heat absorbers consisting of

* Staff contribution.

shallow, glass-covered, water-filled wooden basins of large area, and also the use of ether or sulphur dioxide as the working fluid instead of steam, see articles by Messrs. Shumann and H. E. Willsie, *Eng. News*, May 13, 1909. A brief sketch of former efforts to utilise solar energy, and a bibliography of the subject, are included in the paper by Mr. Ackermann cited above.

HOT-AIR ENGINES*

Hot-air engines are heat engines in which air is employed as the working substance, operating on the Stirling or Ericsson cycles (see p. 319) or modifications of them. Their bulk per h.p. of capacity is great as compared to steam or gas engines and their efficiency low. They find use, however, in small sizes for domestic pumping work. Bryan Donkin ("Gas, Oil and Air Engines") gives the following data on such motors:

Engine	Cyl. diam., in.	Stroke, in.	R.p.m.	I.h.p.	B.h.p.	Lb. fuel per hr. per I.h.p.	Lb. fuel per hr. per B.h.p.
Buckett..............	24.0	16.0	61	20.20	14.40	1.8	2.5
Beniér................	13.4	13.8	117	5.80	4.00	3.1	3.6
Bailey................	14.6	6.9	106	2.40	1.30	4.2	7.6
Rider.................	6.7	9.5	138	0.81	0.23	.....	.....

The actual thermal efficiency of the Buckett engine, assuming the fuel (coke) to have a calorific value of 12,000 B.t.u. per lb., is $2546/(2.5 \times 12{,}000) = 8.48$ per cent. Similarly, that of the Bailey engine is 2.8 per cent. A steam engine of the size and speed of the Buckett engine, with a mean effective pressure of but 30 lb. per sq. in., would develop over three times the indicated horse power.

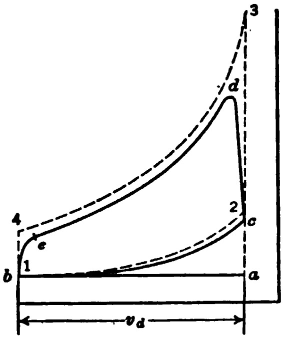
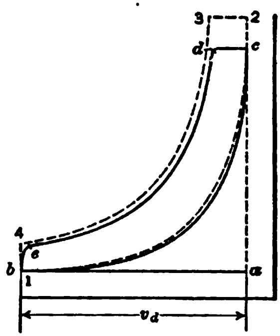
GENERAL FEATURES

Methods of Operation

The term "internal-combustion engine" is applied indiscriminately to gas and oil engines, whether combustion takes place instantaneously (explosively), at constant volume (as in Fig. 1), or gradually, at constant pressure (as in Fig. 2). Both types of operation are used in four- and two-cycle, single- and double-acting, horizontal and vertical engines.





Internal-combustion-engine Cycles.

c–d	Injection and combustion of the fuel.
d–e	Expansion of the products of combustion.
at *e*	Opening of the exhaust valve.
e–b–a	Exhaust.

The Four-stroke Cycle (four-cycle) is most commonly used at the present time for stationary gas engines. All the processes occur in a single cylinder, so that each cycle requires for completion four strokes, of which one only produces useful work. The work of the admission and exhaust strokes amounts to from 5 to 10 per cent. of the power of the engine. This type of engine up to 150 h.p. is ordinarily built single-acting and without a cross head. For larger powers the engines are built double-acting, and have an external cross head.

Advantages of the Four-cycle Single-acting Engine: Simplicity; trunk piston operating as a cross head; water-cooling of the piston not needed except in the largest sizes; can be built for very high rotative speeds; cost of construction for small powers is low. **Disadvantages:** A very variable crank effort, which necessitates for a small cyclic variation of angular velocity a very heavy flywheel or the use of a number of cylinders; power per unit volume of piston displacement is low; imperfect scavenging.

The Two-stroke Cycle (two-cycle) has been used economically only in large, slow-running engines, in which the suction and pre-compression of the mixture take place in separate gas and air pumps. Many small liquid-fuel engines utilise the crank case for the precompression of the charge. In most cases the mixture is not admitted to the combustion cylinder until a blast of scavenging air has been passed through. The exhaust takes place through ports in the cylinder bore, which are uncovered by the working piston; the mixture and scavenging air may be admitted through valves in the cylinder head. Many small motors with crank-case compression are valveless. An explosion takes place at each revolution of the crank. With the present construction, the indicated work of suction and admission of the charge amounts to from 7 to 12 per cent. of the total power. By using scavenging air at a low pressure—from 1.5 to 3.0 lb. per sq. in.—and supplying larger passages for the admission and exhaust, the pump work can be diminished.

Advantages as compared with the four-stroke cycle: The power per unit volume of piston displacement is greater by from 70 to 90 per cent.; the crank effort is more even; with a proper design there is a more perfect scavenging of the exhaust gases; in small engines the construction is cheaper, due to the elimination of valves. **Disadvantages:** Greater difficulty in cooling and oiling the piston in small engines because of its being completely enclosed; with present construction the negative work is larger; a loss of unburnt gases into the exhaust, amounting in some cases to 20 per cent., due to the impossibility of having the exhaust valve open long enough to get the exhaust gases out of the cylinder and still have it close in time to prevent the charge blowing through.

Two- and Four-cycle Double-acting Engines. Double-acting engines are being increasingly used for larger powers—from 75 to 800 i.h.p. per cylinder end.

Advantages as large engines: More uniform running with light flywheels; greater power generated in a single cylinder; a quicker response to change in load, since charges are drawn in twice as often as in the case of the single-acting engine. **Disadvantages:** Complicated and costly construction; great length; heavy reciprocating masses little adapted to high speed and requiring unusually good foundations; the necessity of cooling the piston and piston rod in order to avoid preignitions and distortion of the piston and rod, to insure tightness between the piston and cylinder walls and for adequate oiling; the great difficulties encountered in the design and construction of the piston, cylinder, and cylinder heads; larger consumption of oil and cooling water as compared with single-acting engines.

The **Diesel engine** is usually built 4-cycle and single-acting in sizes up to about 1000 h.p. per cylinder. The 2-cycle single-acting type is made by a number of European builders in sizes up to 1250 h.p. per cylinder; this type is more easily made reversible and consequently has been adopted for marine use. A 2-cycle cylinder develops from 170 to 180 per cent. of the work of a 4-cycle cylinder of the same piston displacement, but its fuel consumption per b.h.p. is about 10 per cent. greater. The best 2-cycle engines have scavenging pumps of from 1.2 to 1.8 times the cylinder volume, which compress air to 4 to 8 lb. per sq. in. and use up about 4 per cent. of the rated power of the engine. The mechanical efficiency of the 4-cycle (2-cycle) type is about 75 (70) per cent.

The air for spraying the oil is supplied to Diesel engines by 2- or 3-stage compressors at a pressure of from 800 to 1100 lb. per sq. in. The air required varies from 16 to 34 cu. ft. of free air per b.h.p. per hour; the power required by the compressor is from 4 to 7 per cent. of the rated power of the engine. Diesel engines are usually rated with an overload capacity of 10 to 15 per cent. The heat carried away by the jackets is 2500 to 3000 B.t.u. per b.h.p. per hour, corresponding to a heat transfer of about 4000 (9000) B.t.u. per sq. ft. of cylinder surface per hour in 4-cycle (2-cycle) engines. Regulation usually within 3 per cent. Fuel consumption as low as 0.4 lb. per b.h.p. per hour, with good fuel (19,500 B.t.u. per lb.). Lubricating oil, about 0.01 lb. per b.h.p. per hour. Attendance, one engineer for 1000 to 1500 b.h.p. Cost of engine per b.h.p., from $63 for 200 b.h.p. to $48 for 1000 b.h.p. units. Weight per b.h.p. from 250 to 500 lb. in American practice; reported as low as 62 lb. in European practice. Fuels containing more than 2 to 4 per cent. of sulphur are liable to cause corrosion.

Heavy liquid fuels can also be used in engines of the **semi-Diesel or hot-surface** type. This type (exemplified by the De La Vergne engine, type FH) has a hot bulb (uncooled) in the clearance space into which the fuel is injected at the end of compression. The compression pressure is from 250 to 300 lb. per sq. in. and the injection air pressure about 600 lb. per sq. in. as compared with 550 lb. and 1000 lb. per sq. in. respectively for the Diesel cycle. The air in the hot bulb is always hot enough to burn the injected fuel. The combustion, at first, is at nearly constant volume, resulting in a combustion pressure at full load of about 500 lb. per sq. in.; it then continues at approximately constant pressure. The lower compression pressures of the semi-Diesel type make the engine less expensive. The efficiency is only slightly lower than that of the Diesel engine; thermal brake efficiencies up to 30.5 per cent. have been recorded. A preliminary heating of the bulb is necessary before the engine will start.

Fuels

The thermal efficiency of an internal-combustion engine increases with an increase in its compression pressure (see pp. 320 and 1031). Furthermore, the compression of the charge results in an increase of the power per unit volume of piston displacement and permits the use of lean gases which otherwise would be difficult to ignite. It is therefore advantageous to compress the charge to as high a pressure as is possible. The upper limit of compression is set by the ignition temperature of the explosive mixture used. The ignition temperature varies with the composition of the fuel and the strength of the mixture. Generally, the lower the heat value of the charge the higher is its point of ignition. Rich fuels can be highly compressed only as dilute mixtures, while lean gases can withstand a higher compression in the presence of a slight excess of air. Pure mixtures rich in hydrogen ignite in the neighborhood of 950 deg. fahr. (the temperature of ignition of one part of hydrogen and one part of oxygen is 957 deg. fahr.), while charges rich in carbon monoxide ignite at about 1110 deg. fahr. The compression pressure can be raised by suitable cooling of the mixture or by separate compression of the fuel and air. The ignition temperature of ordinary liquid fuels lies between 950 and 1020 deg. fahr. Mixtures in which they are present cannot therefore be highly compressed. See p. 1024.

Table 1. Usual Compression Pressures for Internal-combustion Engines

Fuel	Type of engine	Range of compression, lb. per sq. in. gage	Average compression in lb. per sq. in. gage
Gasoline	Automobile	45–95	65
Gasoline	Stationary	60–105	70
Kerosene	Hot bulb, 250–500 r.p.m.	30–75	60
Kerosene	Vaporized before entering cylinder	45*–85†	65
Alcohol	Vaporized before entering cylinder	120–210	150

Fuel oil	Injected after compression	255	255
Fuel oil	Diesel cycle	510	510
Natural gas	Medium and large engines.‡	75–160	120
Coke-oven gas	Large engines (in Germany)	105–135	120
Coal gas	Mostly small, very few large engines.	75–120	100
Carburetted water gas	Mostly small, very few large engines.	75–105	90
Producer gas	Both large and small engines	100–160	130
Blast-furnace gas	Largest engines built	120–190	155

* With hot mixture without water injection. † With water injection.
‡ Wide variation due to variation in composition of natural gas from various localities.

Explosion Limits. In order that a mixture of combustible gas or vapor with air shall be explosive, the ratio of air to gas must lie within certain limits depending on the character of the fuel. In general, the mixture that has just sufficient oxygen for complete combustion of the fuel gives the highest pressures and temperatures and very nearly the highest speed of ignition. If the proportion of oxygen (or air) is increased beyond or decreased from the

Table 2. Limits of Proportion for Explosive Air-Gas Mixtures
(Lucke, "Thermodynamics," p. 869)
Percentage of gas in the mixture by volume

Gas	Combining proportion	When air is in excess	When gas is in excess	Gas	Combining proportion	When air is in excess	When gas is in excess

Ether	3.4	2.75	7.7				

theoretical proportion, the maximum pressures and temperatures are lowered and the speed of ignition decreases until at certain upper and lower limits the mixture ceases to be explosive and only slow combustion can occur.

Tables 2 and 3 give the explosion limits and the theoretical combining proportions for various fuels at atmospheric pressure. Table 2 is for usual room temperatures. The explosion is assumed to be caused by an electric spark.

Table 3. Limits of Percentage of Gas in Explosive Air-Gas Mixtures at Different Temperatures

(Roszkowski)

Gas	Temperatures, deg. fahr.							
	59		212		392		572	
	Limits							
	Upper	Lower	Upper	Lower	Upper	Lower	Upper	Lower
Hydrogen	64.7	9.5	68.2	9.5	72.1	9.6	79.3	9.6
Carbon monoxide	74.6	14.3	77.2	13.2	80.4	12.5	57.4	21.0
Methane	13.0	6.8	12.6	5.8	12.8	5.8	13.0	5.7
Illuminating gas	22.6	7.0	24.7	7.0	26.7	6.5	28.6	6.5

Ignition Temperatures in air at atmospheric pressure are as follows (deg. fahr.): Hydrogen, 1075–1100; acetylene, 760–820; illuminating gas, 1100; ethylene, 1005–1015; alcohol, 950; methane, 1200–1240; ether, 750; benzol, 970; benzene, 780.

Speed of Ignition. The speed with which flame spreads through a mixture of fuel gas and air depends upon the composition of the mixture, the pressure and temperature, the shape of the combustion chamber, and the location of the point of initial ignition. Experiments on the speed of flame propagation at the present give little definite information as to what may be expected in the gas-engine cylinder. In the transmission of the explosion two entirely different processes may be noted. 1. In the process of **slow combustion** the layers of gas adjacent to the ignited layer are brought to the temperature of ignition by conduction. 2. An explosion may be transmitted by a **compression wave,** which is transmitted simultaneously with the ignition at a speed of several thousand feet per second. The character-

istics of compression waves have been studied by Berthelot, Mallard and Le Chatelier, and by Dixon (*Proc. Royal Soc.*, vol. 200 A). As an explosion wave is accompanied by the generation of an enormous pressure almost instantaneously, the production of such waves in gas engines is likely to cause damage. Nägel has investigated the speed of ignition (slow combustion) in a spherical bomb with a capacity of 1.06 cu. ft. Table 4 gives the results.

Gases. The available gases are natural gas, illuminating gas (coal or carburetted water gas), oil gas, coke-oven gas, producer gas, blast-furnace gas and other industrial by-product gases. For average compositions and heating values, see pp. 365, 613 and 1057.

Liquid Fuels. Any combustible liquid can be used as a fuel in an engine adapted to it. Liquid fuels are vaporized either before or during their mixture with the air for combustion. Gasoline and similar light hydrocarbons can be vaporized either by passing air over the surface or bubbling it through the liquid (carburetting by evaporation), or by atomizing them in the air current (carburetting by injection). Petroleum, crude oil, coal-tar oil, alcohol, and other liquid fuels whose boiling points are high, are vaporized by heating the liquid. The lighter of these liquids—petroleum, light crude oil, and alcohol—are used in engines of the explosive type, in which the liquid may be vaporized (*a*) in a vaporizer outside of the engine, which is kept hot by the exhaust gases; (*b*) in a vaporizer—hot bulb—connected to the combustion chamber of the engine and kept hot by the explosions; or (*c*) against a hot part of the combustion chamber—a plate projecting from the cylinder head. In the last case the engine must be started and run on gasoline until the plate becomes sufficiently hot to vaporize the fuel—kerosene. The heavier liquid fuels can be used only in engines of the constant-pressure-combustion type. The heavier the fuel used the more finely must it be divided when injected into the cylinder, in order to insure complete vaporization and ignition. If the heavier oils are injected in large particles only the surface of the particles will be burnt, while the center will be converted by the heat into a pitchy substance, which will be deposited on the cylinder walls and valves. For properties of liquid fuels, see p. 610.

Fuel Consumption. The fuel consumption per horse-power-hour increases with decrease of load below the normal, as is shown in Table 5.

Table 5. Relative Increase of Fuel Consumption per B.h.p. per Hour at Partial Loads

	Full-load	¾ load	½ load	¼ load
Natural-gas engine	1.00	1.05–1.20	1.20–1.50	1.75–2.00
Illuminating-gas engine	1.00	1.05–1.20	1.20–1.50	1.75–2.00
Producer-gas plant (engine and producer)	1.00	1.15–1.25	1.45–1.60	2.30–2.70
Gas producer	1.00	1.04–1.06	1.10–1.15	1.30–1.40
Blast-furnace gas engine	1.00	1.05–1.20	1.20–1.50	1.75–2.00
Low-pressure oil engine	1.00	1.15–1.35	1.45–1.70	1.90–2.30
Diesel oil engine	1.00	1.02–1.15	1.07–1.25	1.40–1.90

In explosion engines the total no-load consumption goes as high as 30–45 per cent. of the total consumption at normal load; in constant-pressure-combustion engines this figure is only 20–25 per cent. In producer-gas plants the coal consumption increases faster at partial loads, more because of the loss of efficiency of the producer than because of the heat consumption of the engine itself. For fuel consumptions under various conditions, see test results, Table 6.

D means double-acting; all engines not so marked are single-acting.

Abbreviations used for fuels are: N.G., natural gas; I.G., illuminating gas; P.G., producer gas; B.G., blast-furnace gas; G., gasoline; K., kerosene; T.O., coal-tar oil; C.O., crude oil; F.O., fuel oil; A., 86 per cent. alcohol; G. O., gas oil.

* Test results of plant I for 3 units; P for 2 units; Q for 4 units.

† This column gives the conditions under which the results were obtained: T, special test; 10d., ten days normal operation; 1 yr., one year normal operation. For plant J is given the average of the U. S. Geol. Survey test on low-grade fuels; for plants BB and DD the average of German practice.

Table 7. Usual Absolute Compression, Explosion, and Mean Effective Pressures for an Average Fuel for Each Group

Fuel	Usual compression pressure, lb. per sq. in.	Usual explosion pressure, lb. per sq. in.	Mean effective pressure, lb. per sq. in.
Rich gas:			
Rich mixture: 1 part of gas to 6–7 parts of air by vol.	60– 75	225–300	70–85
Lean mixture: 1 part of gas to 10–15 parts of air by vol.	75–120	300–375	65–80
Lean gas	120–180	270–375	65–80
Liquid fuel with low boiling point	45– 75	180–300	55–60
Liquid fuel with high boiling point	60–120	150–300	50–70

Regulation

The methods of regulation are: (*a*) The hit-and-miss system; (*b*) quantitative governing—variation of the quantity of charge, the ratio of fuel to air remaining constant; (*c*) qualitative governing—variation of the ratio of fuel to air with change of load; (*d*) variation of the time of ignition; (*e*) combination systems.

The **hit-and-miss system** is not used in modern practice, because of the irregular crank effort it produces; but it is the most economical in fuel. Few of the systems in use at present are purely of one type—they may be mainly of one type, but they have characteristics of the others to a greater or less extent. **Quantitative governing** is open to the objection that the compression decreases with decrease of load, and therefore the efficiency decreases. Cut-off regulation is the only purely quantitative governing system, but is not much used because of the complexity of valve gear required. **Throttle governing** is never purely of the quantitative type, since the mixture proportions are upset by the increased suction on the air, particularly where the gas is supplied under pressure. In such a case, the mixture becomes richer as the load diminishes.

With **qualitative governing,** as the load decreases the amount of fuel should be reduced and the air increased so as to give constant cylinder filling. In an engine using gas fuel, this system actually partakes of the character of quantitative governing, since, as the gas is throttled, the air suction increases and the pressure at the end of admission is thereby lowered. Consequently, with this system the compression is also variable, though less so than with quantitative governing. At low loads this system is inferior to quantitative regulation; the fuel consumption per h.p. increases very rapidly as the load decreases, because as the fuel ratio is decreased the mixture rapidly becomes difficult to ignite and slow in burning. This method of regulation is unsatisfactory at light loads on account of the misfires. Liquid-fuel engines using the heavier fuels, both explosively and at constant pressure, govern qualitatively by forcing more or less oil into the engine, and frequently show maximum thermal efficiency at about 80 per cent. of rated load. Automobile

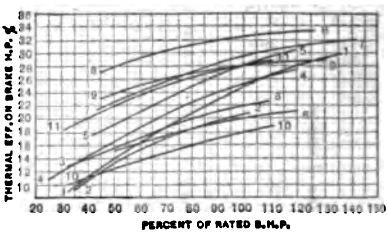

Fig. 3.—Efficiency Curves of Internal-combustion Engines (Figures refer to Table 8).

and motor-boat engines using gasoline and kerosene explosively, regulate by combined throttling and variation of the ignition point.

A few typical **efficiency curves of engines** fitted **with** the **various systems of regulation** for various percentages of the rated load, are shown in Fig. 3, taken from Carpenter and Diederichs' "Internal-combustion Engines." Table 8 gives the explanatory data corresponding to these curves.

GENERAL DESIGN

Notation

Let t and T = temperature, deg. fahr. and absolute, respectively
p = absolute pressure, lb. per sq. in.
v = volume of gas or of mixture of gases, cu. ft.
c_p and c_v = specific heats at constant pressure and constant volume
$x = c_p/c_v$ = ratio of specific heats
$J = 1/A = 778$ = mechanical equivalent of heat
$R = 778\ (c_p - c_v)$ = gas constant. For air, $R = 53.2$
$M = 144\ pv/RT$ = weight of volume v of gas
Q = B.t.u. added or abstracted during a given operation
W = work in ft.-lb. done during this operation
n = exponent of the polytropic curve pv^n = const.
$r_c = v_1/v_2$ = volumetric compression ratio (see Figs. 1 and 2)
$r_d = v_3/v_2$ = constant pressure ratio, ratio of cut-off volume to clearance volume, in the case of constant-pressure combustion
$r_e = v_1/v_3$ = ratio of expansion
b.h.p.$_n$ = rated brake horse power of an engine, usually 0.85 of the maximum power
C = fuel consumption in cu. ft. or lb. per b.h.p.$_n$ per hour
C_h = total fuel consumption per hour at normal load in cu. ft. or lb.
L = volume of air actually in the mixture per cu. ft. of gas or per lb. of fuel, in cu. ft.
H = lower heat value of 1 cu. ft. or 1 lb. of the fuel under standard conditions. (29.9 in. of mercury and 62 deg. fahr.)
d = piston diam., ft.
l = stroke, ft.
v_d = piston displacement per stroke, cu. ft.
N = revolutions of the crank shaft per minute
p_m = indicated mean effective pressure, lb. per sq. in.
E_t = theoretical indicated thermal efficiency
E_i = actual indicated thermal efficiency
E_m = b.h.p./i.h.p. = mechanical efficiency
E_v = volumetric efficiency of the suction stroke (taken at 29.9 in. of mercury and 62 deg. fahr.)
$E_c = E_i/E_t$ = ratio between the indicated and theoretical thermal efficiencies = diagram factor
$E_e = E_cE_tE_m$ = economic efficiency = thermal efficiency at the brake
Unexplained suffixes refer to points on Figs. 4 and 5.

Cycles

The Explosion Method. For equations of work done and thermal efficiency, see p. 320. From the equation for thermal efficiency it is seen (assuming that x, the ratio of specific heats, is constant) that the efficiency depends on the ratio of the compression. The compression pressure should be made as high as possible.

The effect of the variability of the specific heats (see p. 366) on the efficiency as compared to the efficiency with constant specific heats, is shown in the following table based on an average of the results of Clerk and Wimperis:

Ratio of compression, r_c	3	4	5	6	7
Theoretical thermal efficiency (E_t) when the specific heats are assumed					
Constant	35.50	42.75	47.75	51.5	54.25
Variable	28.25	34.90	39.50	43.0	45.50

Constant-pressure Combustion. For general equations in terms of temperature for work done and thermal efficiency, see p. 321. The equation for efficiency in terms of volume ratios, is

$$E_t = 1 - (r_d^x - 1)/[xr_c^{x-1}(r_d - 1)]$$

The efficiency of the constant-pressure cycle is the same as for the explosion cycle with the exception of the factor $(r_d^x - 1)/x(r_d - 1)$. The efficiency depends, therefore, not only on the compression but also upon r_d, that is, the volume at the end of combustion. The smaller the value of r_d—the earlier in the stroke the fuel supply is cut off—the greater is the thermal efficiency. A large number of tests of Diesel engines have shown a greater thermal efficiency at three-quarters than at full load. That this does not hold for still lower loads is due to the influence of other factors.

The Indicated Work. The actual indicated work, W_i, is always less than the theoretical, in consequence of incomplete combustion, losses due to cooling, radiation, etc. (See full lines, Figs. 1 and 2, p. 1020.)

$W_i = p_m(v_1 - v_2) = p_m v_d$ ft.-lb. per combustion stroke.

The volume of piston displacement per stroke in cu. ft. is

$v_d = 66{,}000 \times$ i.h.p.$/Np_m$ for 4-cycle engines

$= 33{,}000 \times$ i.h.p.$/Np_m$ for 2-cycle engines.

p_m depends upon the heat value of the gas and air mixture, $H_m = H/(1 + L)$:

$$p_m = 778\ H_m E_t E_e/144 \text{ (lb. per sq. in.)}$$

With producer gas where $H = 125$ B.t.u. per cu. ft., $L = 1.2$, $E_t = 30$ per cent, and $E_e = 85$ per cent., $H_m = 125/(1 + 1.2) = 56.8$ B.t.u. per cu. ft. Then $p_m = 7.8 \times 56.8 \times 0.30 \times 0.85/144 = 78.25$ lb. per sq. in.

If the total hourly consumption of an engine is C_h lb. or cu. ft. of fuel, of a heat value of H, the actual heat added for each combustion stroke (in B.t.u.) is $Q_a = C_h H/30N$ for 4-cycle $= C_h H/60N$ for 2-cycle.

The **indicated thermal efficiency** $E_i = 2545 \times$ i.h.p.$/C_h H$. The average limiting values of $E_e = 0.5$ to 0.8. The **economic efficiency** $E_e = 2545 \times$ b.h.p.$/C_h H$. For average values of E_e, see Table 15, p. 1036; for values for special engines, see Table 6, p. 1026.

The Working Processes in Four-Cycle Engines

The Suction Stroke. At the innermost position of the piston (Fig. 4) the compression space is filled with v_c cu. ft. of unexpelled exhaust gases whose weight in lb. is $M_r = 144 p_r v_c/R_r T_r$.

If the temperature of the charge before admission is T_m, the weight of the mixture drawn in is $M_m = (E_s v_d / T_m)\ (144 \times 14.7/R_m)$ lb. at the end of the suction stroke, and the weight of the total charge in lb. is

$$M_s = M_r + M_m = 144 p_s v_T / T_s R_s,$$

Then $\quad p_s v_T / T_s = p_r v_o / T_r + 14.7 E_s v_d / T_m.,$

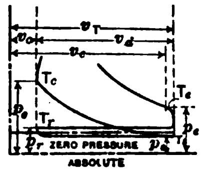

Fig. 4.

provided it is assumed that $R_s = R_m = R_r$, which can be done without sensible error. In order to obtain a maximum amount of work per stroke E_s must be made as large as possible, by diminishing the suction and exhaust resistances and the suction temperature. The influence of atmospheric pressure on E_s and consequently on i.h.p. must be especially reckoned with in plants located at high altitudes.

Table 12. Influence of the Height above Sea Level on the Volumetric Suction Efficiency

(Atmospheric pressure as given by average barometer reading b.

Height above sea level, ft.	Atmos. pressure, in. of mercury (b)	Relative volumetric efficiency (E_s), b : 29.92	Height above sea level, ft.	Atmos. pressure, in. of mercury (b)	Relative volumetric efficiency (E_s), b: 29.92
0	29.92	1.000	4,000	25.85	0.865
500	29.41	0.984	4,500	25.37	0.848
1,000	28.85	0.965	5,000	24.92	0.833
1,500	28.33	0.948	5,500	24.46	0.818
2,000	27.82	0.931	6,000	24.00	0.803
2,500	27.31	0.914	8,000	22.17	0.742
3,000	26.82	0.892	10,000	20.34	0.681
3,500	26.35	0.882			

Practical Values: p_r = 15.4 to 16.4 lb. per sq. in. abs.; t_r = 800 to 980 deg. fahr.; t_s = 170 to 260 deg. fahr. Too early closing of the exhaust valve and a very long (or too small) exhaust pipe may increase these values considerably.

Engine	Inlet valve	p_s (lb. per sq. in.)	E_s
Slow speed.........	Mechanically operated..	12.5 to 14.2	0.87 to 0.90
High speed.........	Mechanically operated..	11.4 to 12.1	0.78 to 0.83
Slow speed.........	Automatic.............	12.1 to 12.8	0.80 to 0.85
High speed.........	Automatic.............	11.1 to 11.8	0.65 to 0.75
Very high speed (automobile)	Automatic (with air cooling)	8.5 to 10.7	0.50 to 0.65

Suction producers and carburetors increase the suction resistance, and in unfavorable cases may decrease the above values of E_s by from 2 to 5 per cent.

The Compression Stroke. The compression line follows the equation pv^n = constant. Values of compression pressures (p_c), temperatures (T_c) and theoretical thermal efficiencies (E_t) for different values of r_c and n are given in Table 13. If, in any actual case, the real suction pressure should be some other value than p_s = 12.5, as p'_s, the values of p_c in Table 13 can be corrected in the ratio $p'_s/12.5$.

Values of n from Practice. The mean value of the exponent n of the compression line varies generally between 1.25 and 1.35. High temperature of the walls may raise it to 1.4 or higher, while leakages of gas diminish its apparent value.

Table 13. Values of Compression Pressures, Temperatures and Theoretical Thermal Efficiencies

[p_s taken at 12.5 lb. per sq. in. abs., and T_s at 700 deg. fahr. (t_s = 240 deg. fahr.)]

	Ratio of compression	r_c =	3.5	4.0	4.5	5.0	6.0	7.0	8.0	9.0	10.0	12.0	15.0
n = 1.30		p_c =	63.7	75.8	88.3	101.3	128.4	156.9	186.6	217.5	249.4	316.1	422.5
	$1 - \frac{1}{r_c^{n-1}} =$	E_t =	0 313	0.340	0.363	0.383	0.416	0.442	0.464	0.483	0.499	.....	.....
		T_c =	1019	1061	1099	1134	1198	1255	1306	1353	1397	1475	1577
n = 1.35		p_c =	67.8	81.2	95.2	109.8	140.4	172.9	207.1	242.7	279.8	357.9	483.8
		E_t =	0.355	0.384	0.409	0.431	0.466	0.494	0.517	0.5 7	0.553	.....	.....
		T_c =	1085	1137	1185	1230	1311	1383	1449	1510	1567	1670	1806
n = 1.41		p_c =	73.1	88.3	104.2	120.9	156.4	194.3	234.6	276.9	321.3	415.5	569.1
		E_t =	0.402	0.434	0.460	0.483	0.520	0.550	0.574	0.594	0.611	.....	.....
		T_c =	1170	1236	1297	1354	1459	1554	1642	1723	1799	1939	2125

The Clearance Volume for 4-cycle engines averages as follows (assuming p_s = 12.8 lb. per sq. in.)

Fuel	p_c, lb. per sq. in.	Clearance, per cent.	t_c, deg. fahr.
Gasoline	42.5	40	530
Illuminating gas	85	25	620
Producer gas	130	15	765
Blast-furnace gas	155	12	850
Fuel oil (constant-pressure engine)	500	7 to 8	1070

According to Illmer (*A. S. M. E.*, Dec., 1915) the volume of the vaporiser in oil engines should vary with the compression pressure. The following values are given as minimum ratios of vaporiser volume, V_v, to total clearance volume, V_c.

Compression, lb. per sq. in. gage	135	160	200	250	300	350	400
V_v/V_c	1	0.8	0.55	0.34	0.18	0.07	0

With compression above 400 lb. per sq. in. the vaporiser could be dispensed with except to allow for cold starting and other contingencies.

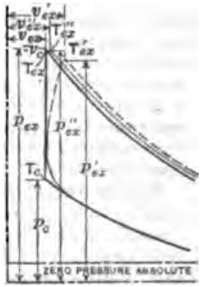

Fig. 5.

The Combustion and Expansion Stroke. For causes of differences between the ideal and the actual explosion temperatures, see section on Combustion, p. 368. The variation of the explosion from the theoretical constant-volume combustion is indicated by the inclination of the actual combustion line and by the varying expansion lines in Fig. 5.

When the explosion is retarded so that $v'_{ex} > v_c$,

$$T'_{ex} = T_c p'_{ex} v'_{ex} / p_c v_c = p'_{ex} v'_{ex} / MR_e$$

If the value of p'_{ex} can be taken directly from an indicator diagram, the above equation will give the actual explosion temperature T'_{ex}; if, however, p_{ex} or T_{ex} is taken from a hypothetical indicator card, the values of T'_{ex} or p'_{ex} can be found only by multiplying by a reduction factor which takes into account the decrease of temperature or pressure due to heat losses, cooling, etc. The value of this factor is not far from that of the card factor E_c of the cycle.

Values of n from Practice: The mean value of the exponent n of the expansion line varies, generally, between 1.30 and 1.50; infrequently an indicator card shows as high a value of n as 1.70. Loss of charge through leaks increases appreciably the apparent value of the exponent, while an indicator with too much frictional resistance gives an apparent error in the opposite direction.

Herberg (Doctor's Thesis, 1903) gives the following values, derived from investigation of an 8-h.p. Koerting illuminating gas engine:

Compression	p_c = 213.0	128.0	100.0	71.0	42.5	28.5	lb. per sq. in.
Mean exponent	n = 1.285	1.295	1.305	1.335	1.395	1.430	

Münsinger found the following results from an investigation of a 15-h.p. Diesel engine:

p_m =	35.3	56.3	68.4	83.0	83.5	88.7	98.3	105.0	107.2	116.7
n_1 =	1.29	1.36	1.33	1.13	1.37	1.33	1.30	1.25	0.85	0.85
n_2 =	1.48	1.46	1.44	1.41	1.45	1.44	1.39	1.40	1.35	1.38

where p_m = mean effective pressure, lb. per sq. in., n_1 is the smallest exponent—at the beginning of the expansion—and n_2 the largest exponent—occurring toward the end of the expansion line. As in the case of the explosion engine, a diminution of the gas temperature also resulted in an increase of n.

Values of explosion and terminal pressures and temperatures from practice are as follows:

t_{ex} = 2240 to 3140 deg. fahr.; p_{ex} = 200 to 375 lb. per sq. in. abs.;
t_e = 1190 to 1940 deg. fahr.; p_e = 37.5 to 75 lb. per sq. in. abs.

The Exhaust Stroke. (See Fig. 4.) The exhaust valve usually begins to open at between 80 per cent. and 90 per cent. of the expansion stroke. During the establishment of pressure equilibrium, the velocity of the gases is very great, in the neighborhood of 2600 to 3000 ft. per sec.

If the opening of the exhaust valve is retarded the negative work is increased and the cylinder temperature is increased, which in turn decreases the volumetric efficiency, E_s, and the allowable compression pressure. With correctly timed valve opening, sufficient valve lift, few changes of direction of the gases, and sufficiently large exhaust pipe, the resistance p_r will be a minimum, and together with properly designed inlet valves and passages, will insure a maximum value of the volumetric efficiency, E_s. Under these conditions and with an exhaust pipe fitted with a long vertical riser, to act as a chimney, it is possible through the kinetic energy of the exhaust-gas column to bring the resistance p_r down to atmospheric or even a little below. It is, however, impossible to predict with certainty the occurrence of this vacuum—several manufacturers having tried without success to utilize this phenomenon.

Values Obtained in Practice. The pressure along the exhaust line is usually from 15 to 17 lb. abs., sometimes more; the exhaust temperature (outside of the cylinder and close to the exhaust valve) varies from 575 to 1000 deg. fahr.; this may be raised considerably by the use of rich mixtures, and by after-burning due to late ignition or improper mixtures. The average percentage composition of the exhaust gases by volume is, CO_2, 10 (about); O_2, 5 to 10; CO, none or only very slight trace; H_2 or CH_4, none; N, 80 to 85. For economical running there should be no trace of combustible gases in the exhaust gas.

The variation of the specific heats of an average exhaust gas with change in temperature, is as follows:

Temperature, deg. fahr.	t = 32	t = 1000	t = 1750	t = 2500	t = 3500
	T = 492	T = 1460	T = 2210	T = 2960	T = 3960
c_p	0.2488	0.2873	0.3173	0.3472	0.3872
c_v	0.1795	0.2183	0.2482	0.2780	0.3180

Determination of the Principal Dimensions of an Engine

1. Dimensions Based on Volume of Air Used

(B.h.p. taken throughout as b.h.p. per cylinder end. For symbols see p. 1030)

A simple basis for determining the principal dimensions is the amount of air necessary for combustion. This method permits of taking into consideration the properties of the various fuels, and requires but few assumptions and established empirical factors.

Let C_s = fuel consumption per suction stroke at the rated brake load, b.h.p.$_n$; for gases in cu. ft., for liquids in lb.

L_s = actual amount of air required per suction stroke at the normal load, determined from C_s and L under standard conditions (29.9 in. Hg and 62 deg. fahr.), in cu. ft. Then

for **four-cycle engines** (per cylinder end),

$C_h = 2545 \times \text{b.h.p.}_n/HE_e$ (cu. ft. or lb. per hour)

$C_s = 2C_h/60N = 84.8 \times \text{b.h.p.}_n/E_eHN$ (cu. ft. or lb.)

$L_s = C_sL = 84.8L \times \text{b.h.p.}_n/E_eHN$ (cu. ft.)

For **two-cycle engines** C_s and L_s must be divided by 2, since there is a charging stroke every revolution.

General Equations for Engines Using Gaseous Fuels. The actual charge drawn into the cylinder during one suction stroke is $= C_s + L_s$ cu. ft. and for **single-acting engines** requires an actual piston displacement of

$$V_d = 84.8 \times \text{b.h.p.}_n \times (1 + L)/E_vE_eHN \text{ cu. ft.}$$

$d = \sqrt{216 \text{ b.h.p.}_n \times (1 + L)/E_vE_eHS}$ ft., where S is the allowable piston speed, ft. per min.;

$l = 108 \times \text{b.h.p.}_n \times (1 + L)/E_vE_eHNd^2$ ft.

$N = 108 \times \text{b.h.p.}_n \times (1 + L)/E_vE_eHd^2l$ r.p.m.

In the case of a **double-acting engine** with a piston rod (of diameter d_r) through each cylinder head, the equation becomes

$$d = \sqrt{216 \times \text{b.h.p.}_n \times (1 + L)/E_vE_eHS\,(1 - y^2)} \text{ ft. for gas fuel,}$$

where $y = d_r/d$. Writing $K = 216(1 + L)/E_vH$, the last equation reduces to

$$d = \sqrt{K \times \text{b.h.p.}_n/E_eS(1 - y^2)}$$

For **engines using liquid fuels**, substitute L for $(1 + L)$ in the preceding formulæ. For values of y, see p. 1042; for E_v, see p. 1032; for E_e, see Table 15; for S, see below; for L, H and K, see Table 14.

Table 14. Values of K in Formula for Cylinder Diameter
(Table based on a value of E_v = 0.85)

Fuel	Lower heat value (H) B.t.u. per		Air required—cu. ft.				K
			Theoretically (L_t) per		Actually, to give best results (L) per		
	cu. ft.	lb.	cu. ft.	lb.	cu. ft.	lb.	
Natural gas	950	....	9.4	....	14	....	4.01
Illuminating gas	600	....	5.5	....	8	....	3.81
Coke-oven gas	580	....	5.4	....	7.8	....	3.86
Producer gas	135	....	0.99	....	1.3	....	4.33
Blast-furnace gas	100	....	0.73	....	1.1	....	5.34
Gasoline	....	20,500	....	189	....	300	3.72
Kerosene	....	20,300	....	187	....	300	3.76
Alcohol, 90% by vol.	....	10,900	....	101	....	165	3.85
Crude oil	....	18,000	....	176	....	305	4.31

2. Dimensions Obtained by Use of Practical Coefficients

The following coefficients are based on experience with actual machines operating under certain conditions, and their use presupposes similar conditions. For special cases, or those which require exact treatment, it is better to use the previous method.

The **ratio of stroke to diameter** (l/d) lies between 1.0 and 2.0. For automobile engines the range is from 1.0 to 1.3. Small stationary engines usually have a little larger ratio, 1.2 to 2.0. In average American practice for the very large double-acting tandem or twin-tandem stationary engines, l/d = 1.37. The **allowable piston speed** S for stationary engines varies between 500 and 1000 ft. per min., as follows:

Horse power	Over 1000	1000	700	500	150	50	Small
Limits, ft. per min.	700–1000	700–1000	700–900	650–850	600–800	500–700	450–700
Average practice, ft. per min.	850	800	750	700	650	600	550

For automobile engines the usual limits are 600–1400 ft. per min., and average practice 750 ft.

Values of the **thermal brake efficiency** for various types of engines are given in Table 15, and **diagram factors** for four-cycle explosion engines using different fuels in Table 16.

Table 15. Thermal Brake Efficiencies of Different Types of Engines

Type of Engine	E_e, per cent.
Small high-speed auto, multi-cylinder, single-acting	15.0 to 27.5
Small or medium, single-cylinder, stationary, single-acting	10.0 to 17.5
Small or medium, two-cylinder, stationary, single-acting	15.0 to 20.0
Small or medium three-cylinder, stationary, single-acting	20.0 to 27.5
Large single-cylinder, stationary, single-acting	17.5 to 25.0
Large two-cylinder, stationary, single-acting	17.5 to 25.0
Large single-cylinder, stationary, double-acting	20.0 to 25.0
Double-acting tandem, two-cylinder	20.0 to 30.0
Double-acting twin tandem, four-cylinder	20.0 to 27.5

Table 16. Diagram Factors for Four-cycle Explosion Engines

Fuel	Compression, lb. per sq. in. gage	Diagram factor, E_e, per cent.	Fuel	Compression, lb. per sq. in. gage	Diagram factor, E_e, per cent.
Natural gas	90 to 140	40 to 52	Gasoline	80 to 105	40 to 65(*b*)
Illuminating gas	80	45	Kerosene, vaporized before injection	45 to 75	30 to 40
Coke-oven gas	100 to 135	45(*a*)	Kerosene, injected. May run as low as 20		
Producer gas	100 to 160	40 to 56	Alcohol	75 to 210	72 to 74(*b*)
Blast-furnace gas	130 to 180	30 to 48			

(*a*) Probable. (*b*) Strong, U. S. Geol. Survey.

In Diesel engines operating at rated load with fuel admission for about 10 per cent. of the stroke, the diagram factor varies between 50 and 70 per cent.; in well-designed engines of good workmanship the diagram factor averages 70 per cent. The diagram factor for a two-cycle engine may be taken as 0.8 of that for a four-cycle engine.

When the cylinder diameter is based on the mean effective pressure of the theoretical air card (p'_m), the diagram factor (E_c), the pressure ratio of compression, and the heat supplied per cu. ft. of best mixture, then, for a four-cycle engine

$$d\ (\text{inches}) = \sqrt{168{,}100 \times \text{b.h.p.}_n \times (1 + a)/E_m p_m S(1 - y^2)}$$

where a = overload factor = (total b.h.p. − b.h.p.$_n$)/b.h.p.$_n$, and $p_m = E_c p'_m$

$$= 5.4\left[1 - (p_s/p_c)^{\frac{s-1}{s}}\right]E_cH/(1 + L) = KE_cH/(1 + L), \text{ lb. per sq. in.}$$

Values of K for various values of p_c/p_s are as follows:

p_c/p_s =	3	4	5	6	7	8	9	10	12	15	18
K =	1.46	1.77	1.99	2.17	2.30	2.44	2.52	2.60	2.75	2.91	3.04

For oil fuels, substitute L for $(1 + L)$.

Capacity Coefficients. In Table 17 the values are referred to normal brake horse power (b.h.p.$_n$) of single-acting four-cycle engines. For maximum load they should be increased in proportion. The table includes:

1. Indicated mean effective pressure p_m, from which b.h.p.$_n$ = 0.066 $p_mE_mV_s$, where V_s = piston displacement, cu. ft. per sec.
2. Specific capacity W_o = power per cu. ft. of piston displacement per sec., expressed in ft.-lb. per cu. ft. per sec.; b.h.p.$_n$ = $W_oV_s/550$.
3. Specific piston displacement V_o, in cu. ft. per sec. for 1 b.h.p.

$$\text{b.h.p.}_n = \frac{d^2S(1-y^2)}{11{,}000\ V_o},\ \text{or } d(\text{inches}) = \sqrt{\frac{11{,}000 \times \text{b.h.p.}_n \times V_o}{S(1-y^2)}}$$

4. Capacity constant K_c. b.h.p.$_n$ = $K_c\, d^2S(1 - y^2)$.

Table 17. Capacity Coefficients for Single-acting Four-cycle Engines

Fuel, assuming E_m = 80 per cent.	M.e.p. p_m lb. per sq. in.	Specific capacity $W_o = \frac{144 p_mE_m}{4}$ ft.-lb. per cu. ft. per sec.	Specific displacement $V_o = \frac{550}{W_o}$ cu. ft. per sec. per b.h.p.	Capacity constant $K_c = \frac{p_mE_m}{168{,}000}$	Relative capacity referred to illuminating gas engine = 1.00
Natural gas	85.0	2450	0.224	0.000405	1.10
Illuminating gas	77.5	2230	0.247	0.000369	1.00
Coke-oven gas	77.5	2230	0.247	0.000369	1.00
Producer gas	62.5	1800	0.306	0.000298	0.81
Blast-furnace gas	57.5	1660	0.331	0.000274	0.74
Gasoline	75.0	2160	0.255	0.000357	0.97
Kerosene	55.0	1580	0.348	0.000262	0.71
Alcohol	55.0	1580	0.348	0.000262	0.71
Crude oil (Diesel)	100.0	2880	0.191	0.000477	1.29

The specific capacity W_o for double-acting four-cycle engines is twice as large as the values given above for single-acting engines. For two-cycle single- and double-acting engines with separate gas and air pumps W_o can be assumed to be respectively from 1.75 to 1.90 and from 3.5 to 3.8 times larger than the values in Table 17. The specific displacement is decreased in the inverse ratio. In small high-speed two-cycle engines with crank-case compression the specific capacity is no larger than for four-cycle engines of the same cylinder dimensions, due to low volumetric and mechanical efficiency.

CONSTRUCTION AND DESIGN

Vertical Engines are used for small and medium powers because of their simplicity and low cost of construction; for medium powers the capacity is obtained by using multi-cylinders, keeping the cylinder dimensions small and retaining the simplicity. Double-acting vertical engines are not built at the present time because of the trouble in locating the valves in the lower head, and because of the fact that the piston must then be water-jacketed.

Advantages of the vertical over the horizontal type: The foundations need not be as large or heavy, since, without counterbalancing, the free force is in the vertical plane. The floor space occupied is about two-thirds of that required for a horizontal single-acting engine of the same power. It is easier to lubricate the cylinder uniformly, and the wear in the cylinder is less.

Disadvantages: In large sizes less accessibility; dust and grit tend to remain in a vertical cylinder and score the cylinder bore and piston packing rings.

Horizontal Engines are built single-acting, using a trunk piston for small and medium powers, and are advantageous because of the simplicity of construction, decreased length of the machine, and consequent lower manufacturing cost. Some medium and all large engines are built double-acting. In the larger sizes of single-acting engines a cross head has to be used to keep down the cylinder wear.

Multi-cylinder Engines. For higher capacity and high coefficients of regulation, multi-cylinder engines can be built at less cost than single-cylinder engines. The arrangements of horizontal multi-cylinder engines in use at the present time are single-cylinder twin, two-cylinder tandem, and twin-tandem engines made up of two two-cylinder tandems. Two-cylinder opposed and twin-two-cylinder opposed engines were formerly built but have now become obsolete, due principally to the difficulty of building a forked connecting rod—to run on the same crank pin as the opposed cylinder—which would run even reasonably cool.

Relative Advantages. The single-cylinder twin engine has the advantage over the two-cylinder tandem that the weight of reciprocating parts is less; the cost of construction, however, is greater. Two-cylinder tandem engines are almost universally constructed with main, intermediate, and tail-guide cross heads. With this construction special provision must be made to allow the engine to expand. In a 600-b.h.p. double-acting tandem producer-gas engine, 45 ft. in overall length, the **expansion from cold to full-load condition** amounts to $^{3}/_{16}$ in. The expansion is generally taken care of by anchoring the main frame rigidly to the foundation and by supporting the tie piece and tail guide on foundation plates. The contact surfaces of the tie piece, tail guide and foundation plates are planed and lubricated. In order that the engine may expand freely in the direction of the center line but be restrained from distorting laterally, the tie piece and tail guide are gibbed to the foundation plates with only enough clearance (0.015 in. total sideways and 0.015 in. up and down) to allow them to slide freely on the foundation plates. The engine is suitably prevented from lifting by bolting the tie piece and tail guide to the foundation plates with bolts which are screwed down on to bushings and machined washers, the bushings being of such a length that there is only a sufficient clearance between the lower side of the washers and the machined pads on the tie piece and tail guide to allow them to slide freely (about 0.015 in.). Care must be taken that there is sufficient clearance between the bushing and the sides of the holes through the pads to allow of the full movement due to expansion.

A larger factor of safety must be employed than in the case of steam engines, because accidental occurrences such as preignitions, the force and time of occurrence of which are not subject to calculation. In few of the smaller engines does the maximum pressure exceed 360 lb. per sq. in., while many of the modern large engines have a maximum limit of 450 to 500 lb.

Foundations. The reciprocating weights of gas engines are greater and the speeds of rotation generally higher than in the case of steam engines, necessitating more mass to the foundation, which should always be carried down to a firm footing. Concrete floors and the walls of the engine house should not be tied rigidly to the foundations, because of the vibration. The average **volume of material in foundations** for the different types of engines may be taken as follows:

For horizontal engines without outboard bearing, 14 to 18 × b.h.p.$_n$ cu. ft.
For horizontal engines with outboard bearing, 21 to 25 × b.h.p.$_n$ cu. ft.
For vertical engines without outboard bearing, 7.7 to 8.8 × b.h.p.$_n$ cu. ft.
For vertical engines with outboard bearing, 9.8 to 10.5 × b.h.p.$_n$ cu. ft.

Frames. The allowable fiber stress for cast iron of the best grade should not exceed 3500 lb. per sq. in. in bending, as computed from the total explosion pressure. It is especially important to take up the maximum total explosion stress as nearly as possible in an axial direction. Frames for vertical engines lend themselves easily to this, but those for horizontal engines do not. Types of frames for horizontal engines in general use are all subject to considerable bending stress; the moment arms of the bending stress, where unavoidable, must be made as short as possible. The foundations should not be figured as taking any of the stress. The unit pressure or load on the foundations due to the weight of the machine and the inertia forces should not exceed ½ to ⅓ of the usual values for the various materials under the main bearings of horizontal engines.

Box and "A" Frames for Vertical Engines. Determinations of the thickness of walls or webs in frames, on the basis of strength, give webs so thin as to give rise to molding and casting difficulties and to bad casting strains. The walls are therefore made thicker than is required for strength. The **box frame** is used more commonly in the United States for vertical engines than the "A" frame. The facility with which it can be completely enclosed makes it especially suitable for dusty locations, and the oiling is simplified as the splash system can be utilized. A special application of this type is its use for automobile engines, where lightness as well as dust-proof construction are prime requisites; lightness is secured by using aluminum alloys and strength by ribbing the crank case on the outside. The usual thicknesses, s, for various cylinder diameters, d, are as follows:

d(inches) =	5	7	9	11	13	15
s(inches) =	½	9/16	⅝	11/16	¾	13/16

Check computations should be made to determine the tensile stress in the smallest cross-section of the frame (and of the jacket wall, if the cylinder and frame are cast in one piece) and the bending stress in the cross-section below the main bearing, taking the distance between the foundation bolts as the moment arm. This latter is especially necessary in case the main bearings are located in a separate base plate, on top of which the frame proper is bolted (the distance between the holding-down bolts in this case being the moment arm).

The **"A" frame**, adapted from steam-engine practice, is used in Germany for medium-sized vertical engines. It is considerably lighter than the box frame, due to the better disposition of the metal. A check computation for this type—in addition to the two mentioned above—should be made for the legs of the "A," which are subject to tension and bending (the forces being the maximum total explosion pressure resolved into components along and normal to the axis of the "A" leg, respectively). The **allowable stresses** should not exceed the following values: Tensile and bending stress, each 2150 lb. per sq. in.; combined tensile and bending stress, 2500 lb. per sq. in.

Frames or Beds for Horizontal Engines. The dangerous section is usually in a plane perpendicular to the center line of the engine, at a place somewhere between the main bearing and the cylinder connection, where the bending moment arm, *i.e.*, the distance between the center line of the engine and the neutral axis of the section, is a maximum. To make this bending moment a minimum the neutral axis of the dangerous section must be as close as possible to the center line of the engine. The side walls should be carried as high as possible—in small engines at least to a level with the center line of the engine, and in large engines still higher. The allowable combined stress is the same as for "A" frames.

The other part of the frame under severe stress is the vertical section through the center line of the main bearing. This section is subject to bending. The best form for the main bearing is the one in which the explosion load is taken up directly by the frame. The bottom shell of the bearing should be fitted with a ball and the frame with a socket. If the bottom of the bearing jaws conforms closely to the curvature of the ball socket, the jaws are stronger than if the bottom of the bearing is horizontal and filleted at the jaws.

Cylinders. The **material** used is generally a hard, close-grained cast iron, and cylinders are designed with an allowable stress of 4250 lb. per sq. in. when the stress conditions are fairly well defined; in other cases the allowable stress is taken at a lower figure.

In medium-sized engines of 8 in. diameter and up, the cylinder wall or barrel is cast separate from the jacket, provided the inlet and exhaust ports do not compel the use of a one-piece casting. The advantages of this construction are that suitable hard iron can be used for the barrel, to withstand the wear, and the jacket can be made of a soft iron to give ease of casting; the cylinder barrel can expand axially independently of the jacket, provided it is fastened rigidly only at the head end.

In large single-acting engines the **one-piece cylinder** has its advantages on account of being a stiffer construction, but the greater difficulty in manufacture and the unequal expansion partially offset this. The total of the stresses due to expansion and to the explosion pressure may far exceed the elastic limit of the material. It is not easy to relieve the jacket walls of double-acting cylinders with valve ports cast integral with the cylinder, of longitudinal temperature stresses, and it is difficult to get good castings. Additional temperature stresses are caused by bad distribution of metal (particularly at the valve ports), therefore a cylinder of this type should be designed with symmetry. Unequal distribution of metal also causes irregular radial expansion of the cylinder bore, which gives rise to cutting and leaking between the cylinder and piston. When this type of cylinder is employed, a hard, close-grained iron liner is almost always shrunk into the cylinder to take the wear. This liner must be securely locked at the middle of the cylinder and left free to expand at the ends; otherwise it may be pulled out of place should a piston ring break and become jammed between the piston and liner. The liner is not figured to take the radial stress at all, but its thickness is determined by the reboring allowance.

A method of obtaining **cylinder castings** which are **free from longitudinal temperature stresses** is to cast the barrel and jacket walls integral, with the exception of a ring of the jacket wall around the center of the cylinder, which is cored out. This ring is closed by split jacket bands or saddles of sheet metal or cast iron, bolted together at opposite ends of a diameter and packed with flexible packing to permit of expansion. When a cast-iron saddle is used it may be cast in such a shape as to form gas and air pipe belts leading to the mixing chambers. A further extension of this method is to cast the cylinder in halves with the joint end up (the poor metal can then be machined off); the faces of the joint are then ground, the two halves held together by means of shrink links, and the opening in the jacket wall covered as in the previous case. A very few manufacturers in this country and Germany adopted cast steel because of the difficulty in obtaining good iron castings, but their use has not been entirely satisfactory in practice. The greater expansion and the much higher modulus of elasticity of cast steel as compared with cast iron, cause increased stresses, while the strength of cast steel is not proportionately greater.

The **water jacket** should cover the entire length of the stroke, to avoid unequal expansion in the cylinder bore and burning of the lubricating oil. The water space should be wide, and, in large cylinders, cleaning holes should be provided. The life of the cylinder can be materially increased if cleaning is done at regular intervals of from 4 to 8 weeks, depending on the water.

The maximum explosion pressure causes tensile stresses in the cylinder walls, both longitudinal and radial. To these must be added, under certain circumstances, secondary stresses due to drawing up on studs or bolts, thrust of the connecting rod (with trunk piston), unequal temperature stresses, etc. If the cylinder and jacket walls are cast integral the longitudinal stress may be neglected since the radial stress is always more than twice the former. If the jacket wall and cylinder are cast separate, the jacket wall alone must sustain the longitudinal tensile stress.

Gas-engine cylinders may have the following wall thickness (in inches) according to Bach:

$$t = \tfrac{1}{2}d[\sqrt{(k_t + 0.4p)/(k_t - 1.3p)} - 1]$$

where d = bore of cylinder, in.; k_t = safe stress in material, lb. per sq. in. and p = maximum explosion pressure, lb. per sq. in. Taking $p = 356$ and $k_t = 3500$, $t = 0.047d$. Where a cylinder liner is not used, a **reboring allowance** X, values of which are given in the table below for various diameters (all dimensions in inches), should be added to this thickness. Where a **liner** is used, X gives its necessary thickness.

d =	4	6	8	10	12	14	16	18	20	24	28	32	40	48
X =	3/8	3/8	13/32	7/16	15/32	15/32	15/32	1/2	17/32	9/16	19/32	5/8	23/32	13/16

The inner fibers of the cylinder wall are under a greater stress than the outer, and this inequality increases rapidly with an increase in the thickness of the wall. Excessive thickness also causes the jacketing to be less effective, consequently **flanging or ribbing the cylinder** is more effective than thickening the wall. The cylinder should be checked for tensile, bending and shearing stresses, due to drawing up the cylinder head. This pressure must at all times exceed the total internal head pressure due to the explosion in order to maintain **tight joints.** Experience has shown that an addition of from 10 to 20 per cent. to the internal head pressure is sufficient to maintain the joint, but by excessive tightening of the bolts this may be increased by 50 per cent. The **allowable stress** for both tension and shear should be 2800 lb. per sq. in. The **jacket wall,** from foundry considerations, should not be less than 7/16 in. thick for small engines.

The **allowable stress in bolts** at the base of the threads may be taken for soft steel as 5500 to 6500 lb. per sq. in. All **joints** should have as little packing material between the surfaces as possible. Wherever possible, the joints should be made metal-to-metal, with possibly the interposition of a very little white lead.

Pistons are usually made from a good grade of close-grained cast iron with an allowable stress of from 5000 to 6000 lb. per sq. in. In the larger engines cast steel is sometimes used.

For single-acting engines the trunk piston is the type generally used (see Table 18 and Fig. 6 for dimensions from Haeder). The length is determined by considering the piston as a cross head, using an allowable unit pressure of 20 lb. per sq. in. without deducting the ring grooves.

Table 18. Dimensions of Gas-engine Pistons
(All dimensions in inches. Letters refer to Fig. 6)

Engine		Piston body					Piston pin (cross head)		Piston rings	
Stroke	*D*	*a*	*b*	*c*	*h*	*k*	*d*	*e*	*f*	*g*
5	3¼	3 11/16	2½	⅜	5/16	3/16	1 3/16	1 9/16	3/32	3/16
6¼	4	4 11/16	3¼	½	⅜	3/16	1⅜	2	⅛	3/16
7½	5	5⅞	4	9/16	7/16	¼	1¾	2⅜	3/16	¼

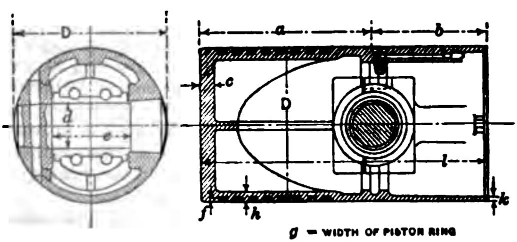

FIG. 6.—Gas-engine Piston.

The maximum thickness of the piston barrel (at the ring grooves) may be made $t = 0.02d +$ thickness of the rings + 0.2 in. If the ribbing is sufficient, the thickness at the open end of a trunk piston may be one-half to one-third of the maximum—the taper to start at about the first ring groove. To allow for expansion, the inner end of the piston barrel should be tapered down by from 0.2 to 0.5 per cent., starting at the last ring groove; when water-cooled, relieve only as far as thickness of the piston face. The **width of the bridge between the ring grooves** should be at least equal to the width of the groove. The **depth of the groove** should be but about 0.02 in. greater than the thickness of the rings. In order to distribute the wear evenly over the cylinder length, a few of the rings are sometimes put near the open end of the piston; this also serves to retain the oil on the piston surface in better shape. In vertical engines with splash lubrication, this arrangement is essential in order to prevent too much oil being sucked up into the combustion chamber during the suction stroke. In order to obtain a uniform distribution of the connecting-rod thrust, the wrist pin should be located at the center of that part of the piston which carries the cross-head load.

If **large pistons** are properly **ribbed**, their stiffness and strength are materially increased. For pistons up to 20 in. in diam. from 6 to 8 radial ribs, sometimes only on the bottom, each from 3/8 in. to 5/8 in. thick, and a couple of strong ribs each side of the wrist-pin bosses, are sufficient. For larger pistons, the lower radial ribs at least should be extended to the open end, and the wrist-pin bosses should be stiffened by two circular ribs. Thin ribs, properly placed and in sufficient numbers, give a lighter construction for equal strength than a few thick ribs, and assist in the cooling of the piston by increasing the radiating surface.

Cast iron is generally used in making **disk pistons** for double-acting engines. Such pistons have been found by American builders to give trouble by cracking across between the cleaning plugs, although they are rendering satisfactory service in Germany. **Cast-steel pistons** have occasionally given trouble either by cutting the cylinder walls or by the slots widening, or by beading over and binding the rings. The trouble due to slot widening was taken care of by making the bridges between the slots much wider than the slots, so that when the slots had become too wide they could be re-turned and wider or double rings fitted. This increased the maintenance and caused most builders to go back to cast iron for all except the largest engines. Modern cast-iron pistons are usually without cleaning holes other than the jacket-water inlet and outlet openings. A double-acting piston is a cantilever beam subjected to a shock load which is applied alternately in opposite directions; the connection between the face of the piston and the rod boss must therefore have enough metal to prevent fatigue of the metal due to this alternating force, otherwise the piston will crack here.

Piston Rods for large engines are either forged hollow, or solid and then bored. Open-hearth steel of the following percentage composition has been found to be very satisfactory for piston rods: C, 0.45 to 0.60; Mn, 0.45 to 0.60; P, under 0.04; S, under 0.04; Si, 0.10 to 0.20. Such steel has an elastic limit of 50,000 lb. per sq. in. and an ultimate strength of 95,000 lb.; elongation in 2 in., 12 per cent. These rods were formerly cambered, but this refinement is not practised at the present time as the deflection is not serious (about 0.035 in. for a 34-in. piston). The outside diameter of the rod, from average American practice, is 31 per cent. of the cylinder diameter (German, 26 per cent.). The diameter of the bore averages 38 per cent. of the outside diameter of the rod. The ends of the rod for the cross-head, intermediate and tail-guide connections should be from 1/4 in. to 5/8 in. smaller in diameter than the body of the rod.

The **strength** of the rods as checked by using the long-column formula of Euler (see p. 435) should not give a factor of safety of less than 20. The ends of the rods should also be checked for tension and shear at the base of the threads if this method of connection is used. The Acme thread is the most satisfactory.

Piston-rod Packing. Metallic packing is universally used, the material generally employed being a good grade of close-grained soft cast iron. Softer alloys have been tried, but the wear and the consequent maintenance are too great.

The packing generally consists of a single or double sectional or segmental ring held to the rod by garter springs. The packing effect is obtained by closely fitting the ring to the rod and by the use of a number of rings or groups of rings in series, separated by solid one-piece rings or the bridges of the packing case. The garter spring should only be tight enough to keep the parts of the ring from displacement by the movement of the rod. The principal trouble with these packings is that the explosion pressure leaks into the space on top of the rings, forces the segments on to the rod and shoulders the rod and wears out the ring in a short time. To reduce the refitting of segmental rings to a minimum, they should be made of as many segments as possible (not less than three, preferably five).

In German practice the packing is housed in the cylinder head itself without a separate packing case, but in American practice a separate packing case is used, which fits into the cylinder head and is sometimes itself water-cooled. This packing case should be uncooled only when the cylinder head is free of valve and igniter openings. Forced lubrication distributing the oil around at least one ring must be used for successful operation.

Piston Rings. Cast-iron snap rings of uniform cross-section give the best service; narrow rings, in a sufficient number, make a tighter packing and with less friction than a smaller number of wider rings; two narrow rings in a groove give better results than one wide ring.

The stress caused by spreading the ring to slip it on the piston should be the same as the stress during operation. With an allowable stress, K_b, of 12,000–17,000 lb. per sq. in., where r_m is the mean radius of the ring $= \frac{1}{2}(d - s)$, the **thickness** in inches $= s = r_m\sqrt{K_b}/2145$. The **width** of the ring $= b = 1.25s$ to $2s$ for one wide ring to the slot. If two rings to the slot are used, width of each $= \frac{1}{2}b$. Dimensions of concentric snap piston rings for the working cylinders of constant-pressure engines, as made by the Davy Robertson Piston Ring Co., Berlin, are as follows (to the nearest 0.001 in.):

Cylinder bore, in........	3.94 to 11.83	11.83 to 15.77	15.77 to 27.57
Width of ring, in........	0.315	0.355	0.394
Thickness of ring, in.....	0.158 to 0.335	0.374 to 0.453	0.473 to 0.788

(The thickness advances by 0.02 in. for an increment of 0.787 in. in the cylinder bore.) The **number of rings** to be used $= n = d/5b$, approx. The gap distance (in.) to be cut from the ring after preliminary turning $= a = 9.5r_m dK_b/2sE$, where E = the modulus of elasticity. The external diam. (in.) for preliminary turning is $d_1 = d + (a/\pi) + 0.12$. The gap is cut either straight across, as a step joint (not used below 8 in. diam.), or diagonally across (the simplest and the best joint for all sizes).

A clearance allowance for expansion a_1 (in.) $= 0.000006\pi d\ (t_r - t_s)$ should be filed out at the joint. t_r is the mean temperature of the piston rings and t_s that of the cylinder barrel. The following estimates are based upon practical experience: Mean temperature of the body of a trunk piston without water-cooling, about 525 deg. fahr.; of the first ring, $t_r = 435$ deg. fahr.; and of the cylinder wall, $t_s = 165$ deg. fahr., approx. Therefore $t_r - t_s = 270$ deg. and $a_1 = 0.0051d$. For trunk pistons without water-cooling, provided the workmanship is good, the clearance for expansion may be taken as $a_1 = 0.0060d$ to $0.0075d$. The temperature of the piston rings decreases very quickly toward the outer end—at the last ring the difference $(t_r - t_s)$ will scarcely amount to more than 90 to 110 deg. fahr. Nevertheless, all the rings of a set or of a size should be given the same clearance in order to make them interchangeable. For large water-cooled pistons the temperature difference is very small and a much smaller clearance (a_1) suffices—from 0.040 in. to 0.2 in., depending upon the diameter.

Ignition is generally by electric spark in modern engines using gas or gasoline as fuel. See p. 1608. Explosion engines working on the lighter of the liquid fuels (kerosene, light crude oil, etc.) use either an electric spark or the hot walls of the gasifier. In large gas engines high-tension electric ignition is never used because of the difficulty of insulation. The most common system is a mechanical make-and-break using a low-tension direct-current make-and-break, with choking coils in the circuit to give sufficient surge voltage to cause the current to arc across the igniter electrodes (see p. 1611). The use of magnetic make-and-break ignition is being discontinued because of the difficulty in accurately timing the ignition, due to the magnetic lag. A high-tension jump-spark ignition is the most commonly used system for gasoline, and in some cases for the other light liquid fuels. If the charge is thoroughly mixed the best results are obtained with the ignition starting at the center of the combustion space. For maximum efficiency in an explosion engine the combustion should take place as nearly at constant volume as possible, but when the explosion takes place in that manner there is too much shock to the engine. The igniter should be set with the ignition advanced so as to give indicator cards with a slightly rounded top. This occurs on the average with the igniter advanced about 35 deg.

For details of ignition systems, see p. 1608. Two arrangements of igniters for double-acting cylinders are used in American practice. When the gas valve closes before the inlet valve—thus filling the mixing chamber and at least part of the inlet port with a stratum of pure air—the usual arrangement is to place two igniter plugs in each combustion chamber, one on either side of the cylinder, 45 deg. down from the vertical, where the mixture is probably purest. When the gas valve closes at about the same time as the inlet valve, the mixture is purest in the inlet port next to the inlet valve. In this case one igniter is located in the onion-shaped inlet port and the other on the opposite side of the combustion chamber, 45 deg. down from the vertical. In the largest engines built, using blast-furnace gas, a third igniter, placed 45 deg. up from the bottom and set to trip 2½ deg. earlier than the other two, has increased the capacity 20 per cent.

Make-and-break igniters are now generally of the hammer-and-anvil type. Steel points are very generally used. An improvement is in the use of hammers and anvils whose surfaces come into contact without the use of points, for which purpose cast iron is the best material. For any type of make-and-break ignition, a known resistance—such as a lamp—should be in each plug circuit to govern the amount of current flowing, otherwise the electrodes will be rapidly burned out. The best results are obtained from 110-volt ignition with from 0.5 to 1.5 amp. per plug, depending upon atmospheric, gas, and operating conditions. With cast-iron hammer and anvil and continuous 24-hr. operation, a surface oxide forms on the electrodes, so that at least 1-amp. current must be used for the igniter. The best results are obtained by using a separate choking coil (so designed as to give a surge voltage of 5000 at the instant of break) for each igniter, or at the most, each two igniters.

Valves. Valve cages or valve seats are made of hard, close-grained cast iron. Valves for small cylinders are made of carbon or alloy steel. Valve disks for large engines are made of cast iron with stems of carbon steel fastened to the disks. The allowable stress in valve disks should be low on account of the high temperature, to avoid warping, and to give enough metal for regrinding.

Gas-engine valves at the present time are of the poppet type, with conical seats, with the exception of some in automobile engines. Automatic inlet valves are used only on small, slow-speed, cheaply constructed engines because of the noise of operation, rapid wear, liability to fracture, and low volumetric efficiency. All valves should be placed in a vertical position to avoid, as far as possible, leakage, sticking, and the extra length of guide necessary for a horizontal valve. The inlet valve should be placed directly over the exhaust valve, in order to cool the exhaust valve by the incoming charge. The exhaust-valve chamber must be cooled. In engines above 100 h.p. the exhaust-valve disk and stem are often water-cooled to keep down the cutting effect of the hot gases upon the valve seat, and to aid lubrication. In Germany the present tendency is to make the exhaust valves for largest engines of forged steel or Durana metal and largely of the non-cooled, mushroom type.

The **dimensions of the ports and passages** in four-cycle engines may be determined from the formula

$$A_g = C_s N/2v = C_s N/9000, \text{ and } A_a = L_s N/2v = L_s N/9000$$

where A_g and A_a are respectively the cross-sectional areas of the gas and air ports and passages in sq. ft., C_s and L_s the volumes of gas and air respectively in cu. ft. per suction stroke (see p. 1035) and v the allowable mean gas, air or mixture velocity = 4500 ft. per min. The smallest **diameter of the valve seat** is d_1 (in.) $= \sqrt{v_d N/49.1}$. For N and v_d see p. 1030. Sometimes it is impossible to realize mean velocities as low as 4500 ft., in large engines the velocity going as high as 6000 to 8500 ft. per min. The **diameter of the exhaust-valve seat** should be larger than that of the inlet valve.

The **valve cages** should be seated in the cylinder or cylinder-head castings on a flat surface with a metal-to-metal joint. The **thickness of the disks** should be determined by considering them as flat plates supported at the circumference, and, because of the high temperature and necessity for regrinding, the allowable stress should be taken at 5700 lb. per sq. in. for mechanically operated valves and up to 11,000 lb. for automatic valves. The **width of** the **valve seat** may be made approximately $b = 0.01d_1 + 3/16$ **in., the angle of the seat being generally 45 deg. The diameter of the valve stem** is $d_s = 1/8 d_1 + 1/4$ to $3/8$ in. The stem of the exhaust valve should be larger than this in order to decrease the wear and to increase the water-cooling surface. The **diameter of** the **valve cage** should be not less than $1.6d_1$.

With mechanically actuated valves the valve spring should exert a tension of not less than 7 lb. per sq. in. of valve surface in engines with throttle governing; with automatic valves from 0.7 to 1.0 lb. per sq. in. according to the engine speed. The strength of the spring must be increased considerably if it has to move part of the valve gearing. In large engines the deflection of springs in operation is considerable, in addition to the load at no deflection; at the maximum deflection of the spring, *i.e.*, with the valve wide open, there should be from 0.05 to 0.10 in. clearance between each two consecutive coils.

Valve Gear. Cam or lay shafts are generally made from machine steel; cams and rollers from hardened steel; eccentrics and eccentric straps from cast iron; valve levers from soft or cast steel (sometimes case-hardened); driving gears generally from steel upon cast iron or upon bronze, or if well lubricated, cast iron on cast iron for screw gears; and cast iron on cast iron for spur or bevel gears.

In small engines the valves are generally actuated by cams, while in medium-sized and large engines the wear on a cam motion is too great and eccentrics are generally employed. In the larger engines the main lay shaft is driven from the crank shaft through an intermediate shaft, so that the half time is obtained through two sets of gears. In such a case the wear on the gears is reduced by introducing a "hunting tooth." Common tooth angles for the screw gears used are 63 deg. 25 min. for the driving gear and 26 deg. 35 min. for the driven.

Large cam diameters permit of accurate adjustment of the valve motion, but the peripheral velocity of the cam should not exceed 3 ft. per sec., as knocking against the cam rollers is likely to result and the torque in the shaft is increased. The **width of cam rollers** for inlet valves can be 0.3 of the diameter of the roller, and for the exhaust valve 0.4. These dimensions should be checked to see that the maximum pressure does not exceed 3000 lb. per in. of width. Computations for strength of **valve levers** should be based on a pressure at the moment of opening of at least 30 lb. per sq. in. for the inlet, and 75 lb. per sq. in. for the exhaust, valve.

Valve Setting. In a single-cylinder, single-acting engine a typical timing of the valve events would be as follows:

Inlet valve starts to open when crank is 20 deg. from head-end dead center (approaching)
Gas valve starts to open when crank is 10 deg. from head-end dead center (approaching)
Exhaust valve closes when crank is 15 deg. from head-end dead center (leaving)
Max. lift of inlet and gas valves occurs when crank has moved through 95 deg. from head-end dead center.
Gas valve closes when crank has moved through 200 deg. from head-end dead center.
Inlet valve closes when crank has moved through 210 deg. from head-end dead center.
Exhaust valve opens when crank has moved through 485 deg. from head-end dead center.
Max. lift of exhaust-valve occurs when crank has moved through 610 deg. from head-end dead center.

Regulation. The regulating device should be as close to the inlet valve as possible, particularly in a multi-cylinder engine. In the case of double-acting cylinders, especially with large mixing chambers, control remote from the inlet valves gives rise to especially poor results, in that one of the ends will take the greater part of the gas in the mixing chamber, and when the suction stroke of the other end starts, the gas has not had time to flow into and fill the mixing chamber. As a result, the first end may take from 60 to 75 per cent. of the load. This is not serious while the load is light, but at and above 0.75 normal load, the first end will be considerably overloaded, often above its designed capacity, and will heat up, resulting in preignitions and back-firing.

Table 19. Weights of Reciprocating Parts for Various Types of Engines

Kind of engine	Weight per sq. in. of piston surface, lb.: Explosion engine	Constant-pressure engine
Single-acting engines:		
Trunk piston, short stroke ($l < 1.5d$)	5.5– 8.5	7.0–10.0
Trunk piston, long stroke ($l \geq 1.5d$)	8.5–10.5	10.0–11.5
With cross head ($l = 1.5d$ to $1.33d$)	12.5–17.0	14.0–18.5
Two-cylinder tandem	17.5–21.5	19.0–23.0
High-speed automobile	0.35–0.60	....
Double-acting engines:		
Single-cylinder, without tail rod	14.0–18.0	....
Single-cylinder, with tail rod	17.0–20.0	18.5–21.5
Two-cylinder tandem	21.0–25.5	23.0–27.0
Three-cylinder tandem, one of which is a blowing tub.	28.5	....

German builders use the center crank exclusively, objecting to the side or overhung crank because of the greater strains due to its being supported only on one side. American builders, however, generally employ the side crank, because of the fact that the center crank requires three bearings, which are difficult to keep in line.

Crank Shafts, especially for large engines, are generally made from open-hearth steel with a tensile strength of at least 64,000 lb. per sq. in. and from 18 to 20 per cent. elongation. The **allowable stress**—on account of the impact effect of the explosion pressure—should be taken at about 12,000 lb. per sq. in.

Crank-shaft Bearings. The allowable **bearing pressure** should be taken at 400 lb. per sq. in. The maximum unit pressure, due to the explosion pressure, should not be so great that the oil film can be squeezed out of the bearing, but say 1400 to 1600 lb. per sq. in. See also pp. 704–708.

Main Bearings. The material generally used for journal diameters (d_j) up to 5 in. is bronze, and the thickness may be $t = (d_j/15) + 0.2$ in. For larger journals a cast-iron shell lined with white metal is used. The thickness of the shell (without the lining) may be $t = 0.1d_j + 0.4$ in. The white-metal alloy used must be hard, but not so hard as to crack under pounding. A mixture found to give satisfaction contains 8 parts by weight of copper, 12 of antimony, and 80 of tin. G. W. Lewis and A. G. Kessler (*Am. Mach.*, 1911) give the data in Table 20 as representing average American practice in allowable unit pressures for a maximum explosion pressure of 350 lb. per sq. in.

Table 20. Allowable Unit Bearing Pressures for Gas Engines

(All dimensions in inches. Allowable unit bearing pressures in lb. per sq. in.)

Item	Horizontal stationary engines	Vertical stationary engines	Automobile engines	Item	Automobile engines
Cylinder diam.	4–20	4–20	4–$5\frac{1}{2}$	Cylinder diam.	4–$5\frac{1}{2}$
Crank-pin diam.	$1\frac{1}{2}$–$8\frac{1}{8}$	$1\frac{5}{8}$–$8\frac{3}{16}$	$1\frac{9}{16}$–$2\frac{1}{16}$	Front-bearing diam.	$1\frac{9}{16}$–$2\frac{1}{16}$
Crank-pin length	$1\frac{5}{8}$–$8\frac{3}{8}$	$1\frac{5}{8}$–$9\frac{5}{8}$	$2\frac{1}{8}$–$2\frac{3}{4}$	Front-bearing length	$2\frac{11}{16}$–$3\frac{9}{16}$

Allowable pressure	647–342	415–360	....	Allowable pressure	760–605

Flywheels (see also pp. 736 and 774). In stationary engines the flywheels are generally made of cast iron, though if the regulation must be close they are sometimes cast steel or occasionally a cast-iron rim with steel or cast-steel arms and hub. For high-speed automobile and motor-boat engines, a steel disk is generally used. The **allowable stress** should not exceed 3000 lb. per sq. in. for cast iron, or 7000 lb. for steel. The **coefficients of fluctuation** may have the following values (for other values see p. 775):

For ordinary power purposes	$1/30$ to $1/40$
For direct-current generators, direct-connected	$1/100$ to $1/120$
For direct-current generators, belt-driven	$1/70$ to $1/80$
For alternating-current generators, direct-connected	$1/175$ to $1/200$
For alternating-current generators, belt-driven	$1/125$ to $1/150$

For the parallel operation of several alternators still smaller values are generally chosen.

In four-cycle engines the inertia effects of the reciprocating weights may be neglected in flywheel computations. The mean pressure of suction and exhaust is only about 1 per cent. of the mean pressure of the positive work in modern large engines with mechanically operated valves of large area, and therefore this negative work has practically no effect on the turning moment; it has less effect upon the coefficient of fluctuation than has the frictional resistance of the reciprocating parts, of whose magnitude and distribution over the four strokes of the cycle nothing is known. Sufficient accuracy is attained by considering only the negative work of the compression stroke and the positive work of the combustion and expansion stroke, neglecting the suction and exhaust strokes.

The following **method of determining the necessary flywheel weight**, devised by Güldner, gives results more quickly than the graphical method and is of sufficient accuracy.

Let M = necessary flywheel weight for a single-cylinder single-acting engine, lb.
i.h.p. = maximum indicated horse power.
p_{mc} = mean indicated pressure of the compression stroke, lb. per sq. in.
p_m = mean effective pressure of the cycle, lb. per sq. in.
k = coefficient of fluctuation.
V = velocity of the center of gravity of the rim cross-section, ft. per sec.
R_w = $\frac{1}{2}D_w$ = radius of the equivalent wheel = distance from center of shaft to center of gravity of rim cross-section, ft.

Then

$$M = \frac{2{,}125{,}000 \times \text{i.h.p.} \times [0.75 + (p_{mc}/p_m)]}{kV^2N} = \frac{77.5 \times 10^7 \times \text{i.h.p.} \times [0.75 + (p_{mc}/p_m)]}{kD_w^2N^3}$$

About one-tenth of the total weight of M is usually assigned to the arms of the wheel, so that only $0.9M$ goes into the rim. This is in error in gas-engine practice, however, since the arms are usually designed much heavier than in steam-engine practice; the added weight in the arms, however, improves the regulation. In the above equation it should be noted that the weight varies inversely as the cube of the speed of rotation. Therefore, the weight of the flywheel may be cut down or the regulation be improved materially by a slight increase in the speed of rotation. The value of the ratio (p_{mc}/p_m) does not depend upon the differences of construction of the various machines as much as it does upon the heating value of the fuel employed and the quality of the mixture. The following results have been obtained experimentally by Güldner:

Illuminating gas.. p_{mc}/p_m = 0.25 to 0.35	Gasoline......... p_{mc}/p_m = 0.10 to 0.2[illegible]
Producer gas..... p_{mc}/p_m = 0.35 to 0.45	Alcohol.......... p_{mc}/p_m = 0.25 to 0.32
Kerosene......... p_{mc}/p_m = 0.30 to 0.40	Diesel oil engine... p_{mc}/p_m = 0.48 to 0.52

For a single cylinder, single-acting four-cycle engine to give a regulation of $k = 1/80$, having a ratio $p_{mc}/p_m = 0.35$, a rim speed V of 100 ft. per sec. and $N = 200$ r.p.m., a flywheel weight of 128.5 lb. per i.h.p. (including the weight of the arms) is required. (For different values of p_{mc}/p_m, and V the required weight can be found by proportion.) Taking the above weight as unity, the relative flywheel weights, under the same conditions, for various types of engines and cylinder combinations, are given in Tables 21 and 22.

Table 21. Comparison of Horizontal Engines Operating on Lean Gases

(Relative flywheel weight obtained from turning moment diagram, derived from actual indicator cards—Güldner)

	Number of cylinders	Cylinder and crank arrangement	Angle between the cranks, deg.	4-cycle engines			2-cycle engines		
				Crank travel between explosions, deg.	Relative flywheel weight for		Crank travel between explosions, deg.	Relative flywheel weight for	
					Equal d, l, & N	Equal i.h.p. max.		Equal d, l, & N	Equal i.h.p. max.

Accessories

Lubrication. The hourly bearing oil circulation should be about 0.05 gal. per b.h.p. to give satisfactory lubrication. The amount of oil actually used up and not recoverable will vary between 0.00035 and 0.00075 gal. per b.h.p. per hour with well-designed lubricating systems; in a poorly designed system it will reach as high as 0.001 gal. The consumption of cylinder oil, none of which can be recovered, varies between 0.00024 and 0.00042 gal. per b.h.p. per hour, depending upon the care and attention of the operators.

Cooling System. While some small automobile engines are air-cooled, most engines are water-jacketed. About one-third of the heat supplied per b.h.p-hr. is lost to the jacket water, and consequently the cooling water must carry off about 4,500 B.t.u. per b.h.p-hr. With a temperature range of 90 deg. fahr. (from 60 to 150 deg.) this gives a jacket-water consumption of 50 lb. (6.0 gal.) per b.h.p. per hour. In large engines the heat given to the jackets will be much less than this, but the jacket water cannot be heated above about 120 deg. to give reliable operation when the hydrogen content of the gas is high, as there may be danger of heating the engine to the point where preignitions are liable to occur. In such a case, the amount of cooling water required may reach 9 gal. per b.h.p. per hour. In designing the cooling system a maximum figure of 10 gal. per b.h.p. per hour should be taken, as the initial temperature may be above 60 deg. fahr. The cooling system for small engines consists of but one inlet pipe and one discharge pipe into and out of each cylinder jacket; the head jacket is in communication with the cylinder jacket, and the exhaust valve chamber a part of the cylinder casting and hence

Table 22. Comparison of Vertical Four-cycle Engines Operating on Various Fuels

	No. of cylinders	Crank angles, deg.	Crank travel between explosions, deg.	Relative flywheel weights					
				Explosion engines operating on lean gas (producer, blast-furnace gas, etc.)		Explosion engines operating on rich gas (illuminating, coke-oven gas, gasoline, etc.)		Constant-pressure oil engines	
				Equal d, l, and N	Equal i.h.p. max.	Equal d, l, and N	Equal i.h.p. max.	Equal d, l, and N	Equal i.h.p. max.
I	1		720	1.0	1.0	1.0	1.0	1.0	1.0
II	2		360	0.86	0.43	0.85	0.425	0.89	0.445

IV	3		240	0.72	0.24	0.65	0.22	0.75	0.25
V	4		180	0.304	0.076	0.265	0.066	0.25	0.06

cooled by the cylinder jacket. Large horizontal engines have separate inlet and discharge pipes for the jackets of important parts, cylinder, cylinder head, pistons, exhaust valves and separate valve chambers. It is undesirable to lead the cold jacket water into parts most exposed to the heat of the explosions (cylinder and piston jackets), and consequently it is well to divide the inlet jacket water between the exhaust valves, exhaust valve chambers and cylinder heads and to send the discharge from each exhaust-valve chamber to the corresponding end of the cylinder jacket. It is often the practice to run the discharge from both the exhaust-valve chamber and exhaust valve (a parallel arrangement) through the cylinder jacket, but this is objectionable because the flow through the exhaust valve may be stopped and not be observed. It is better to run the discharge from the valve jacket directly into the drain pipe through a visible discharge. The usual method of connecting the moving exhaust valve with the stationary supply and drain pipes, is by means of a rubber hose.

In a tandem double-acting engine the discharges from the cylinder heads of one cylinder are usually run through the jacket of the other piston—thus equalising the final temperatures of the two discharges (a parallel-series arrangement)—and are discharged into the common drain through a visible discharge. The water is generally led into and out of the piston by means of swing joints. A telescopic water connection does not give as good results. The discharge from the piston jacket may be through an open pipe which travels with the cross head and leads down through a slot into the base of the frame or tail guide.

To keep the piston jackets of large engines filled, the cooling water must be under a pressure of from 60 to 80 lb. per sq. in. For the other jackets 10 to 15 lb. per sq. in. is sufficient, and therefore two cooling systems at the different pressures may be used or the water may be throttled down at the entrance to the other jackets. Valves on the discharge sides of the jackets should not be used, since by so doing the jacket is put under pressure, and will be more apt to leak. There is one exception to this statement, namely, in the case of the piston jackets. Even with the high pressure of the jacket water there will be a water hammer in the piston jackets unless the area of the discharge is restricted to about 21 per cent. of the area of the inlet opening. The average percentage distribution of the water to the various jackets is approximately as follows: 60 to the cylinder jacket and 40 to the cylinder-head jacket with uncooled piston; 50 to the cylinder jacket, 25 to the cylinder-head jacket, and 25 to the piston and piston rod with water-cooled piston.

The **size of piping** required **for** the **inlet to the jacket** may be determined from the formula d_i (in.) $= \sqrt{0.023 \times \text{b.h.p.}_n \times X/\text{No. of cylinder ends}}$; and the size of the discharge pipe from $d_d = 1.25\ d_i$ to $1.75 d_i$, depending on the length and drop, where X is the percentage of the total jacket water used in the jacket under consideration. This is based on the assumption of 10 gal. per b.h.p. per hour and an allowable velocity in the pipe of 3 ft. per sec.

Air and Gas Suction Pipe. The **mean air velocity** V is taken as 3600 ft. per min. for lines up to 35 ft. long, but should not be greater than 1800 ft. per min. for long lines. The free **cross-section of** the **air suction pipe** may be taken approximately as ⅓ of the effective area of the piston. For abnormally long lines, the diameter should be computed by means of the general formulæ on p. 357, taking into account the pipe friction, pressure drop, etc.

The same velocities may be allowed for gas as for air. For lines of considerable length the pressure drop may be taken at from 0.07 in.–0.12 in. of water for every 100 ft. of pipe. Close figuring on the **size of gas pipe** for industrial gas installations is undesirable, because of the reduction of the normal cross-section of the pipe by tar and dust deposits. In some cases of multi-cylinder engines where the gas for each cylinder is led off from the gas main opposite each cylinder, and where the pipe is not enlarged, there may be robbing of the charge of some cylinders by the others, due to the momentum of the gas column. If a storage chamber of large diameter is formed in the main opposite the engine, the difficulty is overcome. The same troubles may occur in plants where two or more engines are fed from the same gas line, the engine farthest from the source of gas supply refusing to carry as much load as the engine nearest the supply, and both engines backfiring heavily. The same cure must be applied. Formerly gas-engine plants were equipped with holders or pressure regulators, in which case this trouble did not arise. Most of the recent producer-gas power plants have been built without holders or pressure regulators—depending upon a regulating valve at the fan or exhauster to maintain the pressure. This is apt to cause the troubles stated above. The gas line should be free from traps and as free as possible from changes in direction of flow, and should be pitched slightly (¼ in. to the foot) from both ends toward a low point in the center, where a sealed drain should be located. All water seals in the gas line should be as cool as possible, to prevent the gas from picking up moisture.

The **cross-sectional area of the exhaust pipe** from the engine to the muffler should be made from 1.1 to 1.3 times the area of the free cross-section of the exhaust valve, depending upon the length of the connection and the changes in direction of flow. In a multi-cylinder engine the exhaust pipe should be firmly anchored at the center of the engine, so that the bending moment on the connections to the exhaust valves, due to the expansion, may be equalized between the connections and reduced to a minimum. Careful provision must be made for the expansion of the line, especially in the connection to the muffler—if one is used—and therefore the line must be supported by expansion hangers. A drain should be located in the lowest point of the line.

Exhaust **mufflers**, to be efficient as sound deadeners, must have a volume of from fifteen to twenty times the total piston displacement per stroke. Generally the volume is made only from 6 to 8 times the piston displacement. Better muffling and cheaper construction are obtained by connecting two or three small mufflers in series. The use of any device to increase gradually the volume or to change gradually the direction of flow by baffles, etc., permits of a smaller volume in the muffler, but increases the back pressure in the engines. The discharge opening from the muffler should have the same cross-sectional area as the exhaust pipe. When a perforated plate or its equivalent (for instance a grating covered with a bed of cobblestones) is used between the inlet and outlet of the muffler, the free area through such plate or equivalent should be from 5 to 6 times the cross-sectional area of the exhaust pipe. For large engines cast-iron or sheet-steel mufflers are not satisfactory because of the size, radiation of heat and corrosion, and **concrete muffle pits** are more generally used. The following proportions on engines up to 300 b.h.p. give good results: The volume of the pit should be 20 times the total piston displacement per stroke, with a horizontal cross-sectional area of 20 times the area of cross-section of the exhaust pipe. The pit should be divided into three equal horizontal layers by iron gratings and the space between these gratings filled with cobblestones or rubble—care being taken to see that the free area through the grating is at least 5 or 6 times the cross-sectional area of the exhaust pipe. The exhaust pipe is led into and across the bottom division of the pit, with the end flange extending just through the further wall. The end of this pipe should be covered with an explosion door, the best and safest form of which is a wooden cover about ¼-in. thick, scarfed across to a depth of half the thickness, and held in place by only two bolts placed at the ends of the scarf mark. The length of pipe between the pit walls should be drilled full of small holes, whose combined area should equal from 5 to 6 times the area of the pipe. The top of the pit should be covered with a removable iron cover, and from the top a cast-iron pipe of the same diameter as the exhaust pipe should rise high enough to carry off the products of combustion. The pit must be provided with an automatic drain.

The **recoverable waste heat contained in the jacket water and** the **exhaust gases** (amounting to about two-thirds of the total heat consumption) in the case of large installations is approximately distributed as follows:

	Large gas engines	Constant-pressure oil engines
Hourly heat consumption, B.t.u. per h.p.	11,100 to 9,150	7,950 to 7,350
Hourly heat wasted, B.t.u. per h.p.	7,150 to 5,950	4,550 to 4,000
Distribution of the waste heat:		
Hourly heat in jacket water, B.t.u. per h.p.	2,800 to 2,650	2,000 to 1,800
Hourly heat in exhaust gases, B.t.u. per h.p.	4,350 to 3,300	2,550 to 2,200

Where there is need for warm water of from 100 to 120 deg. fahr. the jacket water can be used directly; the utilisation of the heat of the exhaust is much more difficult, however, because of the high temperature existing, the great velocity of flow, the small heat content, and the reluctance with which the exhaust gas parts with its heat (according to Kutzbach about 200 times worse than is the case with steam).

The exhaust gases themselves are not adapted to the development of power; therefore their heat must be absorbed, as close to the engine as possible, by the hot jacket water. In this transfer much of the heat is lost; in large gas engines about 2000 B.t.u., and in Diesel engines about 1400 B.t.u. per h.p-hour of the engine rating is recovered. The back pressure resulting from the use of an exhaust heater may be serious. A crude-oil engine with an exhaust heater shows a back pressure of 2.55 to 2.85 lb. per sq. in. without apparent harmful effect on the action of the engine. A gas engine will give trouble at a much lower back pressure. Cast iron is the best material for the heater, since it is capable of withstanding the action of heat and acids, but wrought iron is also sometimes used. The area of the heating surface varies between 1.05 and 2.15 sq. ft. per h.p., and the heat transfer is about 1100 B.t.u. per sq. ft. According to Cochand and Hottinger, the heat transfer coefficient k, referred to a 1-deg. fahr. temperature difference, for favorable circumstances (high exhaust temperature, clean heating surface, etc.) ranges from 2.5 to 1.2 B.t.u. per sq. ft. per hour. Ordinarily the exhaust-gas temperature at entrance to the heater is 575 to 750 deg. fahr., though with heavily loaded engines or delayed combustion it is much higher, and therefore the heat return is increased.

The following test results of a 1350-h.p. Cockerill blast-furnace gas engine show what is obtainable in the **generation of high-pressure steam by the use of the waste heat from large gas engines:**

Load during test, b.h.p.	1,290.0
Hourly heat consumption, per h.p., B.t.u.	10,080.0
Thermal brake efficiency, per cent	29.0
Water evaporated in the exhaust heater, lb. per hr.	2,405.0
Pressure of the steam generated, lb. per sq. in.	101.7
Percentage of waste heat utilised	30.0

If the steam generated were used in a turbine requiring 14 lb. per h.p-hour., 172 h.p. or 13.3 per cent. of the gas-engine power would be obtained from the waste heat.

RECENT DEVELOPMENTS IN GAS POWER

Precompression of the Mixture. A recent method of operating large four-cycle gas engines consists in scavenging and forcing in the fresh mixture under a pressure somewhat higher than atmospheric. This is accomplished by the use of turbo-blowers compressing to a few inches of mercury above atmospheric pressure. The exhaust heat of the engines can be utilized to generate steam in waste-heat boilers for driving the turbo-blowers. In one plant in Germany to which this method has been applied, an overload of 35 per cent. is obtained without raising the maximum pressure, and the thermal efficiency and the mechanical efficiency are both increased. In another plant two tandem engines of 1360 kw. normal rating (at 65 lb. m.e.p.) carried loads of 1800 to 2000 kw., corresponding to an average increase in capacity of approximately 40 per cent. H. J. Freyn states that in a blast-furnace-gas plant a mean effective pressure of from 70 to 71 lb. per sq. in. was obtained before the adoption of the new method of operation; with a precompression of 3 lb. per sq. in., mean effective pressures of from 90 to 100 lb. per sq. in. were obtained without raising the maximum pressure. At the present state of development it is not known how the life of the cylinders will be affected by the increased average cylinder temperature.

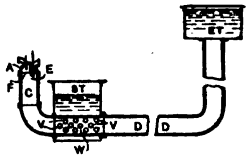

FIG. 7.—Humphrey Gas Pump.

The Humphrey Gas Pump. (Abstract of paper read by H. A. Humphrey, M. I. C. E., before the Manchester Association of Engineers, Nov. 13, 1910.) All types of the Humphrey pump, with the exception of the two-cycle, are fitted with a simple interlocking gear arranged between the inlet and exhaust valves so that when either one closes it locks itself closed and releases the other one. In the **simple type** of pump, referring to Fig. 7, water has to be raised from a suction tank *ST* to an elevated tank *ET*, and the cycle of operations is as follows:

1. All valves are closed when an explosion of the compressed charge occurs, driving water out of the combustion chamber *C* and setting the whole water column in motion. The expanding gases do work on the water column, and, when expansion reaches atmospheric pressure, the column is moving with considerable velocity and cannot be suddenly arrested, and therefore a vacuum is established in the combustion chamber, opening the exhaust valves *E* and water-suction valves *V*. The water sucked in follows the moving column toward the elevated tank, and also rises in the combustion chamber.
2. When the kinetic energy of the column has expended itself by forcing water into the elevated tank, the column comes to rest and starts back toward the pump, gaining velocity until the water reaches the level of the exhaust valve, which it shuts by impact. The exhaust valve projects into the combustion chamber far enough to form the clearance volume desired. The energy of the moving column is expended in compressing the products of combustion remaining in the cushion space *F*.
3. The column is brought to rest by this cushion and a second outward movement of the column results. When the water reaches the level of the exhaust valve, the pressure in the chamber is again atmospheric, and further movement of the column opens the spring-loaded inlet valve *A* and draws in a fresh combustible charge. If there were no friction the water would fall to the same level as that before the last upward movement, but in the actual machine the volume of charge drawn in is slightly less than this movement would represent.
4. The column of water again returns, actuated by the head in the elevated tank, and compresses the charge, which is then ignited and starts a fresh cycle.

In this simple form the degree of compression of the charge depends on the height to which the water is raised and exceeds the static equivalent of the head, due to the kinetic energy of the moving water column. The amount of cushion pressure is also governed by the same considerations, except that in this case the initial volume of the residual gases is the clearance volume, and the cushion pressure rises rapidly as the discharge head increases. At the maximum lift of 40 ft.—the limit of the simple pump—the cushion pressure may exceed the explosion pressure when using producer gas, or may approximately equal the explosion pressure when using illuminating gas or gasoline.

As an example of the pressures obtaining in a pump of this type, the following values—taken from a 45-water-h.p. four-stroke pump, delivering 306 gal. per working stroke against a head of 39.4 ft. and working on illuminating gas—are given: Compression pressure at ignition, 56.5 lb. per sq. in.; explosion pressure, 163 lb. per sq. in.; water suction at start, 2 to 3 ft. of water, decreasing to atmospheric pressure; cushion pressure, 185 lb. per sq. in.; vacuum at start of suction of fresh charge, 4 lb. per sq. in., decreasing to atmospheric pressure.

The action of the pump is not altered if, instead of delivering into an elevated tank, it discharges into an air dome, or into an open-top standpipe—both devices serving to make the flow from the outlet pipe continuous. The reciprocating column of water is analogous to the pendulum of a clock, the length of the column governing the period of the swing. If other things are equal and the column is of uniform cross-section, the period is almost proportional to the square root of the length. The four unequal strokes which result from the free oscillations of the water column give a cycle which is superior to the Otto cycle.

The following table compares the assumed practical efficiencies (0.71 of air standard card) of the Humphrey pump cycle with that for the Otto cycle for various compressions, taking the specific heats as constant:

Compression pressure, lb. per sq. in. gage......	0	20	40	60	80	100	120
Thermal efficiency of pump cycle, per cent....	16.2	26.5	31.5	34.6	37.0	39.0	40.5
Thermal efficiency of Otto cycle, per cent.....	0.0	15.5	22.2	26.5	29.4	31.6	33.4

With a compression of 150 lb. per sq. in. gage, the theoretical thermal efficiency of the Humphrey cycle is 52.5 per cent., and that of the Otto cycle 40 per cent. when all corrections for varying specific heats are taken into account. Using compression pressures under 50 lb. per sq. in., an actual thermal efficiency of over 23 per cent. was obtained on a four-cycle pump working against a head of 35 ft.

Certain **modifications of the simple type** consist in (*a*) the addition of a scavenging valve so that the residual gases are diluted with air; (*b*) the addition of an internal bell in which the cushioning on the residual gases takes place, so that the exhaust gases outside of the bell are all driven out of the combustion chamber and thus the incoming charge is not diluted with the exhaust gases; (*c*) the addition of a second combustion chamber so that the explosions occur alternately in the two chambers and require only two strokes of the main water column to complete a cycle (the other two strokes occurring between the chambers). A two-cycle pump without valve locking gear has also been built.

GAS PRODUCERS

(For general **theory**, see p. 370.)

General Features and Types

The general arrangement of the parts of a gas-producer installation and the type and design of producer depend mainly upon the properties of the fuel to be gasified. The main factors are the moisture content, the quantity and properties of the ash, the proportion of tar-forming constituents, tendency to coke and clinker, and size and heat value of the fuel. A high moisture content reduces the temperature of the producer seriously and causes a lack of uniformity of quality of the gas generated, so that immediately after charging the gas quality falls off rapidly to a minimum and then increases slowly until the next charging period. A large percentage of **ash** quickly clogs up both the fuel and grate, necessitating frequent poking and cleaning. If, with a high ash content, the fuel bed is not frequently cleaned, holes will form in the fire, allowing free passage of air through the fuel bed and resulting in the more-or-less complete combustion of the gas above the bed. An ash which clinkers badly, so that it forms a barrier across the fuel bed, increases the resistance to the air blast, while if it clinkers only partially across the bed, it tends to burn a hole through the area not so covered, by increasing the volume of air and consequently the rate of combustion through that area. In any case, a **clinkering** ash adds greatly to the difficulties of cleaning the fire. Tar-forming coals cause serious trouble because of the extra gas cleaning necessary, and because the **tar** which is not cleaned out of the gas condenses in the pipe lines and valves, soots up the cylinder during combustion, and sticks to the piston-rod packing, necessitating frequent cleaning. Fuels that show a strong tendency to coke interfere with the operation of the producer in much the same way as an excessive ash content.

Small-sized **fuels** have a tendency to pack and thus increase resistance to the air blast, and when the blast pressure is increased to meet this difficulty, the whole fuel bed will lift and dance because of the lightness of the particles. Large-sized or coarse fuel does not burn uniformly, offers too little surface for gasification, and allows steam and carbon dioxide to reach the upper part of the producer without being decomposed. Those fuels which are most free from the above disadvantages, and especially those low in tar-forming constituents, are most commonly used in producer gas plants. The fuels that come nearest to falling within these limitations are anthracite and coke with low ash content and a high fusing point. The sizes of **anthracite** most commonly used are No. 1 pea or No. 1 buckwheat.

The use of **bituminous coal**, lignite and peat has until recently been attended with many difficulties. In the early stages of development the same type of producer was used for the tar-forming coals as for anthracite, but without success, because of the difficulty in cleaning the gas. The next step was so to conduct the gasification process that the tar vapor distilled from the freshly charged fuel should be led through the incandescent zone of the fuel bed, broken up, and fixed as a gas, or partly burnt. With these coals the temperature of the incandescent zone necessary to fix the tar is so great that there is serious clinkering. Part of the tar vapor is also burnt to lampblack, so that the gas washing must be as thorough for clean gas as if the tar were not fixed; the only difference being that the lampblack deposits are not as serious a detriment to operation as is tar. The most recent development is a reversion to the standard type of anthracite producer with its attendant formation of tar, made possible by the invention of a simple process of tar extraction (see p. 1063).

Producer **types** are usually classified by the manner in which the air or air-steam mixture is caused to travel through the producer and washer.

In **suction producers** the air or air-steam mixture is drawn through the fuel bed either by the suction of the engine or by an exhauster, in which latter case the gas is delivered to the engine under pressure. The former type is used only for small installations where the disadvantage of the increased suction resistance and diminished capacity of the engine is offset by the simplicity of the installation. The latter type is employed for large installations. Suction producers are rapidly displacing other types because any accidental leaks are inward and the producer can be cleaned in operation without the loss of gas through the cleaning openings. This type is consequently well adapted to continuous operation.

In **pressure producers** the air or air-steam mixture is forced through the fuel bed by means of blowers. In this type poking of the fuel bed in order to fill up holes that have burned through the fire, to push down clinker, etc., is possible, but it results in a great deal of discomfort to the operator because of the escaping gas. A thorough cleaning of the fuel bed can be accomplished only when the producer is out of operation.

In balanced-draft or combination producers the air or air-steam mixture is supplied underneath the fuel bed under pressure and the gas is drawn off from the top of the fuel bed and forced over to the engine under such a suction that the pressure on top of the fire is exactly atmospheric. In a properly designed system of this sort, cleaning can be accomplished during operation, and there will be no leakage at the poke holes, either of gas into the producer room or of air into the top of the producer.

A further classification is made according to the direction of flow of the air-steam mixture, into (1) **up-draft,** (2) **down-draft** and (3) **double-zone producers.** In the last type the gas is taken off at the mid-height of the producer, the blast is introduced at the bottom, and the fresh coal is fired at the top, where the hydrocarbons are distilled off and partly burned in the presence of a little air admitted at the top—the products of this distillation being drawn down through an incandescent fuel bed and drawn off with the rest of the gas at the gas outlet.

Prevention of Clinkering. The use of steam in the blast is necessary with most coals to prevent clinkering. In some producers the steam is blown in intermittently; clinker is allowed to form during the period in which the bed is not steamed, and then the bed is thoroughly steamed, its temperature rapidly reduced, and the clinker broken into small pieces. During this period water gas is formed, which must be thoroughly mixed with a large volume of producer gas, otherwise preignition troubles will result in the engine. The hydrogen from constant steaming can be kept within allowable limits and improves the quality of the gas. Another method of reducing the fuel-bed temperature below the clinkering point, is to use the exhaust gases from the engine instead of steam—the heat absorbed by the reduction of the carbon dioxide in the exhaust to carbon monoxide being assumed to be sufficient to keep the temperature of the fuel bed below the clinkering point. In practice, except with a few coals low in ash, this method has not proved as successful as the use of steam, there being a great tendency to clinker and a wide variation in the quality of the gas. The gas generated by this method will stand a high compression, since it consists principally of carbon monoxide and nitrogen, but requires larger cylinder capacity than ordinary producer gas on account of its low heat value.

Control. The proportion of air and steam in the blast must remain constant for all loads to produce a gas uniform in quality. To obtain this uniformity some form of automatic control must be used. Up to within a few years it has been attempted to obtain this control by hand regulation, but, while the average quality of the gas could be controlled as desired, there were fluctuations amounting to as much as 40 per cent. in the heat value of the gas corresponding to sudden changes in load, charging, or cleaning the fire. With automatic regulation, charging and cleaning the fire may produce a variation of 5 per cent. as a maximum, and a sudden change of load may cause a variation of 20 per cent. as a maximum. In a plant that is properly designed and operated, these variations will not be over 1 per cent. and 5 per cent., respectively.

Gas from By-product Plants. In England and on the Continent, by-product recovery plants (generally according to the Mond process) are successfully operated. In this process a very deep fuel bed, run at a low temperature (in order not to break up the ammonia), is maintained; the gas generated is consequently of a very uniform quality (about 150 B.t.u.) and because of the by-product recovery is very clean and is therefore well adapted for use in gas engines. Low-grade coals—peat, lignite and brown coal— as well as the ordinary coals, can be successfully gasified. In some plants the sulphate of ammonia recovered is worth $2 per ton of coal fired, which in many cases is as much or more than the cost of the coal. This process has not yet been successfully applied in this country.

A. H. Lymn (*A. S. M. E.*, Dec, 1915) reports the following results from a by-product plant. Coal consumption per day, 64.6 tons; per kw-hr., 1.58 lb.; yield of ammonium sulphate, 60 lb. per ton; of tar, 230 lb. per ton; avg. heating value of gases, 155 B.t.u. per cu. ft.; nitrogen efficiency, 70 per cent. American coals average 1.32 per cent. of nitrogen on dry coal.

Design

Rating. It is customary to rate the capacity of producers in horse power producible in the engine. To do this a definite weight of fuel must be gasified per sq. ft. of grate area per hour. This weight and the quality of gas generated vary with the kind of fuel used.

The following **rates of fuel consumption** are allowable for the various American fuels as fired per sq. ft. of grate surface per hour: Anthracite, 8 to 10 lb.; bituminous, 5 to 11 lb.; sub-bituminous, 7½ to 12 lb.; lignite, 7 to 10 lb.; peat, 12 lb. Consumptions of lignite of more than 40 lb. per sq. ft. have been reported, but it is unwise to choose so high a figure as this unless the characteristics and actions of the particular lignite to be used are very well known. A **moderate rate of driving** for all fuels is absolutely **essential for continuous operation,** since thereby clinkering is reduced to a minimum, and consequently the producer can be easily cleaned in operation.

Dimensions. Producer **shells** are generally built of ¼-in. to ⅜-in. steel boiler plate, the joints being calked gas-tight as carefully as in boiler construction. The **height of the ash pit** from the bottom (which is usually in the form of a truncated cone formed by plates riveted to the shell, or formed in the foundation for the shell) to the top of the grates is generally from 2½ to 5 ft., the distance from the bottom of the shell to the top of the grate varying between 2 and 3 ft. The grate, or the blast hood, if this is used, must be protected from the hot coal by an ash bed from 6 to 12 in. thick. The **depth** of the **fuel bed** varies with the character of the fuel, but will in general be from 2 to 5 ft. The distance from the top of the fuel bed to the bottom of the gas outlet pipe should not be less than 3 ft., otherwise the draft will be pulled toward this opening and the fuel bed will not burn uniformly. The diameter of this outlet pipe should give a gas velocity not to exceed 30 ft. per sec. The **top of the shell must be cooled.** This is generally done by water-cooling, either by having a flanged steel plate riveted to the shell with the flange upward to form an open water basin, which serves as a seal for the cleaning holes as well as cooling the top, or by using for the top a water-jacketed iron casting, the jacket serving either as a vaporizer or a heater for the vaporizer water. Another method of keeping the top cool is to have the part of the producer above the height necessary for the fuel bed serve as a fuel magazine, *i.e.*, fill the producer to the top. This method has the advantage that much of the sensible heat of the outgoing gases is withdrawn and returned to the fuel in the magazine, thus rendering it immediately ready to enter into combustion as soon as the demand is made by a sudden increase in load. The bottom of the shell, except for the blast opening, must be sealed either by means of a **water seal,** the top of which must be high enough above the bottom of the shell to prevent ordinary operating pressures from blowing gas out into the room, or by tightly closing the bottom of the shell by means of a riveted plate, or by grouting it tightly to the foundation. If a water seal is not used, cleaning doors must be provided for the removal of ash. If a water seal is used, the smallest distance between the seal basin and the bottom of the shell must be large enough to enable the removal of the largest clinker that is likely to be formed (at least 5 in.). At the level of the grate, **cleaning doors** of the same size as those in the ash pit must be provided. The top of the producer must be provided with small cleaning holes so located that all parts of the fuel bed can be reached for cleaning.

Distribution of the blast over the whole area of the fuel bed is of the greatest importance in producer design. There is always a tendency for the blast to be strongest next to the lining. This tendency can be minimised only by proper design of grate and by locating the gas outlet at the center of the cross-section of the producer. The grate should be designed to give as nearly uniform a blast distribution as possible, and to permit of easy cleaning and removal of ash. Above the grate, inclined **bosh plates,** projecting inward from the shell, are generally used to prevent the fuel bed from running out over the edges of the grate. The space between the top of the grate and the bottom of the bosh should be between 5 and 6 in.

The **producer lining** should be of a good quality of fire brick set in fire clay. The bricks should be so molded as to give a smooth interior and require a minimum amount of fire-clay binder between the bricks. A space of from ½ in. to 1 in. should be left between the back of the bricks and the shell and filled with a pliable refractory material (such as dry fire clay, or a mixture of fire clay and asbestos fiber) to reduce the radiation of heat, permit of the expansion and contraction of the lining independent of the shell, and prevent the leakage of air between the shell and lining.

Test Results

(For methods of conducting and reporting tests of gas producers, see p. (1767.)

Tables 23–27 summarise results obtained in government tests made at St. Louis, Norfolk, and Pittsburgh, as averaged and reported by R. H. Fernald. In Table 23 all results affected by the load factor are given for loads ranging only from 90 to 100 per cent. of full load, and no test of less than 30 hr. is included in the average. All coal results are referred to weight of coal as fired. All heat values are higher values.

Table 23. Results of Tests of Gas-producer Fuels

Item	Bituminous coal	Sub-bituminous coal	Lignite	Peat
Number of tests averaged	112	7	7	1
B.t.u. per lb	12,370	9,910	7,110	8,130
Yield, cu. ft. of gas per lb	61.1	39.3	27.7	30.3
Rate of gasification, lb. per sq. ft. of grate surface per hr.	7.64	11.02	13.28	16.2

Table 24 gives data on 103 coals, classified into 10 groups according to calorific value, each group embracing a range of 500 B.t.u., the mean figure of which is assigned as the approximate calorific value (on a dry-coal basis) of the group. The duration of the tests from which the results were obtained ranged from 29 to 74½ hr., with an average of 48 hr.

Table 24. Gas Yield of Coals of Different Calorific Values

Approximate calorific value, B.t.u. per lb. of dry coal	Coal per sq. ft. of grate surface per hour, lb.		Gas under standard conditions (62 deg. fahr. and 14.7 lb.)			Producer efficiency, per cent.
			Per lb. of dry fuel		B.t.u. per cu. ft., high value	
	As fired	Dry	Calorific value, B.t.u.	Yield, cu. ft.		
15,000	5.64	5.50	13,350	91.1	153	74.7
14,500	6.10	5.92	12,460	80.5	160	74.2
14,000	6.45	6.22	10,890	72.1	152	71.9
13,500	6.97	6.54	10,070	67.8	150	69.3
13,000	7.88	7.30	9,360	61.8	152	67.5

10,500	13.26	11.53	5,790	40.9	135	50.5

Table 25. Typical Analyses of Producer Gases from Various Fuels
(Values in percentage by volume)

Constituents	Up-draft pressure-producer gas				Down-draft producer gas		
	Anthracite	Bituminous coal	Lignite	Peat	Bituminous coal	Lignite	Peat
Carbon dioxide..... CO_2	5.2	9.84	10.55	12.40	6.22	11.87	10.94
Oxygen............ O_2	0.4	0.04	0.16	0.00	0.13	0.01	0.41
Ethylene........... C_2H_4	0.0	0.18	0.17	0.40	0.01	0.00	0.06
Carbon monoxide... CO	22.9	18.28	18.72	21.00	21.05	16.01	16.91
Hydrogen.......... H_2	15.3	12.90	13.74	18.50	12.01	14.76	10.19
Methane........... CH_4	1.0	3.12	3.44	2.20	0.49	0.98	0.66
Nitrogen........... N_2	55.2	55.64	53.22	45.50	60.09	56.37	60.83
	100.0	100.00	100.00	100.00	100.00	100.00	100.00

The quantity of gas obtained varies with the fuel used, the type of producer plant, and the method of operation. Table 26 gives the average yield per pound of fuel (in cu. ft. and B.t.u.) as obtained at the government testing plant at St. Louis (with the addition of values for coke or charcoal, and anthracite).

Table 26. Average Yield of Gas per Pound of Fuel

Character of fuel	Yield of gas, cu. ft. per lb. of fuel		Higher heat value of the gas B.t.u. per cu. ft.	Higher heat value of the gas, B.t.u. per lb. of fuel	
	As fired	Dry		As fired	Dry
Coke or charcoal.....	85	90	140	11,900	12,600
Anthracite coal......	70	75	135	9,450	10,100
Bituminous coal.....	60	65	152	9,120	9,880
Lignite..............	36	46	158	5,690	7,270
Peat................	30	38	175	5,250	6,650

The results obtained from some of the low-grade fuels are summarized in Table 27.

Table 27. Typical Analyses of Producer Gas from Low-grade Fuels
(From Bulletin No. 13, U. S. Bureau of Mines)

Fuel	H_2	CH_4	C_2H_4	N_2	CO	O_2	CO_2	B.t.u. per cu. ft. at 62 deg. fahr. and 14.7 lb. pressure
Coke	11.10	0.20	0.10	57.50	21.90	0.00	9.20	120.6
Coke breeze	12.81	0.37	0.00	54.80	23.28	0.00	8.74	136.9
Illinois bituminous coal	15.60	1.90	0.40	52.00	20.90	0.00	9.20	156.1
Pennsylvania bituminous coal	12.50	2.50	0.00	55.60	20.70	0.00	8.70	140.6
California lignite	12.67	4.16	0.00	57.82	13.19	0.25	11.91	126.7
Montana lignite	16.00	2.90	0.60	52.90	14.20	0.20	13.20	147.5
North Dakota lignite	14.33	4.85	0.00	51.00	20.90	0.23	8.69	188.5
Texas lignite	9.63	4.81	0.00	57.54	18.22	0.20	9.60	156.2
Florida peat	18.50	2.20	0.40	45.50	21.00	0.00	12.40	175.2
North Carolina peat	10.19	0.66	0.06	60.83	16.91	0.41	10.94	109.7

Producers Using Crude Oil have been developed to such an extent that fair results are obtainable. The heat value of the gas generated varies from 105 to 450 B.t.u. per cu. ft., depending upon the producer and method of operation. In these producers, the tar-forming constituents of the oil are cracked and fixed as gases and lampblack. The quantity of lampblack exceeds that made in down-draft producers fired with bituminous coal so that gas cleaning in an oil-producer installation is a serious problem. Owing to the price of oil, the oil producer has only a limited application.

GAS CLEANING

(See "The Cleaning of Blast-furnace Gas," W. A. Forbes, *Bul. A. I. M. E.*, Oct., 1913)

Cleanliness Requirements. Most engine builders specify that the dust and other solid impurities contained in the gas shall not be in excess of 0.02 gr. per cu. ft. at 62 deg. fahr. and 30 in. of mercury, and that the moisture shall not be in excess of 10 gr. per cu. ft. The German standard is 0.009 gr. per cu. ft., which can easily be attained by the use of Theisen or similar washers. Such a cleanness, however, is out of proportion in a blast-furnace plant unless the air also is washed, as the air often contains much more dust than this. Most producer manufacturers guarantee their scrubber plants to clean the gas to a dust content not to exceed 0.01 gr. per cu. ft. at 62 deg. fahr. and 30 in. of mercury.

Determining the Dust or Tar Content of Gases. The simplest method consists in filling the vertical legs and bulbs of a so-called "**Peligot tube**" (a glass U-tube with an enlarged bulb in each vertical leg and in the bottom connection of the U) with clean, dry, absorbent cotton, weighing the tube and cotton, allowing a metered quantity of the gas to be tested to pass through, and weighing again. The increase in weight gives the weight of impurities removed from the gas by the cotton. This apparatus is accurate only within about 16 per cent., as in operation the cotton in the discharge leg becomes nearly as dirty as that in the inlet leg, showing that some of the impurities pass out with the gas. The **Leo Martius dust determinator** consists of two flanges, held together by wing screws, between which a piece of chemical filter paper is placed. The filter paper is sometimes backed on the discharge side by a perforated plate of thin sheet metal or a wire screen to prevent the paper breaking if there is much moisture in the gas. The filter paper is weighed before and after passing through it a metered quantity of gas, and from this the dust content per cu. ft. is determined. This method is very accurate. The apparatus as used generally consists of two determinators in parallel (so that alternate determinations can be carried on continuously) and a wet meter. The **Brady filter** consists of a brass cylinder, in which is supported the filter itself—an ordinary Soxhlet extraction shell. When the gas contains moisture the cylinder must be heated. This method has the advantage that the cylinder filter resists the gas pressure much better than the sheet of filter paper used in the other; the filter shell maintains a porous condition even though much fine dust has been deposited, owing to the formation of concentric layers of dust and their subsequent cracking by action of gravity and slight jarring, whereas in the filter-paper method the pores of the paper fill up, clog, and finally prevent the passage of gas, if the gas is very dirty. On account of maintaining a porous condition, gas samples of twice the size permissible in other instruments can be passed through this filter. As is the case in the other methods, the shell is weighed in an analytical balance before and after passing the metered gas sample through it.

With any of these methods, in case the gas contains moisture, the filter must be kept at a temperature a little above the boiling point. The moisture can be determined by passing the sample through a tube filled with a dehydrating agent, such as calcium chloride, and weighing the tube before and after. If the gas contains much heavy dust, a sample pipe bent in a 90-deg. curve with a radius of not less than 6 in. should be used. The end of this pipe should be reduced to a sharp edge and it should be inserted in the gas main, if possible, on a horizontal diameter at least 15 ft. away from any bend or obstruction, to a distance of one-quarter to one-third of the diameter of the main.

Gas Cleaning. The general methods for the removal of both moisture and solid impurities from gas are: (*a*) A reduction of temperature; (*b*) a sudden change of direction of flow; (*c*) a sudden reduction of velocity; (*d*) utilization of the weight of the impurities to effect separation by centrifugal force; (*e*) by increasing the weight of each particle by enveloping it in a particle of water. For use in gas engines the temperature of gas must be reduced to as low a point as is conveniently possible, to decrease the amount of saturation vapor and to increase the weight of gas per cu. ft. To wash gas in the most efficient manner the gas must be brought into intimate contact with the smallest particles of water possible. If the drops of water are as small or smaller than the size of the dust particle, the dust particle will penetrate the water film, be enveloped by the water particle, weighted down, and carried to the bottom of the washer by the increased density of the combined mass. Combined dust-and-water particles too small to have sufficient weight to resist the upward force of the gas current, tend to unite with similar particles, and soon become heavy enough to fall to the bottom of the washer.

Types of Gas-cleaning Apparatus. There are in general two types of apparatus for gas cleaning, static and mechanical. **Static cleaners** are either (1) **dry cleaners** which remove the impurities either by an abrupt change in the direction of flow, a sudden reduction of velocity of flow, giving the gas a whirling motion and thus utilizing centrifugal force, or a combination of some or all of these methods; (2) **filters** which are mechanically cleaned; or (3) **tower washers** of the hurdle, baffle, rain, or impinging type. **Mechanical washers** are those in which centrifugal force is used by giving the gas a whirling motion, and in which the water is broken up into a very fine mist by means of (1) **fans** or (2) **disintegrators.**

Dry Cleaning is used only in blast-furnace gas plants, as it is effective only in removing the heavier impurities. Blast-furnace gas in its raw state contains from 3 to 10 gr. per cu. ft., while at the time of slips of the charge in the furnaces or other sudden changes in furnace conditions, the dust content will be much more. The gas is usually conducted from the furnace to some form of dry-dust catcher through a self-cleaning zigzag flue.

The velocity in the catcher should be about 1.5 ft. per sec. An improved form has conical top and bottom and introduces the gas through a tangential, inclined inlet near the top of the shell and takes it off through a vertical riser projecting down through the center of the shell to a point near the bottom of the shell; the gas travels from the top to bottom in long spirals. Two of these catchers are usually used in series. This type of apparatus will clean the gas on an average to a fineness of 1.8 to 3 gr. A very recent dry-dust catcher is the Dyblie. Three of these catchers (which can be much smaller than the older type) are generally used in series and clean the gas to an average fineness of a little less than 0.5 gr. per cu. ft.

Some plants use a horizontal centrifugal separator after the dry-dust catchers, consisting of a helical gas passage with a dust trap at the bottom of each turn. Five or six turns of the helix are usually as many as can be effectively used. Efficiency, about 70 per cent. Mains or risers in the dry gas system must be either vertical or inclined so as to be self-cleaning. The mains and dust catchers are generally unlined so as to cool by radiation. The average radiation is about 1⅛ B.t.u. per sq. ft. of the radiating surface per deg. difference in temperature per hour. The average temperature of the raw gas as it leaves the furnace is 400 deg. fahr., but it may reach 700 or 800 deg.

In Germany, a **dry filtration process** (the Halberger-Beth), which takes the place of the primary and secondary wet cleaning plants, is coming into use. The gas is cooled by radiation to about the dew point (approximately 130 deg. fahr.), to condense as much vapor as possible, and then is superheated 20 or 30 deg. by the sensible heat of the raw gas, to avoid clogging the filter bags with moisture. The gas is then passed through a number of filter bags in parallel. Once every 4 min. each group of bags is shaken for a period of from 15 to 20 sec., and the gas current reversed through it long enough to remove the accumulated dust by causing a partial collapse of the filter bags, and deposit it in dust traps. With this apparatus the dust content is reduced below 0.0004 gr. per cu. ft.—which is 15 to 30 times the fineness obtained with Theisen washers. The power consumed is ⅗ to ⅓ of that used for hydraulic fans or Theisen washers and the water consumption is only ⅙ to ⅛.

Wet Cleaning is accomplished in **tower washers.** In these washers it is important to secure a uniform distribution of both gas and water over the cross-sectional area.

Hurdle scrubbers are towers filled with staggered rows of slats, set on edge, the alternate rows running at right angles so as to form a checkerwork. In blast-furnace plants, the slats are spaced 3 in. on centers, with about 2 ft. left between the hurdles to allow of cleaning and repairs without removing all the hurdles from each compartment. Hurdle scrubbers will deliver gas containing from 0.15 to 0.3 gr. per cu. ft.

At the South Chicago plant of the Illinois Steel Co., on the average the gas reaches the wet scrubbers containing 1.533 gr. of dust per cu. ft. and after passing through two of these towers in series contains 0.3183 gr. of dust and 6.62 gr. of moisture per cu. ft., or 2¼ times the moisture content of the atmosphere (efficiency, 79.3 per cent.). Most of the cooling is effected in the first tower as the gas is here brought to within 1½ deg. of the water temperature—with a water temperature rise of 20 deg. fahr. The water consumption varies between 103.2 and 68.6 gal., with an average of 82.8 gal. per 1000 cu. ft. of gas washed. The power consumption for pumps is about 0.33 per cent. of the total output of the engines. When the amount of gas cleaned was increased 25 per cent. the dust content delivered to wet scrubbers averaged 1.806 gr. per cu. ft., the wet scrubbers cleaned to an average fineness of 0.1488 (efficiency, 91.5 per cent.), the water consumption averaged 63.1 gal. per 1000 cu. ft. gas cleaned, and the moisture content 4.735 gr. per cu. ft. or 2.38 times the moisture content of the atmosphere.

In the **rain-type scrubber** the water is broken up and distributed by means of a revolving screen, or by spraying or atomizing. The water particles are a little finer than with splash plates, and there is a consequent increase in efficiency. The water consumption and power to drive the pumps is increased, since the water must be delivered to the spray heads at a considerable pressure in order to be atomized. **Baffle scrubbers,** in which the gas is caused to pass many times through sheets of water flowing from one baffle to the next, are very efficient but require a great deal of water. In the **impinging type of washer** the gas comes into the top of the washer, passes down through tubes, impinges upon a water surface, and then is taken off in a reverse direction. The efficiency of this type is very high but it does not cool the gas. All of these types of static wet scrubbers are applied to producer-gas plants with about the same efficiency and water consumption as with blast-furnace plants.

Mechanical Washers. The **Bian gas washer,** which is a primary washer, consists of a stationary horizontal steel cylinder with a slowly revolving shaft carrying a number of vertical disks of fine-meshed wire netting. The clearance between the edges of the disks and the inside of the cylinder is very small. The disks dip for nearly half their diameter in water at the bottom of the cylinder and are consequently kept covered with thin films of water, compelling thorough contact with the gas as it passes through the perforations.

It is necessary to use **tar extractors** in bituminous-coal producer plants, since static washers will not remove the tar. The most common type is the **fan washer.** The gas enters around the shaft on one side of the fan and is taken off on the other side. The water is injected at the top of the casing and the water and tar are drawn off at the bottom through a water-sealed tar leg. The fan is built with a central partition plate which causes the gas to pass through the water film which seals the edges and end of the fan. The impurities are separated by centrifugal force. Efficiency rarely exceeds 30 per cent. When the tar is sticky, the extractor may be shut down by it, necessitating boiling out the tar with steam or even removing the casing and scraping it off. The **inertia extractor** is another variation in which centrifugal force is utilized only in an incidental manner, the real cleaning effect being produced by an extremely rapid change in the direction and velocity of flow of the gas current. The gas is passed through alternate sets of steel blades revolving in opposite directions, and the particles of impurities are projected violently from the blades running rapidly in one direction against the next series running with equal speed in the opposite direction. The impurities are separated by inertia and are thrown out against the housing and washed away by the scrubber water. This type is much more efficient than the previous one, but still leaves much to be desired. In both types the speed of rotation is of vital importance; any deviation from the proper speed seriously affects the successful working, especially if the variation is a reduction. Both types require between 3 and 4 per cent. of the total output of the engines to drive them.

The **Theisen washer** is very efficient and requires relatively little power and water. The apparatus consists of a closed cylindrical drum fitted on its outer surface with longitudinal blades arranged in spirals, which decrease in depth from inlet to outlet, rotating at high speed in a stationary conical housing. The drum is equipped at the inlet end with suction vanes, while on the discharge end an exhaust fan is attached. The suction vanes draw the gas from the inlet pipe and deliver it to the longitudinal vanes, which have an inclination to the axis of the drum so as to oppose the flow of the gas through the washer. The discharge fan at the outlet end of the drum overcomes this tendency and discharges the gas under a positive pressure of 8 to 10 in. of water higher than the pressure or suction on the inlet side. The clearance between the outer edge of the blades and the inner surface of the housing is not more than 1 in., and the gas passing through this narrow space under high pressure imparts to the water introduced at several points into the casing a movement in long spirals in an opposite direction to its own travel—this flow of water, in the form of a film covering the inner surface of the housing, being assisted by the conical shape of the latter. The surface of contact between the gas and water is increased by wire netting closely fitting the inside of the housing. The dust particles weighted down by the water drops are thrown by centrifugal force into the rotating water film. The moisture in the gas leaving the washer is removed in a separator consisting of a removable box filled with iron shavings held in place by wire netting and located close to the discharge of the washer. This washer is self-cleaning except for a slight mud deposit at the inlet ends of the blades. The wire netting is entirely self-cleaning. The efficiency of the Theisen washer—taking gas from wet scrubbers—is from 80 to 85 per cent., the dust content in the discharge gas is about 0.005 gr. per cu. ft., the water consumption is 17 to 20 gal. per 1000 cu. ft. of gas, and the power consumption 3 per cent. of the total power of the engine.

The Theisen system of final wet cleaning is now being superseded by systems whose first cost and operating expense are less. Most of these systems can be used for primary cleaning as well as for final cleaning, by installing in two stages. The most important of the wet-cleaning systems which clean as efficiently with the consumption of less power and water than the Theisen and Schiele systems are the **disintegrator systems** of Theisen and of Schwarz-Bayer, the Fowler and Medley rotary washer, and the Feld rotary washer, while the Halberger-Beth dry cleaning system of filtration through canvas (see p. 1061) is remarkably efficient in cleaning and is cheap to operate. The **Feld washer** is built in seven sections; the upper four acting as cooling chambers and the lower three as cleaning chambers. Its action is based on the fact that fine powders will mix readily with hot water, Each section contains a series of perforated truncated cones, the lower ends of which dip into water contained in a tray provided with gas ports. By revolving these cones (with a peripheral speed of 1600 ft. per min.) the water is carried up inside the cones and hurled out through the perforations in a finely divided spray. The gas is cooled to about 85 deg. fahr. in the upper four sections by the use of 31 gal. per 1000 cu. ft. of gas. Then 7½ gal. of this hot water is taken into the three lower sections and used for cleaning. The washer is self-cleaning and the water and dust leave it in the form of mud which is easily handled in centrifugal pumps. The first cost of installation, as well as the ground space occupied, is less than with static towers, and the power required is less than for Theisen washers. The Feld washer will clean to a fineness of at least 0.01 grain per cu. ft.

A New Type of Tar Extractor (Smith). With this type of apparatus, the standard anthracite producer is **used with bituminous coal** and no attempt is made to fix the resulting tar. The raw gas on leaving the producer is first cooled to a point where the tar vapors are condensed, by being passed through a primary cooler or condenser, from which the gas is carried into a rotary gas pump or exhauster, which delivers it under pressure into the main. It is then delivered through a porous diaphragm of spun glass into the engine main, where a sump or separator is provided in which the tar accumulates. The diaphragm must be sufficiently porous to permit the gas and tar to pass freely, and is in the form of a uniform layer of glass wool retained between two metal screens. Ordinarily, the thickness is about ¼ in. and the diameter must be adjusted in accordance with the quantity of gas to be treated. About 400 cu. ft. per hour can be handled per sq. in. of diaphragm area. No tar is retained in the diaphragm, both tar and gas being discharged together, but in passing through, change in the physical state of the tar occurs. On the entering side the tar exists in a large number of minute particles, known as tar fog, while in passing the diaphragm these particles are caused to coalesce, so that on the discharge side the tar particles are of relatively large dimensions and separate out by gravity and drain into the sump. It appears to be possible to secure any desired degree of gas cleanness by regulating the velocity of flow through the diaphragm. In ordinary commercial operation, it is found that a difference in pressure of from 2½ to 4 lb. per sq. in. will clean the gas so that no discoloration will be produced on a white filter paper through which 30 cu. ft. of gas has been passed. No water is used except that required to cool the gas, and therefore the tar separated is practically water-free (less than 1 per cent.). This process is not well adapted for gas containing large quantities of lampblack or from coals yielding a very heavy, viscous tar. It has, however, been used with success with Ohio, Illinois and Indiana high-volatile coals and with lignite.

Removal of Sulphur from Gas is accomplished chemically by the use of iron oxide sponge, which must be frequently renewed; the efficiency of the process is from 80 to 85 per cent. It has been found that sulphur as high as 2 gr. per cu. ft. can be successfully handled in an engine if water can be kept out of the gas in the cylinder and exhaust so that acid is not formed, and if the piston rods are kept at a sufficiently high temperature to prevent condensation and the consequent formation of acid. The piston rods must also be thoroughly flushed with a continuous stream of oil, as with normal lubrication the rods tend to become dry in places.

INSTALLATION AND OPERATING COSTS OF GAS-POWER PLANTS

Cost of Gas Engines and Gas Producers. Table 28 gives average costs taken from those published by R. H. Fernald in Bulletin No. 55, Bureau of Mines, 1913. **Producer costs** are made up approximately in the following percentages: Producer, 35; gas-cleaning plant, 21.5; piping and auxiliaries 43.5. Blast-furnace-gas-cleaning plants cost approximately $5.75 per b.h.p.

Cost of engine accessories, auxiliaries and erection, in percentages of the cost of engine F.O.B. factory, are given in Table 29.

Cost of producer accessories, auxiliaries and erection, in percentages of the cost of producer F.O.B. factory: Foundations, 3.5; erection, 25.5; coal-handling and storage plant, 34.0.

Costs of installation of large plants using blast-furnace gas (H. J. Freyn, Am. Iron and Steel Inst., May, 1913) are given in Table 30.

Cost of buildings includes cost of parts of buildings occupied by engines and part of buildings housing final gas cleaning apparatus which serves to clean the gas for the engines.

Table 29. Cost of Engine Accessories, Auxiliaries and Erection

(Costs in percentages of cost of engine F.O.B. factory)

Item	Cost, per cent.	Item	Cost, per cent.
Foundations, engines under 1000 h.p.	5.0	Station wiring, installed (average)	20
Foundations, engines over 1000 h.p.	3.5	Engine auxiliaries, air compressor, storage tank, motor-generator set, etc., installed (average)	20
Erection, engines under 1000 h.p.	10.0	Station piping from ends of foundation to producer piping or street mains, exhaust stacks, etc., installed (average)	5
Erection, engines over 1000 h.p.	8.5		
Piping and mains to end of foundations, installed (average)	10 0		
Switchboard, erected (average)	8.0		

Table 30. Actual Installation Costs of Gas Electric Stations*

(In plants of subsidiary companies of the United States Steel Corporation)

Power plant No.	1		2		3		4		5	
No. of units	17		2		4		4		5	
Capacity: kw.	40,000		4,500		9,000		9,000		11,400	
Capacity: b.h.p.	56,400		6,400		12,800		12,800		16,300	
Cost of installation per kw. max. con. rating:		%		%		%		%		%
Buildings	$9.87	11.3			$10.17	10.6	$10.90	10.8	$10.52	10.3
Engine equipment	71.78	82.0	$75 50	81 8	72.75	74.6	77.78	76.4	80.32	77.3
Gas-cleaning plant	5.85	6.7	16.80	18.2	14.40	14.8	13.00	12.8	12.76	12.4

* All cost figures based on maximum continuous rating of generator at 40 deg. cent. temperature rise. Engines have a greater b.h.p. capacity than corresponds to this generator rating and the figures in table are computed assuming a mean effective pressure of 70 lb. per sq. in. (a value universally adopted by gas-engine builders) and a mechanical efficiency of 80 per cent.

Engine equipment includes engine, generator, switchboard, station wiring (but no transmission lines) and all auxiliaries, installed. Does not include rotary converters storage batteries and switchboards for these appliances.

Cost of gas-cleaning plant includes cost of final gas-cleaning plant for the engines only, as the gas must be cleaned in the primary plant for use in stoves and boilers.

Operating Costs

Depreciation. The average life of cylinders in large steel plants is from 5 to 6 years, consequently the expense of a new cylinder must be distributed over this period. In general, an allowance of from 7 to 10 per cent. of the capital outlay for the power plant should cover depreciation, the lower figure for a producer power plant, and the higher for engines alone.

Attendance. From data by H. J. Freyn on the cost of attendance in three large blast-furnace gas-electric stations containing 26 units of an average capacity of 2300 kw., 3 men were required per unit per 24 hr. at an average attendance cost of about $8 per unit per 24 hr.

Maintenance and Repairs. The annual charge for these items should not exceed 3 per cent. of the purchase price of the engines and producers in a well-designed and built plant where the operation is normal. Freyn gives the following as average annual percentages of the cost of the separate items for a blast-furnace gas-power plant: Engines and electric generators, 2.5; cleaning plant, 7.0; air compressor used for starting, etc., 5; piping, etc., 2. To these may be added from 1 to 2 per cent. of the cost of the building for its maintenance.

Freyn (*op. cit.*) gives the following figures on the average repair and maintenance costs for 3 years operation, in eight American blast-furnace gas-engine plants. The use factors vary between 22 and 71.5 per cent. The repair and maintenance costs are expressed as a percentage of the net operating expenses (*i.e.*, total cost of power production less the fixed charges and cost of fuel):

Plant capacity, kw.	40,000 to 50,000	11,400	9,000	9,000	5,000	4,500	2,500	1,500	Avg. 11,600
Costs, 1910, per cent.	28.0	50.5	31.0	50.5	34.5	38.0	55.0	52.5	42.5
Costs, 1911, per cent.	29.5	51.0	35.5	64.5	21.5	31.5	50.5	48.0	41.5
Costs, 1912, per cent.	33.0	61.0	41.0	60.0	17.0	43.5	57.5	51.0	45.5

Average for 3 years' operation, 43 per cent.; average use factor, per cent.: 1910, 46.3; 1911, 46.8; 1912, 53.9. Average for 3 years' operation, 49.0 per cent. See also Tables 32 and 33.

Power Costs. The costs given in Table 31 are reported by J. R. Bibbins (*Trans. A.S.M.E.*, vol. 28, p. 559) as approximate power costs. This plant consists of three 150-kw. 3-cylinder vertical Westinghouse single-acting four-cycle engines running on producer gas. The coal has a heat value of 13,500 B.t.u. per lb. and costs $2.30 per short ton delivered. The plant is run 24 hrs. a day for 6¼ days a week at a labor cost of $14 a day for the two shifts. Supplies and repairs are estimated as 15 per cent. of the total other operating costs at 50 per cent. load factor. The cost of the plant, including engines, generators, switchboard, gas holder, producers, auxiliary pumps, and motors, coal-handling apparatus erected, is given as $125 per b.h.p. ($180 per kw.), or a total of $81,000.

Tables 32–34 (Freyn, Am. Iron and Steel Inst., 1913) give operating cost data for large blast-furnace gas plants.

Table 31. Power Costs in a 450-kw. Producer-gas Power Plant
(Running on bituminous coal)

Cost of cleaning gas for power engines per 1000 kw-hr., $0.32379.

GAS TURBINES

By L. C. LOEWENSTEIN

The fundamental difference between a gas turbine and a steam turbine is that in the gas turbine the products of combustion have, with the exception of a little water vapor usually present, no latent heat of vaporization, and also that their specific heat is comparatively low. For these reasons, the utilization of large quantities of heat in the gas turbine generally involves the employment of very high temperatures.

Classification. The rotor of a gas turbine may be of the impulse or of the reaction type, and may be classified in the same manner as the steam turbine. The classification of gas turbines is usually according to the manner in which the fuel is burned in the combustion chamber, as follows: (*a*) **Continuous combustion**, in which the combustion takes place continuously and at constant pressure, the fuel and the air entering and leaving the combustion chamber in a uniform stream; (*b*) **explosion**, in which the combustion takes place intermittently, and at constant volume, the inlet and the exit of the combustion chamber being closed while the actual combustion is in progress. The isothermal generation of heat in the combustion chamber according to the Carnot cycle and its various derivatives (like the Diesel, the Stirling, and the Ericsson) has not found practical application in the gas turbine.

The Air Compressor. The effective utilization of the heat generated in the combustion chamber requires a large pressure range between the combustion chamber and the exit of the rotor. For large powers, the pressure in the combustion chamber may reach 8 to 10 atmospheres, the turbine exhaust being atmospheric. For smaller powers, to avoid too short bucket heights on the rotor and to reduce rotation losses, the pressure in the combustion chamber is lower, the exhaust gases being cooled and their pressure reduced to a fraction of an atmosphere by means of an exhauster. Except in the very smallest sizes of the explosion type, an air compressor or an exhauster, therefore, forms a part of every gas-turbine installation.

The Regenerator. Only a small part of the chemical energy of the combustible is recoverable directly as mechanical work; another part must be recovered as sensible heat. The heat contained in the exhaust gases may be transferred from them by means of a regenerator to the compressed air on its way from the compressor to the combustion chamber. With gaseous fuel, a regenerator may also be used for preheating the gas. The regenerator may consist of a series of iron tubes like those of a surface condenser, or of stoves like those used with blast furnaces, or of a combination of the two, and may have a transmission efficiency as high as 75 per cent. Another type of regenerator consists of a tubular boiler for generating steam from the heat of the exhaust gases, this steam being used in an independent steam turbine. When working with exhaust at a fraction of an atmosphere, regeneration through steam will in general be impracticable.

Injection of Water. The injection of water or preferably of steam into the combustion chamber makes possible the use of fuels of high calorific value without excessive air dilution. Water injection may thus reduce the size of both the compressor and the turbine for a given output.

Overall Shaft Efficiency. The overall shaft efficiency of a gas-turbine plant is the ratio of the power given out by the plant for external uses to the chemical energy in the fuel; it depends on the shaft efficiency of the gas turbine (or gas turbine and steam turbine combined) and the efficiency of the air compressor. If L_t represents the theoretical power developed by the gas turbine (including that of the steam turbine, if any), L_c that required for compression, and L that available for external purposes; then $L = L_t - L_c$. If the efficiency of the gas turbine (and steam turbine) is e_t, and that of the compressor is e_c, the **actual external power available** $L_a = L_te_t - (L_c/e_c)$.

To illustrate the sensitiveness of a gas-turbine plant to the efficiencies of its component parts, assume the two extremes of efficiencies which are likely to be met in practice. Let the heat developed per lb. of gas mixture be 500 B.t.u., and let 80 per cent. of this, or 400 B.t.u. per lb., be available for mechanical work. The theoretical work of air compression is assumed as 80 B.t.u. per lb. of gas mixture. With a turbine efficiency of only 0.40, and a compressor efficiency of 0.50, the actual external power available is $L_a = 400 \times 0.40 - (80/0.50) = 0$, so that the overall shaft efficiency of the plant is zero. Again, assuming a turbine efficiency of 0.65, and a compressor efficiency of 0.75, the external power is $L_a = 400 \times 0.65 - (80/0.75) = 153$ B.t.u. per lb. of gas mixture, giving an overall efficiency of $153/500 = 0.306$.

The **power** available for external purposes may be about **doubled by** the use of a **regenerator**, whether it is for gas to gas or for gas to water. The efficiency of the regenerating apparatus is therefore of great importance. Thus, in the case of gas-to-gas regeneration, an increase in the number of stoves used may increase the regenerative efficiency from 0.50 to 0.75, and thereby increase the net output of the turbine plant by over 30 per cent. The **efficiency** of a gas turbine **increases with** the **pressure ratio and** with the **temperature** in the combustion chamber, but increasing the pressure ratio beyond 10, or the combustion chamber temperature beyond 3000 deg. fahr., results in very little gain.

Advantages and Applications. The gas turbine should present the same advantages as the steam turbine, namely, smaller dimensions and weight for a given output, lower first cost, less lubrication and attendance, less wear and repairs, comparative freedom from vibrations, and perfectly uniform torque. Not all of these advantages have as yet been demonstrated. A number of gas turbines have been installed on torpedo boats. The best prospects, however, for the gas turbine are for large units of, say, 2000 kw. and over, where the dimensions of the gas engine become unwieldy.

In a **continuous-combustion turbine** the compressor, in the case of liquid fuel or of powdered coal, forces air alone or gas and air into a chamber where combustion takes place continuously at constant pressure. If the temperature of combustion is T_3 and the temperature within the turbine to which the gas mixture expands adiabatically is T_4, there becomes available for mechanical purposes c_p $(T_3 - T_4)$ B.t.u. per lb. If the compressor takes in air and fuel at a temperature T_1, there is available for regenerative purposes, as explained before, c_p $(T_4 - T_1)$ B.t.u. per lb. of gas mixture, the turbine exhaust pressure being the same as the compressor inlet pressure. The overall shaft efficiency of a continuous-combustion gas-turbine plant will, without regeneration, rarely exceed 15 per cent. With regeneration, 25 per cent. and even 30 per cent. (with steam-turbine regeneration) may be reached.

In the **explosion turbine** air and fuel are introduced into a comparatively cold combustion chamber at a pressure p_2, temperature T_2, and specific volume v_2. The inlet of the chamber is then closed and the gas mixture is ignited, when the pressure and the temperature rise to p_3 and T_3, respectively, at constant volume. With the inlet still closed, the exit from the combustion chamber opens, and the contents are expelled adiabatically into a region of pressure p_4 and temperature T_4. The energy liberated for mechanical work is c_p $(T_3 - T_4) - (144/778)v_2(p_3 - p_4)$ B.t.u. per lb. of gas mixture. When the pressure p_4 has been fully established in the combustion chamber, the inlet is opened mechanically and the remaining gases are expelled by the new charge or by scavenging air. If the inlet temperature of the compressor is T_1, there is available for regenerative purposes $c_p(T_4 - T_1)$ B.t.u. per lb. of gas mixture. The compressor may be replaced by an exhauster so that p_2 is atmospheric pressure. To eliminate wheel-speed irregularities while the pressure in the combustion chamber is gradually falling from p_3 to p_4, a number of combustion chambers may be arranged around the periphery of the turbine wheel and the various chambers opened and closed successively one after another by a special mechanism. This mechanism, by varying the lapse of time between the opening of the successive chambers, may also regulate the power developed by the turbine. Steam-turbine regeneration only has been used with explosion gas turbines. With a high-pressure air compressor isothermally cooled and with efficient regeneration, the overall efficiency of an explosion gas-turbine plant may exceed 30 per cent.

WATER POWER

WATER WHEELS

By C. M. SAMES

Water wheels—the earliest forms of hydraulic motors—have been almost entirely displaced by turbines. They are in general of three **classes**: Overshot wheels, which receive the water at the top and are of a diameter less than the total head (commonly adapted to high heads); breast wheels, which receive the water on their upstream side and pass it underneath (used for medium heads); and undershot wheels, which are rotated by water passing below them and are adapted to the lowest heads.

Overshot Wheels are suitable for water falls ranging between 10 and 70 ft. where the water supply is from 2 to 30 cu. ft. per sec., corresponding to a maximum development of 75 h.p. when the economical range of head (10 to 40 ft.) is considered.* In these the water enters along a sluice at the summit of the wheel and falls in a parabolic path into the buckets. The diameter D of the wheel (ft.) may be from $H - 1.33$ ft. to $H - 2.25$ ft., where H = available fall, ft., and the circumferential velocity v from 5 to 7 ft. per sec. For maximum efficiency of operation the velocity of the entering water should be approximately $1.1v$.* The radial depth d of the (steel) buckets may range from $0.16\sqrt[3]{H}$ to $0.25\sqrt[3]{H}$ (and up to $0.5\sqrt[3]{H}$ where narrow wheels are desired), and the number of buckets about $\pi D/d$. The width of the buckets b (ft.) between shrouds should be from $2Q/vd$ to $4Q/vd$, where Q = flow, cu. ft. per sec. When b is greater than 5.5 ft. the buckets should be braced at their mid-width.

The **horse power of a water wheel** $= 0.1134QHe$, where e = total efficiency (hydraulic efficiency × mechanical efficiency) expressed as a decimal. The efficiency of a properly designed overshot wheel, operating under favorable conditions, computed on the basis of output at the wheel shaft, may be as high as 90 per cent. (a 10-ft. wheel tested at the University of Wisconsin gave e = 89 per cent.).* For maximum efficiency the point of impact of the water should lie as high in the wheel as possible. Submergence of the wheel in the tail water seriously decreases the efficiency.

Breast Wheels. In these the water enters the wheel at the upstream side, either (1) flooding the buckets or (2) being directed against them in a stream making an angle of about 27 deg. with a tangent to the circumference at the point of entry, and is prevented from leaving them by a breast wall just clearing the lower quadrant of the wheel on the entry side. Type (1) is available for heads of from 1.3 to 12 ft., and type (2) for heads of from 5 to 17 ft. For (1), $D = 3H$ to $4H$; for (2), $D = H + 11.5$ ft.; $v = 4.6$ to 5.6 ft. per sec. for (1), and 5.3 to 7.2 ft. per sec. for (2). For both types $d = (0.4 \text{ to } 0.5) \times \sqrt[3]{D/H}$; $b = (2 \text{ to } 3) \times Q/vd$; circumferential pitch of bucket $= 0.5d$ to $0.7d$; efficiency, up to 85 per cent.

Undershot Wheels. Where the head does not exceed 6 ft., the Poncelet undershot wheel is probably the best type to employ. In this (impulse) wheel the water jet (thickness t = 8 to 10 in.) flows down a 1 : 10 slope,

* From Bulletin of the University of Wisconsin No. 529, by Carl R. Weidner, entitled "Theory and Test of an Overshot Water Wheel."

enters the wheel without shock, follows up the curved vanes or buckets (never, however, entirely filling them), falls back and leaves the wheel practically without velocity. A close-fitting breast at the bottom should cover 15 deg. each side of the vertical wheel diameter. $D = 2H$ to $4H$ (generally not less than 14 ft.); $d \geq 0.5H$; $b = Q/tv$, where t is taken in ft.; $v = 0.55\sqrt{2gH}$. Circumferential bucket pitch, about 1 ft.; efficiency, ≥ 70 per cent.

Curvature of Buckets. Overshot Wheels (Fig. 1): Take $AB = \frac{1}{3} \times$ radial distance AC, and $CE = 1.2 \times$ circumferential pitch GC. Draw FE at an angle of from 10 to 15 deg. with radius EH. From a point on FE as a

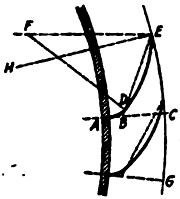

Fig. 1.—Overshot Wheel.

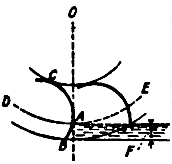

Fig. 2.—Breast Wheel.

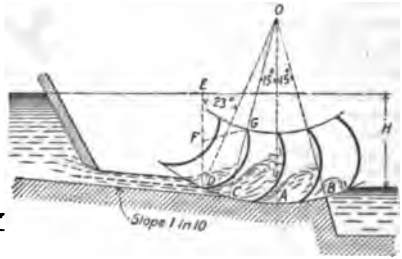

Fig. 3.—Undershot Wheel.

Curvature of Water-wheel Buckets.

center, describe an arc passing through E and D (near B), and round this arc into the radial portion AB of the bucket. Breast Wheel (Fig. 2): From the wheel center O draw the dotted circle DE with a radius equal to the radius of the wheel minus the depth F of tail water. The outer part (AB) of the bucket should be an involute unwrapped from DE; the inner part(AC) should curve sharply after leaving A. Poncelet Undershot Wheel (Fig. 3): Draw vertical radius OA of wheel and lay off AC and AB (each 15 deg. of circumference), making breast BC. At mid-depth D of jet as it strikes the wheel, draw radius OD; also draw DE at an angle of 23 deg. to OD. Take $DF = 0.5H$ to $0.7\ H$ and draw arc DG, which is the bucket curve desired.

HYDRAULIC TURBINES

BY

W. M. WHITE

German Texts: Brauer, "Theory of Turbines;" Budau, "Computation of Hydraulic Governors," and "The Speed Regulation of Hydraulic Motors;" Escher, "The Theory of the Water Turbine;" Gelpke, "Turbines and Turbine Plants;" Honold and Albrecht, "Francis Turbines;" Mueller, "Francis Turbines;" Pfarr, "Turbines for Hydraulic Power Plants;" Quantz, "Water Power Machines;" Thomann, "Water Turbines;" Wagenbach, "Modern Hydraulic Turbine Plants."

Water may do useful work in four general ways: (1) By its pressure; (2) by its velocity; (3) by its weight, and (4) by combinations of (1), (2) and (3). Of these, (2) and (4) are employed most generally in impulse and reaction turbines, respectively. Other types of hydraulic prime movers such as the overshot wheel and breast wheel of the third class, the undershot and current wheels of the second class, and all forms of pressure motors of the first class except in small sizes, as well as modifications of reaction and impulse turbines, including Girard wheels, Fourneyron wheels, Jonval wheels, etc., are not in general use because of inherent disadvantages as to size,

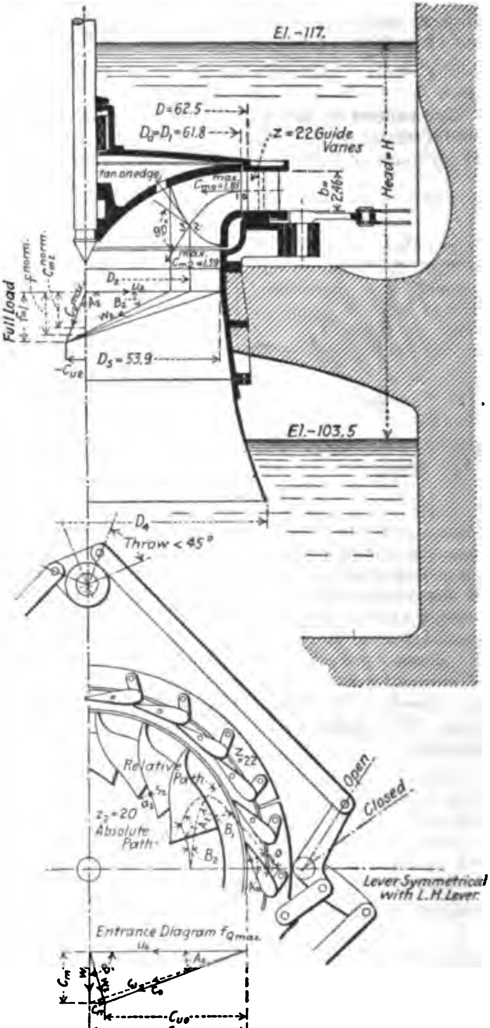

Fig. 1.—Francis Reaction Turbine for Low Head.

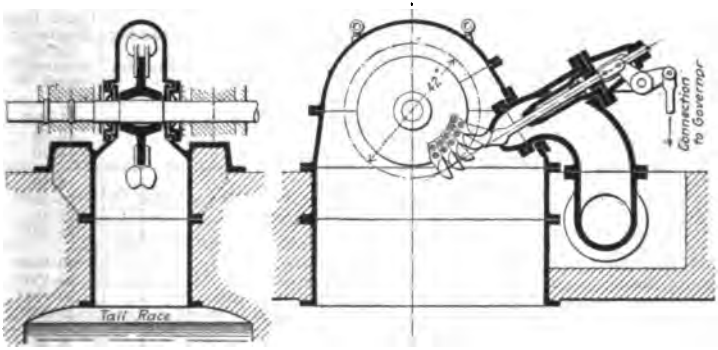
cost, efficiency, durability or regulation which make them uneconomical or impractical.

CHARACTERISTICS AND CLASSIFICATION OF TURBINES

Types of Turbines. Of the many possible designs, two types only are of special interest. These are the **reaction** (or pressure) **type,** where the head is only partly transformed into velocity in a stationary guide case, and the **impulse** (or action) **type,** where the head is completely transformed into velocity in a stationary nozzle before acting on the runner. In either case, the direction of the water flowing through the runner is forcibly changed. The impulse turbine revolves at a lower speed than the reaction turbine for a given head, and because it offers advantages of simplicity in design it is preferred for high heads and small discharges. Its lower speed makes it more adaptable to direct connection to electrical generators of economical speeds, and its simplicity of construction permits of a design less subject to deterioration under severe pressure and velocity conditions.



$Q = 14$ cu ft/sec., $H = 650$, $n = 500$, $Q_1 = 0.55$ cu ft/sec., $n_1 = 19.62$, $n_s = 4.4$, $D_0 = 42$, $u_0 = 3.6$ ft/sec., Jet Diam $3\frac{5}{8}$ in.

FIG. 2.—Impulse Turbine (Pelton Wheel).

Reaction (Francis) turbines have normally a radial inlet and discharge the water in a direction more or less parallel to the shaft. Regulation is usually accomplished by wicket-type gates or guide vanes. A plurality of smaller runners may be placed on a single shaft for the purpose of obtaining higher speeds (twin turbine, quadruplex turbine, etc.). An example of a reaction turbine for low head is given in Fig. 1.

Impulse (action) turbines (Fig. 2) are designed with a runner in the form of a disk, upon the rim of which buckets are mounted, these buckets usually being of the double-lobe form, the two parts coming together in a common splitter. Tangent to the runner one or more jets impinge upon the splitters of the buckets and are diverted approximately 90 deg. from their initial absolute direction. The jet is usually circular in section and is adjusted by moving a needle which is concentric with the axis of the nozzle. The water is brought to the wheel through a pipe line. For the purpose of obtaining higher speeds in connection with low or moderate heads or for extremely large units, a plurality of wheels or of jets per wheel may be made use of, though simplicity and (usually) efficiency are sacrificed by so doing.

General Arrangements of Turbine Installations. Turbines are either set in an open flume or in an enclosed casing of concrete or metal. Impulse turbines have the latter arrangement, while reaction turbines have either. The limits of head to which the various types and forms of both reaction and impulse turbines are adapted are dependent upon the comparative economy (*i.e.*, first cost, maintenance charges, efficiency and value of power) effected by the use of the various arrangements. These limits are fairly well defined in modern engineering practice and are outlined roughly in Table 1. The arrangements marked* are those most generally adopted, no attempt having been made to list the various modifications of construction sometimes used. The limits given should not be taken as representing absolute points beyond which the various types are not suitable, but rather as indications of general practice.

Table 1. General Arrangements of Turbine Installations and Usual Head Limits Employed

Type	Setting	Construction	Number of runners	Usual head limits for direct-connected units, ft.
Reaction turbines, 5 to 600 ft. head	Open flume, 5 to 50 ft. head.	Vertical	1	15-30*
			2	10-30

Impulse wheels, 300 to 3000 ft. head.	....	(Stationary or deflecting nozzles).	1	300-3000*
			2	400-2000*

Selection of Turbine Types. After the available head, quantity of water and power available are determined, the probable turbine arrangement may be decided upon, though additional factors such as extent of variation of head- or tail-water levels, penstock or pipe-line length and closeness of speed regulation required, have considerable influence upon the selection of type. The following general rules will serve as an additional guide in selection of type.

1. If the head is under 30 ft. the open-flume type should nearly always be used, except for small single-unit plants of less than 100 h.p. in capacity where an encased turbine might be preferable.

2. If the head is between 30 and 50 ft. either the open-flume or plate-steel-encased type will be used, the latter usually working out the most economically for units less than 500 h.p. in capacity. The final decision in any case depends on the local conditions, being based on the relative cost of concrete retaining walls as compared with plate-steel casing.

3. If the head is between 50 and 100 ft., the plate-steel-encased construction is ordinarily the most economical, except in units of small capacity where the cast-iron casing is often less costly.

4. If the head is above 100 ft. and not over 600 ft., the cast-iron casing is usually used on reaction turbines of all moderate or large sizes, cast steel being more economical for large turbines under high heads.

5. For heads between 300 and 600 ft., the impulse type is used for all wheels under about 500 h.p.

6. For heads between 600 ft. and 3000 ft., the impulse wheel is used, though the reaction type is suitable for heads above 600 ft. under special conditions where little or no regulation is required.

Having determined the general forms of construction, the following more specific points may be given consideration.

Vertical Shaft Layouts are ordinarily the more suitable (1) where the most efficient setting of runner is desired; in this case the single-runner vertical-shaft type of reaction wheel is the best and permits of the highest efficiency; (2) in connection with direct-connected hydroelectric units where a large fluctuation of water levels exists and it is of importance to place the electric generator above the extreme high water level and not run into excessive draft-tube length or place the turbine too near the head water level; (3) in connection with direct-connected hydroelectric units when a limited space is available for the power house and forebay. In this case, the width of the power house, measuring in the direction of flow, may be greatly reduced, as the generators are located directly above the turbines.

Horizontal Shaft Arrangements, particularly when used with direct-connected hydroelectric units, ordinarily possess advantages over the vertical-shaft types when considered from standpoints of first cost of machinery, accessibility of parts, ease of erection and inspection, and by reason of having only journal bearings in the place of a special thrust bearing.

Characteristic Speed. Turbine runners of different types may possess characteristics of power, speed, dimension and operating head which vary widely, and it therefore is difficult to draw direct comparisons. In order that there may be available a common basis for comparison of all turbine runners, the value designated hereinafter as "characteristic speed" is used. The *characteristic speed of a runner* (sometimes designated "specific speed" or "type characteristic") *is the speed in r.p.m. which a model of that runner would have if operated under a head of* 1 *ft., this model to be reduced proportionally in all dimensions from the original until it will develop* 1 *h.p. under* 1 *ft. head.*

Since the angles of the buckets of a runner are fixed, the linear speed of the bucket should at all times bear a constant relation to the linear velocity of the entering water in order to secure operation without disturbance. The linear velocity or r.p.m. (n) of a runner is proportional to $\sqrt{H}$, where H in the head in ft., and the speed at 1 ft. head $(= n/\sqrt{H})$ = is called **unit speed,** and designated n_1.

The power (N) developed by a runner is a function both of the pressure and the amount of the operating water. The pressure is proportional to the head and the amount proportional to the velocity, which in turn is proportional to the square root of the head. Therefore the power of the runner is proportional to $H \times \sqrt{H}$, and the power of a runner at 1 ft. head is equal to $N/H\sqrt{H}$, and is called **unit power,** being designated N_1.

The **characteristic speed** $n_s = n_1\sqrt{N_1} = \sqrt{N/H\sqrt{H}} \times n/\sqrt{H} = n\sqrt{N}/H^{5/4}$. In general, impulse wheels have a characteristic speed of about 3 (and not over 6), and reaction wheels as ordinarily used one ranging between 12 and 120. In European practice the characteristic speed for impulse wheels goes occasionally as high as 9 for a single nozzle, and may be increased proportionately to the square root of the number of nozzles. The characteristic speed of reaction wheels may similarly be increased by using two or more runners. The practical **limits** of characteristic speed are determined by the following considerations: With low characteristic speed the narrowness of the passages may result in clogging, their increased length tends to high frictional loss, and the increase in overall diameter of the unit runs up initial cost. In securing low speed, the peripheral coefficient (or ratio of the peripheral velocity of the runner rim to the spouting velocity of the water) is first reduced as far as is possible without causing pressureless flow at the runner entrance (as in impulse turbines). The practical limit in this direction is given in Fig. 3. With this as a basis, speed might be reduced indefinitely by increasing the diameter of the runner, but in so doing the net area of the runner inlet must be kept constant in order to conform to the above velocity requirements, consequently the runner entrance narrows directly as the diameter is increased. A practical limit is reached in this direction very quickly by reason of the likelihood of clogging in the runner passages.

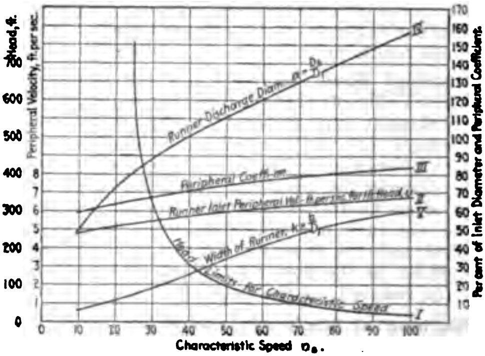

Fig. 3.—Practical Limits of Characteristic Speed of Turbine Runners.

In obtaining high characteristic speed, the reverse of the above holds. The peripheral coefficient is made as high as possible with limits as per Fig. 3 and the runner diameter reduced. This reduction of diameter requires a corresponding increase in the width of the runner inlet in order to conform to velocity requirements. Reducing the diameter of the runner causes the discharge diameter to be relatively small and the discharge velocity correspondingly high. This latter feature is undesirable because the energy of the discharging water can be but partially regained in a flaring draft tube.

TURBINE DESIGN

Notation:

Q = Quantity of water flowing, cu. ft. per sec.
N = brake horse power.
n = revolutions per minute (r.p.m.).
H = head, ft.
Q_1 = unit discharge, or discharge for 1 ft. head (cu. ft. per sec.) $= Q/\sqrt{H}$.

N_1 = unit horse power, or h.p. for 1 ft. head = $N/H\sqrt{H}$.
n_1 = unit speed, or r.p.m. for 1 ft. head = $n/\sqrt{H}$.
n_s = characteristic speed = $n_1\sqrt{N_1}$, r.p.m.
z = number of buckets or vanes in the runner.
t = thickness of blades, ft.
s = pitch of blades, ft.
e_m = mechanical efficiency.
e_h = hydraulic efficiency.
e = $e_m \times e_h$ = total efficiency.
j = percentage of gate opening.
u = peripheral velocity of runner rim at unit speed n_1 ft. per sec. (The corresponding velocities at any given head H are obtained by multiplying by $\sqrt{H}$.)
m = peripheral coefficient, or ratio of the linear velocity of the runner rim to the spouting velocity of the water = $u/\sqrt{2gH}$ where H = 1 ft., = $0.000544D_1n_1$. (D_1 = runner inlet diameter in inches.)
c = absolute velocity of the water, ft. per sec.
w = relative velocity of the water with reference to the runner, ft. per sec.

Velocities at various points are indicated by subscripts (see Fig. 1):
No subscript at the outlet of the guide vanes.
0, immediately in front of the runner inlet.
1, immediately back of the runner inlet.
2, immediately in front of the runner outlet.
3, immediately back of the runner outlet.

Further, c_u indicates the component of c in the direction of u, w_u the component of w in the direction opposite to u, and c_m is the component of c at right angles to u (in the meridian plane).

The angles between the absolute runner and water paths are designated A_0, A_1, A_2, etc., and the relative angles (with the negative direction of movement of the runner), B_0, B_1, B_2, etc.

For a given turbine the values of discharge and speed are proportional to the square root of the head. $Q_1 = Q/\sqrt{H}$ and $n_1 = n/\sqrt{H}$ are therefore constant for any one turbine or runner. It is sufficient to know the values Q_1, n_1 and the operating head H when computing the proportions of a turbine. For different sizes of turbines homologously built, any dimension, such as runner diameter, D_1, may be expressed as follows, k being a constant: $D_1 = k\sqrt{Q_1}$ (areas are proportional to discharge). Hence $n_1 = 60u/\pi k\sqrt{Q_1} = K\sqrt{Q_1}$. K is constant for turbines of the same characteristic speed. It is now customary to introduce the value N_1 in place of Q_1, as turbines are rated more often in h.p. than in discharge, whence $N_1 = Q_1e_m/8.82$, and $n_1 = 60u/\pi k\sqrt{8.82N_1/e_m} = n_s/\sqrt{N_1}$. N_1 and Q_1 are maximum values at wide-open gate.

Francis Turbines (n_s = 12 to 90 for one runner). It has been found in actual practice that there are certain practical limits of characteristic speed beyond which it is not desirable to go for any given head. These limits may be imposed by reason of runner strength, tendency toward erosion or pitting of runner vanes, or may be fixed by limits in generator construction. In Fig. 4 there are plotted a number of runner characteristics taken from actual American installations which have worked out satisfactorily, the examples being selected by reason of their being rather extreme. The arbitrary curve is drawn in as nearly as possible to include all the points representing runners that are known to be commercially successful, and to exclude those which are questionable or that are known to show signs of pitting or other defects. A limit is thus obtained giving the highest characteristic speed which is suited to any particular head. The curve thus derived is drawn in on Fig. 3 (Curve I). The dimensions A, B, C, D, E, F, G and H show the ranges of heads appropriate for the corresponding turbine types as listed in Table 2.

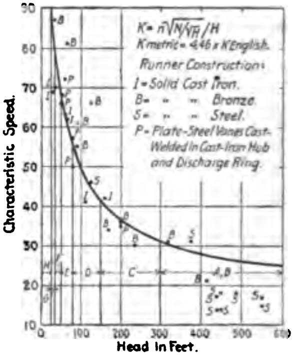

FIG. 4.—Relation of Characteristic Speed to Head (American Practice).

Fig. 3 serves as a guide for the selection of the allowable characteristic speeds and the main runner dimensions. The several curves are based largely on experimental data, and represent modern practice as followed by the leading turbine designers. Knowing the head, the limiting characteristic speed may be taken from Curve I. The power (N) per runner being decided upon, N_1 can be obtained from $N_1 = N/H\sqrt{H}$. Knowing N_1 and n_s, n_1 is obtained from $n_1 = n_s/\sqrt{N_1}$, and the r.p.m. n computed from $n = n_1\sqrt{H}$. As stated above, Curve I is an approximate upper limit and is not to be adhered to rigidly. If the r.p.m. as thus computed is higher than desirable, say, for an electric drive, a lower value of n_s is obtained by computing n_1 = desired r.p.m./$\sqrt{H}$, whence $n_s = n_1\sqrt{N_1}$.

If the speed as first computed is lower than desirable and a higher characteristic speed is not advisable, a remedy is found by dividing the desired h.p. between two or more runners and computing n_1 and n from the smaller values of N_1 and n_s, as before. Knowing n_s, the peripheral speed u may be taken directly from Curve II, whence the entrance diameter of the runner D_1 is obtained from $D_1 = 60u/\pi n_1$. Expressed in inches as is usually customary, D_1 (in.) $= 229u/n_1 = 1835m/n_1$, where m, the peripheral coefficient, is obtained from Curve III or by dividing u by $\sqrt{2gH}$, the value H being unity. The diameter D_1 is measured at the center line of the inlet of the runner (see Fig. 1). The diameter of the runner D_2 at its discharge side fixes the diameter of the draft-tube top and equals aD_1, the constant a being taken from Curve IV, Fig. 3. The width b of the guide case or speed gate $= kD_1$, the constant k being taken from Curve V, Fig. 3.

Examples. LOW HEAD: Given $H = 25$ ft., $N = 4000$ h.p., four units of 1000 h.p. each being desired. From Curve I, Fig. 3, $n_s = 90$ (permissible). For a single-runner unit $N_1 = 1000/25\sqrt{25} = 8$; $n_1 = 90/\sqrt{8} = 31.8$; $n = 31.8\sqrt{25} = 159$ r.p.m. For a 60-cycle installation a synchronous speed ($2 \times 60 \times 60$/No. of poles) must be used, and 150 r.p.m. would probably be adopted. Recomputing on this basis, $n_1 = 150/\sqrt{25} = 30$; and $n_s = \sqrt{8} \times 30 = 85$. From Curve III, Fig. 3, and $n_s = 85$, $m = 0.81$, whence runner diam. $D_1 = 1835 \times 0.81/30 = 50$ in., approx. Similarly, width of runner inlet (guide-case height) $b = 0.54 \times 50 = 27$ in., and runner discharge diam. $D_2 = 1.44 \times 50 = 72$ in. These values would be typical of a single-runner vertical-shaft layout, but considerations of higher speed (lower cost), balanced arrangement and more symmetrical setting would probably warrant the use of a twin turbine if a horizontal unit were desired. In this case N per runner $= 500$ h.p.; $N_1 = 4.0$; $n_s = 90$;

* All values of discharge Q_1 are calculated from unit horse power N_1, using an efficiency of 80 per cent.

† $D_1 = 53$ in. ‡ $D_1 = 56$ in.

$n_s = 45$, and $n = 225$ r.p.m. Whence $D_1 = 33$ in.; $b = 18.5$ in.; $D_2 = 1.48 \times 33 = 49$ in.

HIGH HEAD: Given $H = 420$ ft. and $N = 4000$ h.p. in one unit. From Curve I, Fig. 3, n_s (permissible) $= 27$; $N_1 = 4000/420\sqrt{420} = 0.465$; $n_1 = 27/\sqrt{0.465} = 38.6$; $n = 38.6\sqrt{420} = 810$ r.p.m. This would ordinarily be too high a speed for economical generator construction. On the basis that a 450-r.p.m. machine would be best, the hydraulic end would work out as follows: $n_1 = 450/\sqrt{420} = 21.9$; $n_s = 21.9\sqrt{0.465} = 15$; $D_1 = 1835 \times 0.62/21.9 = 52$ in.; $D_2 = 0.85 \times 52 = 43$ in.; $b = 0.09 \times 52 = 4.7$ in.

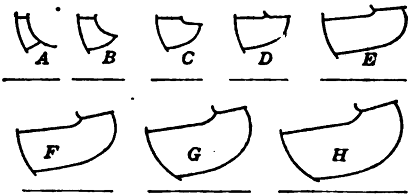

FIG. 4a.—Typical Profiles of Runner Blades.

In general practice it is advisable to design the runner for each given set of conditions. This procedure is adhered to for all large or important installations by the leading designers. It is possible, however, to design a line of wheels which will cover more or less closely all ordinary requirements. A typical line of this kind is shown in Table 2, the field of the various types and the heads to which they are adapted being shown diagrammatically in Fig. 4. The approximate outline or profile of the runner blade of each type is shown in Fig. 4a, the proportions being in accordance with the ratios shown in Fig. 3.

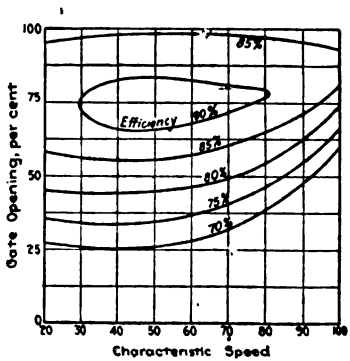

FIG. 5.—Relations Between Characteristic Speed, Efficiency and Gateage of Reaction Turbines.

Fig. 5 shows diagrammatically the general relations between characteristic speed, efficiency and gateage of reaction turbines, it being assumed that the proportions and main dimensions of the turbine are determined from Fig. 3. The vertical scale as shown is based on the percentage of gate opening, but for approximate purposes may be considered as the percentage of discharge, which is roughly proportional to gate opening. Above 50 per cent. the vertical scale may also be taken as percentage of h.p. output for approximate work.

These values of efficiency are relative rather than absolute and represent the efficiency of the guide case, runner and draft tube, rather than that of the complete unit as installed, the efficiency of which may depend as much on the setting as on the turbine design. Besides the proper selection of main dimensions and the proper design and construction of buckets, the other points of considerable influence on the efficiency may be cited as size, draft tubes and settings.

Influence of Size on Efficiency. Turbines which have a large output either by reason of their size or the head under which they operate, are more favorable to high efficiency than those of smaller capacity. Fig. 5 may be said to hold roughly down to $D_1 = 30$ in., $H = 10$ ft. With the larger sizes or higher heads the frictional losses become relatively smaller, consequently the efficiency—particularly at the smaller gate openings—becomes relatively higher than shown.

Draft Tubes. The draft tube is an essential part of the Francis turbine, as it serves the double purpose of permitting the placing of the machine high above tail water, thereby making it more accessible, and of reducing the loss incident to the velocity of discharge to a negligible amount. If a Francis turbine is so placed above the tail water, part of the total head acts on the wheel by suction.

The velocity at the discharge of the draft tube may be determined as follows: For low heads up to 20 ft., the velocity at the discharge end of the draft tube should correspond to a loss of not more than 1 per cent. of the head. For medium heads from 20 ft. up to 60 ft., the velocity at the discharge end of the draft tube should be limited to 0.08 to $0.1\sqrt{2gH}$ (or less for the upper limit of heads), on account of the resulting high absolute velocity. For heads from 60 ft. up to 600 ft., the velocity should be still lower, on account of the great disturbance in the tail race. For instance, for a head of 450 ft., $0.1\sqrt{2gH} = 17$ ft. per sec. Good practice would limit the discharge velocity in this case to about 7 ft. per sec.

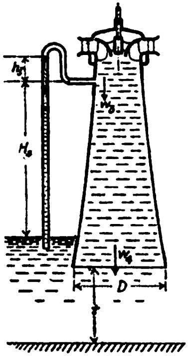

FIG. 6.—Conical Draft Tube.

Shape of Draft Tube. In a conical draft tube (Fig. 6) part of the loss due to the discharge velocity from the runner can be utilized; theoretically, to the amount $h_s = (w_3^2 - w_4^2)/2g$ in ft. of head, where w_3 and w_4 = velocity in ft. at entrance to and exit from the draft tube; or, more correctly, $h_s = \frac{w_3^2 - w_4^2}{2g} - \frac{(w_3 + w_4)^2}{2g} \sin a - h_f$, wherein the second member expresses the loss due to the widening of the passage, with the angle of flare, a, and h_f the friction loss due to the flow through the draft tube. Not more than from one-half to two-thirds of the theoretical gain can be expected in actual operation.

Assuming a straight conical draft tube, the space t between the draft-tube discharge and the bottom of the flume should not be less than $0.6D$ if the water can flow away on all sides, and not less than D if it can flow off on one side only. The angle of flare a should be small to avoid the danger of the flow leaving the walls. For straight conical draft tubes, the side angle should not exceed 7 deg. In curved concrete draft tubes a larger flare than 7 deg. can be used below tail-water level. The **correct shape** (see Fig. 7) can be designed, according to Prof. Prášil (Zürich), by the rule $\pi D^2 Z/4$ = constant. In many cases a shape like this can be approximated in steel-plate construction. Where sufficient depth is not available, it is of advantage to bend the draft tube around to discharge in the direction of the flow in the tail race; this is best accomplished in concrete draft tubes. The shape of the draft tube should in any

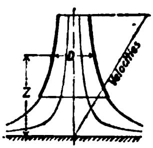

FIG. 7.

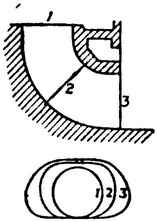

FIG. 8.

case be such as to join correctly to the discharge ring of the runner, and the cross-section be approximately circular in form down to the bend. An oval discharge opening (Fig. 8), possibly unsymmetrical, with a flat bottom and arched top, is the best design because it combines the circular cross-section with a shape which allows the water to spread in going through the bend and permits of minimum excavation. The increase of sectional area should take place as much as possible before the bend, that is, in the straight part of the draft tube, because a gain in head in the bend and beyond that point is doubtful.

With the horizontal twin-runner arrangement of turbines a center discharge casing is required to conduct the water to the draft tube proper. This arrangement necessitates a 90 deg. bend in the flow practically at the point of highest discharge velocity. At best it introduces considerable losses, particularly in connection with high-speed runners (characteristic speeds above 65). The length of the casing between runners should not be less than 1.6 times the discharge diameter of the runner. The discharge opening at the bottom of the casing (top of draft tube) is preferably circular in form and should have an area of approximately 1.25 times the sum of the areas of the runner discharges.

Limits for Draft Height. The theoretical maximum is 33.8 ft. for a barometric pressure of 30 in. This will naturally be reduced in the case of a conical draft tube by the amount $(w_3^2 - w_4^2)/2g$; for example, if $w_3 = 13$ ft. and $w_4 = 4$ ft., this is equal to 2.38 ft., leaving the net theoretical maximum $H_s = 31.42$ ft. (see Fig. 6). In actual practice a draft-tube height of 20 ft. is to be considered as a safe limit, and 22 ft. to 24 ft. possible but risky, especially for part-load operation or when the action of a governor is apt to impose sudden and severe velocity changes. In many cases the water contains a large quantity of air which will impair the action of the draft tube, and this must be considered in case the draft-tube head is more than 20 ft. For the same reason also the flare of the draft tube should be small in cases where large amounts of air can be anticipated. The draft head is to be measured from the tailwater level to the highest point of the turbine on the discharge side of the runner where the vacuum will occur.

For small sizes the **material** used in the construction of draft tubes is steel plate or cast iron; for large sizes, generally concrete. The surface of the concrete should be smooth.

Setting. The efficiency of a turbine is influenced by its setting. The waterways should be so formed as to properly guide the water in its flow to and from the turbine. Smooth and unobstructed passages are desirable and low velocities should be adopted as much as possible. Velocities through trash racks are commonly kept below 2½ ft. per sec. for all heads. In low head (up to 30 ft.) open-flume plants the maximum velocities in the turbine chamber seldom reach 3 ft. per sec., and from the draft tube about 4 ft. maximum. The velocity in the turbine chamber or penstock should preferably be under $0.08\sqrt{2gH}$ for all heads, an absolute velocity limit of 10 ft. per sec. being common for large high-head plants. The exit velocity from the draft tube should be kept under $0.1\sqrt{2gH}$, with an additional limit of 6 ft. per sec. for all loads. The spiral form of turbine chamber is possible with vertical-shaft single-runner units of the open-flume and concrete-cased types, and represents best practice for low- and medium-head (up to 100 ft.) plants.

Impulse Wheels (n_s not over 6 for one jet). Fig. 9 shows the approximate relations between characteristic speed, efficiency and gateage. These values are given with the same general reservations mentioned in connection with Fig. 5. General computations as to speeds are obtained as for reaction wheels, using a constant peripheral coefficient of about 0.47. Detailed methods of calculation of overall dimensions are given later.

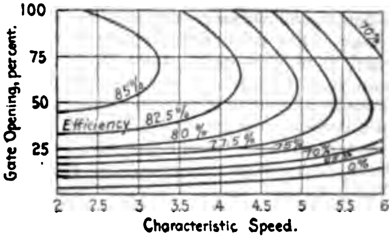

FIG. 9.—Relations Between Characteristic Speed, Efficiency and Gateage of Impulse Wheels.

COMPUTATION AND CONSTRUCTION OF TURBINES

Francis Turbines

The Runner. After determining the type of turbine and the characteristic speed of the runner, the main dimensions are determined by the use of the curves of Fig. 3 and the outlines and diagrams of Figs. 1 and 10. The blades should not be too long measured along the flow lines, as this produces too much friction. On the other hand, blades that are too short cause excessive eddy currents due to the abrupt curvature.

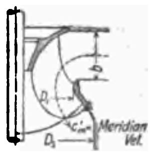

FIG. 10.

In determining the size of the blades in connection with the number to be used and the power to be developed it is often convenient to figure with the working pressure per sq. ft. of blade area, which should not be more than $h = 0.15$ to $0.25H$. From this the product of blade area, projected on the meridian plane (blade profile), and the number of blades (z) $= Az = Q_1 e_h H / h u_s$, where u_s is the peripheral speed of the center of gravity of the profile of the blade for $H = 1$ ft.

Prof. Zowski gives the following rules for determining the number of vanes: "High-capacity runners which have a high guide case should have a larger number of vanes than low-capacity or high-head runners. In all cases an uneven number (z_1) of vanes should be used, determined approximately by $z_1 = C\sqrt{D_1}$ (in.), where C may be taken as about 3.7 for low characteristic speed runners, 3 for medium characteristic speeds and 2.2 for high characteristic speeds." In order to prevent clogging, the minimum width between blades should never be less than 1¼ in. to 2 in. Abrupt turns in the runner profile should be avoided, particularly at the outer rim. The discharge loss $c_3^2/2g$ varies from $0.02H$ to $0.16H$, for characteristic speeds of from 10 to 100, respectively. Theoretically, all of this energy can be regained in the draft tube down to the small amount contained in the necessary velocity at the discharge end of the tube. Actually, it can be only partially regained by reason of frictional and eddy-current losses in even the best-designed tubes. A safe assumption is that one-half of the theoretical energy may be regained.

The materials used for runners are cast iron, bronze, plate steel cast into hubs of cast iron and bronze, and cast steel. The choice is governed by local conditions of head, water and characteristic speed, as it is a generally accepted fact that the chief cause of pitting is improper design, or conditions of loading for which the wheel was not intended, rather than the material of which the runner is made. Erosion should be distinguished from pitting, as the former is due to the abrasive action of foreign material in the water, rather than to design. The principal advantage of bronze is its strength and the ease with which it may be cast. Cast steel also gives strength and toughness, but the complicated shapes of buckets, excepting in high-head Francis-type runners, make it difficult to obtain good castings with this metal. Where the conditions do not require great strength or stiffness, as in runners of high characteristic speed, both cast iron and composite runners are satisfactory and much cheaper. [From Report of Committee on Prime Movers, N. E. L. A., Chicago, June, 1913.] Except where the water carries a heavy content of acid, alkali or air, the material used for any particular condition is usually fixed by requirements of strength, rigidity or ease in manufacture.

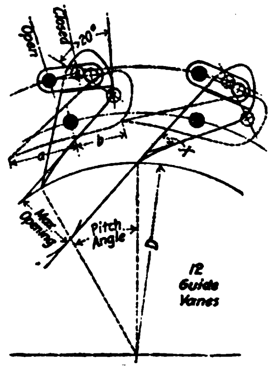

FIG. 11.—Guide Vanes for Francis Turbines.

The Guide Case is commonly designed for the maximum discharge rather than for the normal. The **number of guide vanes** is selected arbitrarily and should preferably be a multiple of four, from manufacturing reasons. The number used varies from about 12 for small runners to 28 for large wheels. For equal diameters, high-speed wheels have fewer guide vanes than low-speed wheels. The gate opening varies from 2 in. for small runners to 10 in. for large runners. The **form of guide vanes** generally used is shown in Fig. 11. The inner end of the vane is wedge-shaped for the purpose of guiding the water between parallel or converging walls at all gate openings. The angle X should never exceed the pitch angle, and is usually somewhat less. For a small number of vanes the angle X becomes large, and the vane is extended at the tip so as to reduce the disturbances between the water flowing in adjacent openings. The form shown in Fig. 11 is adapted to the open-flume type of setting where the water approaches the guide case in practically a radial direction.

In laying out the guide case, the **pivot** should, when possible, be located slightly nearer the large end so as to divide the vane into parts (a, b) proportioned approximately in the ratio 6 to 4 for the average form of vane. This permits the gates to be balanced when about one-third or one-fourth open, and makes the maximum tendency to open approximately equal to the maximum tendency to close. It is undesirable to locate the pivot close to the point of the vane in order to secure a tendency to close at all positions, as so doing places the pivot in a smaller vane width and either necessitates a smaller and weaker pivot or a reduction of vane strength. At the same time, the unbalanced moment of the vane at the wide-open position is greatly increased, being roughly doubled if the gates are laid out so as to be balanced when closed.

The guide vanes are controlled by the regulating cylinder of the governor through a shifting ring to which all the vanes in a guide case are connected by means of links. Two general styles of connections are used and are designated as the "inside" and "outside" types of **gate gear.** The former is operated inside the wheel pit and is submerged. The vanes are usually made of cast iron, but in some cases this material is not strong enough and steel is used. All working surfaces exposed to the action of the water should be bronze-bushed or lined. The outside type of gear works outside the turbine chamber and permits of oil or grease lubrication. The guide vane is practically always cast solid of steel and is provided with a stem which projects through a stuffing box to a lever-and-link connection to the shifting ring. The inside type of mechanism is commonly used on all open-flume turbines, while the outside type of gear is used with single-runner concrete-spiral-flume turbines and all high-head units.

Pressures Due to Thrust. Exclusive of the weight of the runner (which has to be considered when the setting is vertical) there is a certain resultant hydraulic thrust to be taken care of in computing the load to be carried by the thrust bearing. The load imposed by the runner may be divided into three parts; the weight of the runner, P_1; the static pressures upon the exterior areas of the runner, P_2; and the dynamic pressure or reaction resulting from acceleration which the water attains within the runner in an axial direction, P_3. For characteristic speeds above 30 the weight P_1 (lb.) may be determined with a sufficient degree of accuracy from $P_1 = CD^2b$, where C varies from 0.1 to 0.12 for plate-steel-vane-runners and from 0.9 to 0.11 for solid cast runners, the runner diameter D and width b, being in inches. This weight P_1 should be reduced by the weight of the water displaced by the runner, which introduces a reduction of about 13 per cent., but usually this reduction is neglected.

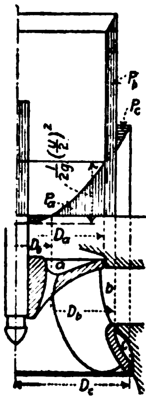

FIG. 12.

In calculating P_2, assume the runner to be adjacent to the tail-water level and consider the static pressures on the external surfaces of the runner as equal to or a function of the working head. This is practically correct regardless of the position of the runner with respect to the water levels. The water rotates in the spaces a and c (Fig. 12), and consequently the pressure increases with the radius. Assuming that the water rotates with one-half the velocity of the runner, or $u/2$, the pressure difference in ft. between any two points x and y will be $(1/2g)[(u_x/2)^2 - (u_y/2)^2]$. In addition to the pressure difference between the two points, the actual pressure at one of them must be determined. For very accurate work the pressure at the diameters D_a and D_c (Fig. 12) may be determined from the known areas of the clearance and drain openings. A relationship between total pressure available, velocities and coefficients of contraction may be drawn, keeping in mind the fact that the same quantity passes through both openings. The drain openings should ordinarily have a net area about five times that of the clearance space, in which event the pressure above them may be assumed to be 0. Similarly, the pressure is 0 at the diameter D_c on account of the large lower clearance.

Considering that the volume of a paraboloid of revolution equals that of a cylinder of equal base and half its height, $P_a = (62.4/144)A_a(1/2g) \times [\frac{1}{2}(u_a/2)^2 - (u_c/2)^2]$, where A_a is the annular area between the diameters D_a and D_c. If large drain openings connected to the draft tube are provided on the cover at the diameter D_a and the inner clearance is closed off, zero pressure may be assumed at the outer periphery D_a and the total due to pressure in the chambers will be $P_a = -A_a(0.434/4g)(u_a/2)^2$. If no drain holes are provided, the maximum obtainable pressure h_{max} at D_a reaches the value of the pressure in the guide case adjacent to the clearance, or $h_{max} = H - (c_0^2/2g)$, and the total load due to this pressure will be $R = 0.434A_a[h_{max} - (1/4g)(u_a/2)^2]$. Assuming that the guide-case pressure is constant from D_a to D_b, the load on the ring area between D_a and $D_b = P_b = 0.434A_b h_{max}$. In Fig. 12, P_b is shown as increasing with the radius. Actually this is more correct, though only a slight error is introduced in determining P_b as above.

Considering the pressure as zero at the lower clearance, the pressure in the chamber c is negative and the load will be

$$P_c = \frac{0.434}{2g}\left\{A_b\left[\left(\frac{u_c}{2}\right)^2 - ½\left(\frac{u_b}{2}\right)^2\right] - \frac{A_c}{2}\left(\frac{u_c}{2}\right)^2\right\},$$

where A_c is the annular area between D_b and D_c. For runners of higher characteristic speeds (over 40) P_c is negative and tends to reduce the load on the thrust bearing (when the lower clearance is large). The same result is obtained for runners with characteristic speeds below 40 by making the lower clearance small so that positive pressure is built up underneath the discharge ring which for these runners slopes inward. In extreme cases this effect may be increased by supplying the chamber c with pressure directly from the penstocks.

The **total load resulting from static pressure** is $P_2 = P_a + P_b + P_c$. To this should be added the pull exerted by the suction action on the end of the shaft. This is shown in Fig. 12, but it is practically negligible. The reaction force P_3 produced by the axial acceleration is $P_3 = (62.4Q/g)(c_{z0} - c_{z2})$, where c_{z0} and c_{z2} are the axial components of the water velocity at the runner inlet and outlet, respectively. For radial inlet c_{z0} will be zero and c_{z2} will be the velocity figured from the discharge area of the runner. P_3 has a balancing effect which increases with the gate opening. In determining the load on the thrust bearing P_3 is commonly neglected, as the unit should be capable of operating at low gate openings for an indefinite length of time.

An arrangement shown in Fig. 13 (Allis-Chalmers patent) is frequently used to balance automatically the end thrust of single-runner horizontal turbines. Annular spaces (a, c) are provided on opposite sides of the runner and so arranged that a slight axial movement of the runner causes a throttling and consequently a pressure increase in the flow through one side and a corresponding relief on the other. The result is that the runner is returned automatically to its original position. The clearances are kept small to prevent loss, so that the rotor has practically a fixed position and permanent oscillations are prevented. In connection with this device it is usual to provide at least a small thrust bearing for starting service, but it is given considerable clearance so as to allow the automatic balancing.

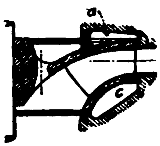

FIG. 13.

Thrust Bearings. Plain collar thrust bearings are commonly used for horizontal-shaft units, steel shoulders or collars on the shaft turning against the babbitt of the bearing. For vertical-shaft units thrust bearings of the collar, ball, roller or oil-pressure type are used. Close-grained cast iron has given very satisfactory results in connection with the former, though great care is required in fitting the disks to the shaft and base and securing perfect finish of the bearing surfaces. Pressures (p) as high as 850 lb. per sq. in. are allowable. For bearings not supplied with water cooling, $pv \leq 1000$; for cooled bearings, $pv \leq 3500$, where v = mean rotating velocity of rings, ft. per sec. Cooling is usually effected by bringing the lubricating oil in contact with water-cooling coils, either within the housing or outside of it. The coefficient of friction f varies from 0.01 to 0.005 (see p. 243). Ball bearings are frequently used for small sizes of bearings and roller bearings for the larger sizes, their small coefficients of friction (see p. 244) resulting in a saving of power and a very low starting torque.

The **Kingsbury thrust bearing**, now in general use, consists of a rigid collar, usually of cast iron, secured to the shaft and having a carefully finished bearing surface. This collar rests on several babbitted shoes or bearing blocks, which are so supported that they may tip at a very slight angle. The entire bearing is submerged in an oil bath and the coefficient of friction is stated to be from 0.001 to 0.003 for ordinary conditions.

For extreme cases an **oil-pressure type of bearing** is often used, though it usually necessitates a complicated and expensive auxiliary oil-pressure system. Sometimes it is possible to combine the regular pressure system of a plant with the thrust-bearing supply or utilize the penstock pressure for emergency purposes and reduce the cost and complications. This type of bearing has the lowest coefficient of friction of any here considered, approximately 0.0005. Roughly, it consists of two disks, one rotating and one stationary, between which oil is pumped under pressure. When sufficient pressure is maintained the disks separate slightly so that the runner practically floats on an oil film of greater or less thickness depending on the pressure used and the amount of oil pumped.

For a discussion on thrust and guide bearings, alignment, starting, shaft deflection, etc., see N. E. L. A. Reports, 1913 and 1914.

The Holyoke Testing Flume

The testing flume of the Holyoke Water Power Co. at Holyoke, Mass., was reconstructed to its present form about 1883 under the direction of Clemens Herschel. Between 2000 and 3000 tests have been made to date. Much experimental work has been carried on at this flume, and standard and special runners developed.

The tests furnish an absolute comparison of runners, tested under uniform conditions. Their application to actual installations requires good judgment in estimating the influence of difference between the test conditions and the actual power-house setting. A high-speed runner tested in Holyoke with a long flaring draft tube will not show equally good performance in a power-house setting with practically no draft tube.

The capacity of the Holyoke Testing Flume is desirably limited by the discharge conditions to 150 sec.-ft., although tests are frequently made with about 200 sec.-ft. The maximum head is 17 ft., but falls to as low as 9 ft. with a discharge of 300 sec.-ft. Test runners 30 in. in diameter are commonly used for the high-speed types, larger sizes up to 40 in. or 50 in. being permissible for medium- or low-speed forms. The higher the head and the larger the runner, the better will be the performance of a hydraulic turbine of a given type. Consequently, the majority of actual installations should show efficiencies exceeding these obtained at Holyoke.

Impulse Wheels

The Nozzle (Fig. 14). Jets of circular section are used exclusively in modern design, needle regulation being employed for controlling the diameter of the jet. The velocity in the upstream end of the nozzle pipe proper should be from 0.06 to $0.10\sqrt{2gH}$, and increase toward the nozzle tip. Smooth surfaces with carefully designed curves and passages are of great importance in reducing frictional and eddy-current losses resulting from the high velocities used. The velocity should be increased quickly at the nozzle tip and kept practically constant along the nozzle body. Also the diameter of the needle should be kept small further to reduce frictional losses. Directly at the nozzle tip f_0 the transformation of pressure into velocity is completed only at the outer surface of the jet, while in the inner portions there is still slightly more than atmospheric pressure due to the curvature of the flow, and a slightly lower velocity. On an average the velocity at the nozzle tip is 0.75 to $0.85\sqrt{2gH}$, depending on the shape of the nozzle, and the maximum velocity in the free jet is about $0.985\sqrt{2gH}$, corresponding to an efficiency of about 97 per cent. The angle of the cone of the nozzle tip at exit should be from 70 to 90 deg. With the velocities given above, the

diameter of the nozzle pipe in inches will be $d_1 = 20$ to $15\sqrt{Q_1}$, and the **jet diameter** in inches $d = 4.8\sqrt{Q_1}$. At the largest opening the needle ordinarily occupies 0.10 to 0.16 of the area of the nozzle opening. The largest diameter of the needle is fixed by the requirement that the point of inflection W (Fig. 14) of the profile of the needle should be within the nozzle when the needle is closed. This condition is necessary to prevent the jet from leaving the needle for the smaller openings, which would result in rapid corrosion. Buckets are usually made of bronze or cast steel for larger sizes of turbines and the higher heads, and frequently of cast iron for low heads (under 400 ft.). The nozzle body is of cast iron or cast steel, depending upon its diameter and the working pressure. The nozzle tip is ordinarily of the same material as the nozzle body and is frequently equipped with a renewable wearing ring of bronze. The needle is made of steel and should be provided with a removable tip to permit replacement in case of wear. All surfaces adjacent to water flowing at high velocity should be carefully finished and polished smooth to avoid eddies. Jet diameters up to about 8 in. are common, but for commercial reasons larger diameters are seldom used.

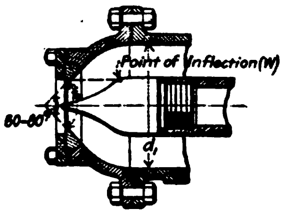

FIG. 14.—Impulse Wheel Nozzle.

Wheel Disk and Buckets. The horse power of an impulse wheel is fixed by the working head and size of the jet. The **wheel diameter** D may be chosen to suit any desired speed, except that D should never be less than about $9d$, the most favorable ratio being between 15 and 20. If a sufficiently high speed is not obtained using one nozzle, two jets may be used in connection with two wheels. Sometimes two or more jets are directed against one wheel, but this frequently results in a reduction of efficiency owing to interference of the jets. Theoretically, the most favorable **peripheral speed** of the buckets should be one-half the jet velocity, but in practice a lower value is taken, as the water must leave the wheel with some velocity and at an angle to avoid interference with the following bucket. On this account the peripheral velocity should be from 0.42 to $0.48\sqrt{2gH}$, the smaller coefficient applying to high characteristic speeds (6) and the higher value to lower speeds (up to 2).

In **laying out the buckets** care must be taken that no water is allowed to pass through the wheel without reacting fully on the buckets. To determine this the path of the water relative to the wheel should be drawn, as in Fig. 15. Relatively to the buckets every point of the jet describes an extended involute which may be constructed by rolling a straight line LL upon the circle K, assuming that the points of the jet are rigidly connected to the straight line LL. The circle K has a radius r_0c_0/u_0, so that its peripheral

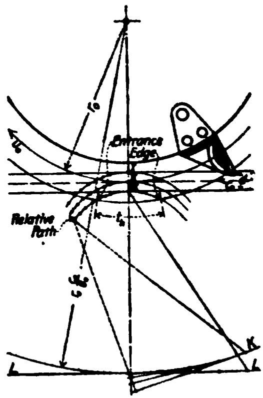

FIG. 15.—Layout of Impulse Wheel Buckets.

velocity is equal to c_0. As all of the involutes traced by the points on one flow line are congruent, it is most convenient to draw them but once as shown for the jet lines *I*, *II*, and *III*, and to turn the buckets into their relative positions. A section of the jet is cut off between adjacent buckets, the outline of this intercepted portion being shown in its relative form in Fig. 16. The ends of the various intercepted threads of the jet lie along a cycloid generated by a point which moves with the circle *K* (Fig. 15) as it rolls on the line *L*. The curve is actually the path of the entering edge of the bucket relative to the jet. Bucket No. 2 is shown in Fig. 16 in its position relative to the jet at the instant of entering the jet. The preceding bucket 1 is shown at the instant when the last thread *III* of the jet is intercepted. Position 1′ shows the bucket at the instant when the last end of jet line *I* reaches the bucket, and position 2′ when the last end of thread *III* reaches it. It should be clearly understood that the bucket positions 1, 2, 1′ and 2′ are not the actual positions corresponding to the events just mentioned, but show only the relations between bucket and jet at those times. (See also article by S. J. Zowski, *Eng. News*, Feb. 10, 1910.)

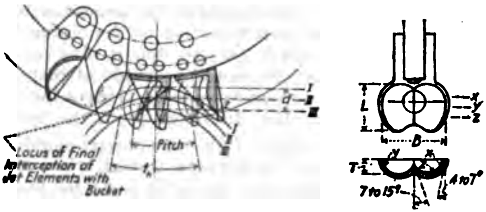

Fig. 16.—Layout of Impulse Wheel Buckets.

Where there is doubt as to whether complete reaction will be obtained, the length of the intercepted portion of the jet may be decreased by increasing the number of buckets. The limit in this direction is fixed by the difficulty in properly fastening the buckets to the disk. The alternative remedy consists in lengthening the arc t_k (necessitating increasing the wheel diameter, which in turn reduces the r.p.m.) or in increasing the radial height of the bucket. The latter is undesirable as it results in excessive friction and increases the difficulties in securing a good mechanical connection between the buckets and disk. Experiments have shown that a large number of buckets is desirable.

The connections between the buckets and disk must receive both the intermittent impact of the jet and the centrifugal force of the bucket itself. The latter increases to about 3.25 times its normal value in case of runaway, and if the wheel is blocked the strain due to impact is about 1.8 times the normal. As far as possible the splitter should be at right angles to the relative path of the jet. The main proportions of the bucket are shown in Fig. 16. The width *B* in inches should be about 15 to 19 times $\sqrt{Q_1}$, which corresponds to about 3 to 4 times the jet diameter. The length should be $L = 11$ to $14 \times \sqrt{Q_1}$, and the depth $T = 4.5$ to $5\sqrt{Q_1}$. The angle of the splitter should be between 14 and 30 deg. The exit angle is ordinarily made between 4 and 7 deg., and should be kept as small as possible, as so doing increases the efficiency even though the discharging water interferes slightly with the adjacent bucket at full gate opening. In securing the extended outer lips of the discharge edge of the bucket, the edge receiving the jet takes the form of a recess. This recess is shown in Fig. 16 and has a width only slightly greater than the jet diameter, as otherwise flow line *III* would not fully react toward the end of its flow in the bucket. The back surface of the bucket adjacent to this recess is finished at such an angle that the jet does not strike the back of the bucket, or at most at a very small angle.

The Casing (Fig. 2) consists of a lower housing into which the nozzle extends. This housing is usually of cast iron and either rests on a base flange or is secured directly to the foundations. For very small units it may support the bearings, though usually the wheel disk is attached on an extension of the generator shaft and carried by the generator bearing when used for hydro-electric units. The upper portion of the casing, called the cover, is usually separate from the lower part so that it may be removed for inspecting the wheel or nozzle tip. It should be made of plate steel so that it will not be destroyed if a bucket comes loose and leaves the disk. The width (in.) of the casing adjacent to the discharge from the buckets should be at least 30 to $40\sqrt{Q_1}$. The width of the upper part should be of sufficient radius and width to safely clear the buckets, though when its dimensions are reduced to a minimum it is advisable to put in deflector plates to prevent water which may splash on the disk and buckets from being carried around by the wheel. At high heads the surfaces exposed to the discharging jet should be carefully protected by plates of steel or cast iron, as the jet passes through the wheel freely and with almost no reduction of velocity when the wheel runs away. Efforts have been made to utilize a draft head by making the casing and housing tight and controlling the amount of air in the casing by means of floats. The complication involved can hardly be compensated for, as the maximum additional head gained is so small a percentage of the heads to which impulse wheels are usually adapted.

Regulation. Impulse wheels are regulated either by varying the size of the jet (needle regulation) or by varying the amount of the jet that impinges on the buckets (using a deflecting nozzle). The former is employed when economy in the use of water is of greatest importance. The latter finds its greatest application when a constant amount of water is to be discharged (as for irrigation purposes) or where the length of the penstock is so excessive as to preclude the possibility of quickly changing the velocity of flow by the governor. Special arrangements of either type may be adapted to this condition of extreme pressure surges.

Efficiency. A rough indication of the variation of efficiency of impulse wheels is given in Fig. 9, which is based on wheels designed in accordance with the proportions given above. As contrasted to reaction wheels the efficiency remains high over a wide range of characteristic speed and for a large variation in percentage output. Power-plant efficiencies between 85 and 90 per cent. at the maximum point are reached with careful design.

REGULATION OF HYDRAULIC TURBINES

General. Direct regulation of hydraulic turbines is prevented by reason of the considerable amount of power required to operate the gates. It is therefore necessary to make use of indirect regulation, a flyball governor (see p. 777) being employed to control the distribution of power developed in the servomotor or **regulating cylinder.** The parts which transmit the gate motion back to the flyballs in order to bring about "dead beat" regulation are usually designated as the **relay.** Means for adjusting this relay are necessary for starting, stopping or changing the speed of the unit. The earlier forms of governor embodied a design wherein the power was developed mechanically through gears from the turbine itself, but at present the hydraulic- or oil-pressure form is used almost exclusively. In this type oil or other working fluid under pressure is distributed to the regulating cylinder through a control or regulating valve actuated by the flyball governor.

The Regulating Cylinder. The design of the regulating cylinder is dependent upon the stroke used to give full travel to the gates, the maximum resistance occurring along this stroke, and the operating pressure used in the cylinder. The product of the maximum resistance (in lb.) and the stroke (in ft.) may be considered as the maximum energy required for regulation, though it is larger than the actual energy required for moving the gates from one extreme position to the other. The maximum energy required for regulating the gates of Francis turbines with guide vanes of normal design may be determined approximately from $E_r = KBDH$ or $E_r = kN_{max}/\sqrt{H}$, where E_r = energy required in the regulating cylinder, ft.-lb., D = runner diam., B = width of guide case—both in ft., H = maximum head (ft.) under which the turbine is to be regulated, and N_{max} = b.h.p. of turbine at full gate under head H. For large turbines with horizontal shafts, $K = 12.5$ and $k = 30$; for medium-sized and small turbines with vertical shafts, $K = 16.5$ and $k = 40$; for small turbines and those with slot-and-sliding-block connections, $K = 20.5$ and $k = 56$.

Determination of Speed Regulation and Flywheel Effect. In general practice a certain percentage of speed variation (usually 3 per cent.) is allowed between normal operation at full load and at no load. Within this range of speed, which corresponds to a certain definite travel of the governor collar, any one position of the collar corresponds to a certain gate opening of the turbine and consequently to a fixed number of revolutions. Let n and n_2 be the r.p.m. at full load (considered normal) and no load, respectively. Then the ratio $(n_2 - n)/\frac{1}{2}(n_2 + n) = J_r$ is termed the "**degree of speed variation of the regulation,**" and is commonly expressed as so many per cent. no load to full load. Let n_0 be the r.p.m. of the governor corresponding to the highest position of the collar travel and n_3 that at its lowest position. Then the ratio $(n_0 - n_3)/\frac{1}{2}(n_0 + n_3) = J_g$ and is termed the "**degree of speed variation of the governor**" and is commonly expressed (for example) as "a 6 per cent. flyball." J_g should always be equal to or greater than J_r.

The ratio of the change of load from N_1 to N_2 to the maximum load N_{max} is $(N_1 - N_2)/N_{max} = L$ and is termed the "**relative change of load.**" By "**speed change**" is meant the temporary percentage change in speed resulting from change of load. If n_1 is the initial speed and n_{max} is the extreme speed (n_{min} for load thrown on) the speed change is expressed by

$$(n_{max} - n_1)/\tfrac{1}{2}(n + n_2) = S \qquad (1)$$

"**Flywheel effect**" is the polar moment of inertia of the rotating masses, wr^2, in which w is the total weight of the rotating masses (lb.) and r the radius of gyration (ft.). (See also p. 218.) The maximum turning moment (ft.-lb.), corresponding to the maximum capacity of the unit at normal speed $= N \times 550 \times 60/2\pi n = 5250\ N/n$. For any load change from N_1 to N_2 the average excess or deficiency of turning moment will be proportional to $(N_1 - N_2)/2$ and the total kinetic energy (ft.-lb.) stored in or absorbed from the rotating masses will be $E = 550\ T(N_1 - N_2)/2$, where T is the regulating time in seconds. (See Fig. 17; area $AOC = \frac{1}{2}NT$.)

The corresponding energy absorbed or given out by the rotating masses is expressed by $[2wr^2\pi^2/(g \times 60^2)](n^2_{max} - n_1^2)$. Equating these two quantities and designating the speed change by S, approximately

$$S = 800{,}000\,(N_1 - N_2)\,T/wr^2n^2 \qquad (2)$$

It is evident that the speed changes are inversely proportional to the constant

$$K = wr^2n^2/N$$

where N is the maximum turbine rating. For satisfactory regulation K should ordinarily be 5,000,000 or greater, the higher the value the better being the regulation that is possible. (For derivation of formula for S, see Mead "Water Power Engineering," p. 462.) The constant K may be expressed in terms of the "starting time," T_a, in sec., which would be required for the turning moment M to start the rotating masses from rest and bring them up to normal speed n_1. $T_a = wr^2n_1^2/417N_{max}$.

The regulating time T is the time which elapses between the start of the load change and the time at which the power produced is equal to the load. (For full-load condition see Fig. 17.) It is the time required for the regulating cylinder to make its initial stroke and must not be confused with the total duration of the regulating period, which is usually considerably greater than T, as it extends up to the time when conditions have become steady. The regulating time T is composed of three parts (see Fig. 17): $T = T_1 + T_2 + T_3$. T_1 is the time which elapses until the speed is changed sufficiently to overcome the frictional resistance and lost motion in the flyballs and connections to the control valve and to open the ports of the valve enough to cause the start of the motion. As the gates are not moved during this period the speed change that takes place during the time T_1 is termed the total "unsensitiveness" S_i, and is practically uniform for all load changes. S_i = 0.5 to 1.0 per cent. T_2 is the time which elapses between the beginning of the motion of the regulating cylinder and the instant when the control valve has attained its maximum opening. During this time the gates are moved with increasing velocity. T_3 is the time from the termination of T_2 up to the instant when the output of the turbine first equals the load.

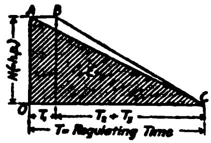

FIG. 17.

In actual practice T is nearly constant for all load changes, this resulting from the fact that the control valve does not open its full amount for the smaller loads. For very small changes (under one-fourth load) T often shows considerable reduction, but in the general determination of speed changes this reduction is neglected. The relative values of T_2 and T_3 depend upon the details of the design and on the amount of load change. On the basis of the foregoing and considering that T_1 is practically a fixed quantity, it follows that: (1) If T_1 is always large in proportion to T_3, it must be practically constant for all load changes and the speed variations occurring during the time T_2 are roughly proportional to the load changes. (2) If T_3 is large in proportion to T_2 for all load changes, the resulting regulation approaches that secured with mechanical governors where energy is supplied at a constant rate. T_3 is then proportional to the load change and the speed variations are roughly proportional to the square of the load change.

The relative values of T_2 and T_3 in proportion to the total time T will determine the relationship between the speed variations due to partial load changes and those due to a full-load change. With modern governors this relationship may be approximated from the equation S(effective) $= S_i + aS$, where a has the following values:

Load change L, per cent..........	100	75	50	25	10
a........................	1	0.6 to 0.7	0.3 to 0.4	0.15 to 0.2	0.07 to 0.1

S is ordinarily determined directly from (2), but may be closely approximated from T_2 and T_3, assuming that T_2 is small compared with T_3, that for T_3 the closing time T_s may be inserted, and that the turning moment varies directly with the time, as follows:

$$T_aS = C(T_s + T_2) \tag{3}$$

T_s is the "closing time," or the time required by the regulating cylinder for closing or opening the turbine gates, with maximum opening of the regulating cylinder valve. The usual value of T_2 is betweeen 0.1 and 0.2 sec. For short closing time (T_s = 1 to 2 sec.) $C = 40$; for long closing time (T_s = 5 sec. or more) $C = 45$.

So long as L does not exceed J_rT_a/T_s, the regulation is "dead beat" (Fig. 18*a*). If $L > J_rT_a/T_s$, the "dead beat" condition is reached only after a series of decreasing oscillations of the speed (Fig. 18*b*). The more nearly the regulation approaches the condition shown in Fig. 18*c*, the better it becomes for any given value of S (maximum). In order to obtain this condition, the governor motion is so influenced that its sensitiveness is temporarily decreased. This is accomplished either by arranging the connections in such a manner that the motion of the regulating cylinder has the effect of a brake on the governor or by means of a double or flexible relay. Both means are theoretically of equal value and in actual practice have given good results, but the latter is more commonly adopted as it is slightly more sensitive.

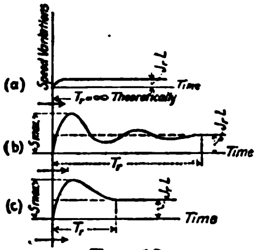

FIG. 18.

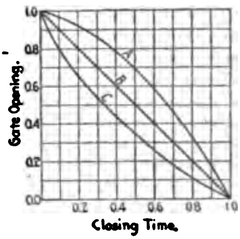

FIG. 19.

Influence of the Pipe Line. When the turbine is set in a closed flume or casing and supplied with water through a pipe line of length L (ft.) and of such dimensions that the velocity in the pipe is c_{max} for the maximum load N_{max}, the characteristics of the pipe line influencing the regulation are given by $T_l = Lc_{max}/gH$, which represents a period of time. The inertia of the mass of water causes a pressure change in the penstock close to the turbine whenever the velocity of the water is changed. This change of pressure depends on the rate of change of the gate opening. For a total closing of the gates, Fig. 19 shows three typical examples of the relationship between closing time and gate opening. Curve A indicates a slow initial motion which is accelerated toward the end of the closing time. C shows a rapid initial motion, while B indicates a fair average (used in Fig. 17).

On the basis of the average condition B and taking the pressure rise in per cent. of the head as dH,

$$dH/H = (1.3 \text{ to } 1.5)T_l/T_s \tag{4}$$

The elasticity of the water and material of the pipe line should be taken into account if $Ac_{max}/gH < 1$, where A is the average velocity of a pressure wave in the pipe. For steel-plate penstocks $A = 4700/\sqrt{1 + 0.008(d/s)}$, where d is the inside diameter of the pipe (in.) and s the thickness of the walls (in.). This expression also takes into account the effect of rivets, flanges and supports, and is based on data taken from actual installations.

For a total unloading of the turbine the effect of the penstock on speed regulation may be approximated very closely by extending the regulating time T the amount $1.35T_l$. From this, in place of (3), $T_aS = C(T_e + T_2 + 1.35T_l)$. For partial loads the speed changes will lie slightly above the values originally given in the table preceding (3), but the proportional increase will be less than that for full load.

For Francis turbines in closed casings it becomes necessary in extreme cases to take into consideration the effect of the moving water in the casing and guide case, and with open-flume turbines the draft tube sometimes has considerable effect. For casing inlet velocities of 0.25 to $0.3\sqrt{2gH}$ the pipe-line length and that of the casing may be reduced to equivalent lengths for a single velocity. The length of path in a spiral-cased turbine will be approximately $6(D + 3.3)$ where D is the runner diameter, ft.

No permanent or accumulative pressure surges will be set up by the regulation provided that $J_rT_a > 1.5T_l$, which represents the condition of stability. Pressure variations of more or less severity are permissible in connection with pipe lines, the following values of dH/H representing extreme upper limits: For heads up to 150 ft., 40 per cent.; up to 400 ft., 20 per cent.; up to 600 ft., 15 per cent.

In some instances, particularly in connection with high head installations (200–600 ft.) with long penstocks (above $3H$ in length), the closing time T_e obtained from (4) gives values of T_a larger than necessary for certain speed variations which may be desirable. Supplying additional wr^2 in the form of a flywheel gives a direct solution, and pressure regulators or by-passes are frequently used. The method adopted to take care of the surges depends upon the comparative cost of the regulators and of additional flywheel effect. If the water-saving by-pass arrangement be used care must be taken to make the time for opening the gates sufficiently long to prevent injurious pressure decreases which would be succeeded by corresponding surges on account of the elasticity of the penstock. Lengthening the opening time is not ordinarily detrimental to good speed regulation, as load increases usually occur gradually or at least very slowly in comparison to the extreme load decreases.

Often an **equalizing reservoir or standpipe** works out economically and may obviate entirely all necessity of regulators or flywheel. The maximum rise or **surge** of water level h_{max} when the total flow is suddenly shut off can be computed by equating the change in kinetic energy (ft.-lb.) in the penstock to the work done (ft.-lb.) in raising water in the standpipe or reservoir. In this determination that portion of the penstock upstream from the reservoir is all that need be considered. Let L_p = length of penstock (ft.); A_p = area of penstock (sq. ft.); v_1 and v_2 = initial and final velocities in penstock (ft. per sec.); A_s = area of standpipe or reservoir (sq. ft.); h_0 = theoretical surge neglecting friction; h_w = friction loss in ft. in penstock length L_p due to velocity v_1. Then $h_0 = \sqrt{(A_pL_p/A_sg)(v_1^2 - v_2^2)}$. For full load off, *i.e.*, $v_2 = 0$, this becomes $h_0 = v_1\sqrt{A_pL_p/A_sg}$. $h_{max} = h_0 - 0.6h_w$, and is measured above the final static or running water level. It is assumed that h_0 is greater than h_w.

The time required for the water level to reach its maximum is very nearly one-quarter of the oscillating period T of the system, which is determined from $T = 2\pi\sqrt{A_sL_p/A_pg}$. On account of the automatic action of the governor, accumulative oscillations or surges may occur if h_{max} is too large by reason of choosing too small a value of A_s. This can be obviated by making

$h_0 < \sqrt{2Hh_w}$, where H is the net working head on the turbines under steady conditions and with the velocity v_1 in the penstock.

The foregoing approximations are based on conditions of surge resulting from closing of the turbine gates. This corresponds to sudden decrease of load and is the most extreme condition ordinarily experienced in power plants. Conditions during increasing load are not usually of like intensity, as loads are picked up more or less gradually and an abrupt drop in pressure or level is avoided. For approximate purposes it is ordinarily assumed that the maximum drop below running level for any given increment of velocity does not differ greatly from the corresponding surge figured as above for a like decrease of velocity, though in actual practice when there is a large friction head to be considered it will usually exceed it. In special instances where it is desirable to determine the extent of water-level variation very closely, the method described by R. D. Johnson (*Proc. A. S. M. E.*, June, 1908), by D. W. Mead ("Water-power Engineering"), or by Prášil (*Schweiz. Bauzeitung*, 1908), may be used.

Pressure regulation by means of a standpipe or reservoir is frequently uneconomical on account of the local limitations, and pressure regulators in the form of automatic by-passes or compressed air tanks are made use of (see Johnson, *op. cit.*). By-passes or relief valves may be either governor-operated or pressure-operated, or a combination of the two. They regulate the pressure variations by causing the desired velocity change to take place gradually, the time of this change being fixed by the by-pass adjustment, which is independent of the governor time. The usual form of by-pass is so connected directly to the turbine gates that upon closure of the latter the regulator opens sufficiently to by-pass the amount of water rejected by the turbine. If it is being used as a synchronous by-pass (water-wasting) it continues discharging this water until there is an opening motion of the gates calling for additional flow. Ordinarily, however, the adjustment is such that the by-pass will close slowly so as to permit of greater water economy. The time of this closing is regulated by an adjustable dash pot and is fixed so that no injurious surge is produced. The synchronous by-pass gives ideal results so far as regulation alone is concerned, as it keeps the penstock velocity constant for both increase or decrease of load on the turbine, but is employed infrequently on account of its wastefulness in the use of water.

Working Fluid. Oil is ordinarily used as the working fluid in hydraulic governors. Water pressure is economical only for higher head installations and even then presents such operating disadvantages that it is not made use of frequently. Oil pressure is used to operate the turbine gates in practically all modern plants. The oil pumps may deliver into pressure tanks or accumulators or they may be of sufficient size to supply continuously the oil required for the regulation; the former method is followed in the majority of cases, the oil being pumped against air pressure. The usual operating pressures are between 100 and 300 lb. per sq. in., but preferably not over 200 lb.

For a plant consisting of several units a separate pump and tank may be used for each turbine or there may be a central pumping system for the station supplying oil to all the governors. The former is designated as a unit system. The pump should have a capacity per min. of three to five times the displacement of the regulating cylinder; the volume of the air space of the pressure tank should be approximately equal to the oil space (each being about five to nine times the volume of the regulating cylinder) for the unit system, and six to ten times the cylinder displacement of all units simultaneously operated for central systems. Central systems are usually in duplicate. The rotary type of oil pump is preferable except possibly in extremely large plants, as it is very simple and reliable, and the high speeds permissible allow direct connection to motor drive without special gearing. The closed arrangement of oil system wherein the oil is prevented from coming in contact with air by maintaining a vacuum in the discharge lines and receiving tanks, is not found to give satisfactory results. It greatly shortens the life of the oil and requires greater attention than does the open system. The latter is more commonly used in important installations on account of its simplicity and because it requires no special brand of oil.

Usual Governor Guarantees. Large direct-current or alternating-current generators usually furnish sufficient flywheel effect for obtaining commercial speed regulation. Values of the constant K (p. 1092) varying from 4,000,000 to 10,000,000 are found, the larger values occurring with larger sizes and higher speeds where best regulation is obtained. The closing time for open-flume units varies from 1 to 3 sec., 2 sec. being the usual rate. The difference between no-load speed and full-load speed is chosen between 2 per cent. and 6 per cent., but can be reduced to zero (constant speed) by special relay construction. For paralleling of generators some inherent drop is necessary. The higher grades of governors are so constructed as to make this difference adjustable to suit any desired operating condition. Conservative speed-regulation guarantees for open-flume settings are ordinarily made as in Table 3, these values to be corrected to allow for the influence of a pipe line.

Table 3. Approximate Speed Regulation of Open-flume Turbines

(Speed variation in percentage of normal speed)

Value of K	Regulating time of governor								
	1 sec.			1½ sec.			2 sec.		
	Percentage of load change								
	100	50	25	100	50	25	100	50	25
5,000,000	16	7.5	4.5	24.0	11.0	7.0	32	15	9.0
6,000,000	14	6.5	4.0	21.0	10.0	6.0	28	13	8.0
7,000,000	12	5.5	3.5	18.0	8.0	5.0	24	11	7.0
8,000,000	10	4.5	3.0	15.0	7.0	4.3	20	9	6.0
9,000,000	9	4.0	2.5	13.5	6.0	4.0	18	8	5.0
10,000,000	8	3.5	2.3	12.0	5.5	3.5	16	7	4.5

Overgating. A wheel is said to be "overgated" at the guide-vane opening where any increase in opening results in decrease in horse power. It is the point where the efficiency begins to drop faster than the discharge increases. The gate stops should be set so that this point cannot be reached when the unit is controlled by a governor, as it is impossible to secure regulation at or beyond this critical opening.

Hydroelectric Units. In proportioning hydroelectric units it has been general practice to choose a turbine of such size as to be able to drive the generator at 25 per cent. overload when operating at full gate. The average turbine shows best efficiency at about 0.8 load, a condition that permits of best hydraulic operation when the generator delivers its rated output and still permits of overload capacity. A more recent practice, and one which is rapidly gaining favor, consists of rating the turbine to give only a very slight percentage increase (for regulating purposes) on a generator rating known as "maximum continuous capacity." This practice reduces the probability of operating the unit continuously at some overload which, while being entirely within the range of output for which the turbine was designed, might be injurious to the generator. Furthermore, recent developments in turbine work have been in the direction of higher-speed types which show their highest efficiency usually above 90 per cent. load. It is better to place the generator and turbine ratings on a common basis and discard the separate "normal" generator rating and "full-gate" turbine rating. In alternating-current work it is necessary to consider the probable power factor in order to place the generator rating on a power basis (kw.) rather than on a current basis (kva.) which offers no indication on which to fix turbine capacity unless the power factor is known.

Outside of speed and capacity, two other features of generator design may depend on or be limited by the hydraulic end of the installation. They are the moment of inertia, upon which speed regulation depends (see p. 1091), and the rotor construction, which depends on the maximum speed attainable. The overspeed of a turbine never exceeds certain definite limits (Mead, *Proc. A. I. E. E.*, July, 1912, p. 1391), and it is customary to design the generator rotor to safely withstand this speed. Failure to do this has caused several very serious accidents in hydroelectric plants. The speed of reaction turbines at wide-open gate and no load varies from 68 to 80 per cent. above normal, while that of impulse wheels is theoretically between 90 and 100 per cent. These limits are based on normal head only, that is, the head at which the turbine gives best efficiency at normal speed. If the operating head should exceed this at times, the runaway speed limit should be raised in proportion to the square root of the head.

For example, assume 25 ft. head and a speed of 100 r.p.m. with a medium- or high-speed runner correctly designed for these conditions. The maximum overspeed would not exceed about 170 r.p.m. If, however, the head at times reached 36 ft., the maximum overspeed would not exceed about $170\sqrt{36}/\sqrt{25} = 204$ r.p.m.

This varying head feature is of importance principally in low-head plants where the ordinary head variation is a large percentage of the total. In higher-head plants this variation is not so noticeable, though the higher overspeed characteristic of low-speed reaction runners used for such heads requires a usual overspeed of about 75 to 80 per cent.

Costs of Hydroelectric Machinery. Hydraulic machinery must generally be adapted to each particular set of natural conditions. The variation of costs is so wide that a special study is required for each installation. The limits given in Table 4 represent in a rough way the usual limits of cost for the more common forms of machinery. These approximate costs are f.o.b. manufacturers' works per h.p. of maximum turbine capacity, and cover complete generating equipment from the penstock up to but not including the switchboard. Turbines, governors, generators, exciting equipment and any auxiliary gate valves or pressure regulators are included. Considerable variation from these values may be met with, though such variation will not exceed 25 to 30 per cent. on the average except where individual units, developed machinery or extremely large installations are the influencing factors. A single machine may be high in price by reason of requiring a relatively large outlay for patterns and drawings, or the equipment may be installed at an exceptionally low rate on account of some manufacturer having on hand suitable patterns. As a rule, however, the larger the installation the lower the cost per h.p. for a given head, though extremely large developments are not readily approximated on account of the special features of each case.

Table 4. Approximate Costs of Hydroelectric Machinery
(For complete generating equipment from the penstock to switchboard, but not including the latter)

H.p. of unit	Head, ft.	Cost per h.p., dollars	H.p. of unit	Head, ft.	Cost per h.p., dollars

HYDRAULIC POWER TRANSMISSION *

The use of water under high pressure as a medium for transmitting energy offers decided advantages (1) where it is required to operate slow-acting but powerful machinery whose movements must be regulated with great precision; and (2) where the motion is continuous in one direction and the demand for power is very intermittent, a large force being required at intervals for but a very short time. Water under high pressure is therefore well adapted to the operation of presses, flanging and riveting machinery, elevators, hoists, cranes, and testing machines. A number of cities in Great Britain have central stations for supplying high-pressure water to docks and factories through underground mains of cast iron or steel (when over 10 in. in diam.) and at pressures varying from 700 to 1600 lb. per sq. in. The mains have flanged joints which are grooved for the insertion of a triangular-section gutta-percha packing ring, and are bolted together. The water is received by **accumulators**, or vertical cylinders having heavily weighted plungers working through stuffing boxes at the tops, by means of which a quantity of water is stored and made available at the pressure which the weighted plungers will yield. In the **differential accumulator** the plunger is fixed and made with two diameters, the pressure acting upon the difference of area of the two diameters and the cylinder moving upon the plunger. The energy (ft.-lb.) stored in an accumulator = weight of plunger and load (lb.) × height of lift, ft. Capacity in h.-p. hours = $pAL/(33{,}000 \times 60)$, where p = pressure, lb. per sq. in., A = sectional area of plunger, sq. in. and L = length of plunger

* Staff contribution.

travel, ft. Mechanical efficiency, from 95 to 98 per cent. Where it is desired to use a pressure higher than that afforded by the accumulator, or where a moderately high pressure is wanted and only the ordinary city water pressure is available, an **intensifier** is employed. In this the low-pressure water is conducted into a large cylinder having a piston connected to a plunger of smaller diameter which works in another cylinder. Thus, if city water at 40 lb. pressure works in a 20-in. cylinder to drive a 5-in. plunger in the second cylinder, the pressure of the water in the latter, neglecting friction losses, will be $40 \times 20^2/5^2 = 640$ lb. per sq. in.

The essential apparatus of a **hydraulic crane** consists of a cylinder, a ram or plunger, and pulleys. For a direct lift the efficiency is 87 to 90 per cent. and even higher. Where pulleys are used to multiply the effective pull, the efficiency in per cent. is roughly equal to $84 - 2m$, where m = number of pulleys used. In direct-acting **hydraulic elevators** the principal resistance to be overcome is the friction of the cup leathers. According to Hick, total friction, lb. $= F = kpd$, where d = plunger diam., ft., p = water pressure, lb. per sq. ft., and $k = 0.00393$ for new or badly lubricated leathers $= 0.00262$ for leathers in good condition and well lubricated (see also p. 236). Since the total pressure on the plunger is $P = \pi d^2p/4$, the fraction of P required to overcome the friction of the leathers $= F/P = 0.005/d$ to $0.0033/d$. The velocity of the water in the mains should, in general, not exceed from 3 to 5 ft. per sec., nor the velocity through the valves of hydraulic machines exceed 100 ft. per sec.

The percentage **loss of head in hydraulic transmission** $= 63.5flH^2/p^3d^5$, where f = coefficient of friction of pipe, say 0.006; l = length of pipe, ft.; H = h.p. transmitted; p = pressure in main, lb. per sq. in.; d = pipe diam., ft. For economy, a size of pipe should be chosen that will allow a pressure drop p_d of about 10 lb. per sq. in. per mile.

Example. $H = 200$ h.p.; $p = 800$ lb. per sq. in.; $f = 0.01$; $p_d = 10$; $l = 1$ mile. The percentage loss of head is $\frac{10}{800} \times 100 = 63.5flH^2/p^3d^5$, from which $d^5 = 0.20955$, or $d = 0.732$ ft. = 8.78 in., say 9 in. Velocity of water through main, ft. per sec. $= 550H/(p \times 9^2 \times \pi/4) = 2.16$.

TIDAL POWER

Where a tide range H of 6 ft. or more is available, water may be impounded in natural or artificial basins and power developed by its flow back into the ocean through low-head turbines or undershot water wheels. According to J. Royden Peirce (*Eng. Rec.*, Jan. 27, 1912), the maximum number of horse-power hours obtainable from a tide basin is $N = [HQ - (Q^2/2A)]/31{,}800$, where Q is the available drop in the level of the basin (ft.), multiplied by the area A of the basin (sq. ft.). At a basin in Mamaroneck, N. Y., $H = 7$ ft., $A = 1{,}200{,}000$ sq. ft., and the drop = 1.4 ft., making $N = 330$ h.p.-hr. The power is used over a period of 6⅔ hr., developing on an average about 50 h.p. The author estimates that the power derivable from natural basins along the N. Y. and Conn. coasts of Long Island Sound would amount to less than 5000 h.p. Decoeur, a French engineer, proposed in 1890 to construct two large basins in the estuary of the Seine, the basins being separated by a bank or wall rising above high water, in which were to be placed low-head turbines of about 300 h.p. The upper basin (A) was to be open to the sea during the higher one-third of the tidal range (H) when rising, and the lower basin (B) during the lower one-third of the range when falling. The level in A was never to fall below ⅔H (ft.) measured from low water, nor that in B to rise above ⅓H. The available head would then vary between

0.53H and 0.8H, with a mean value of $\frac{2}{3}H$. Letting S (sq. ft.) be the area of B, $\frac{1}{3}SH$ cu. ft. of water would flow from A to B during 9¼ hr., or a mean flow of SH/99,900 cu. ft. per sec.; or, taking mean fall = $\frac{2}{3}H$, available gross horse power = $0.033S_1H^2$, where S_1 = area of basin B in acres. (See *Proc. Inst. C. E.*, 1890.)

WAVE POWER

According to Albert W. Stahl, U. S. N. (*Trans. A. S. M. E.*, vol. 13 p. 438), the total energy of an indefinite series of trochoidal deep-sea waves may be expressed as follows: H.p. per ft. of breadth of wave = $0.0329 \times H^2\sqrt{L}[1 - 4.935(H^2/L^2)]$, where H = height of wave, ft., and L = length of wave between successive crests, ft. For example, with L = 25 ft., and L/H = 50, h.p. = 0.04; with L = 100 ft. and L/H = 10, h.p. = 31.3. Not much more than a quarter of the total energy of such waves would probably be available after reaching shallow water, and apparatus rugged enough for this purpose would doubtless be unable to utilize more than a third of this amount. **Wave motors** brought out from time to time have depended for their operation largely on the lifting power of the waves. One installed at Atlantic City, N. J. (*Power*, Jan. 17, 1911), consisted of six 4-ft. cylindrical floats 4 ft. high. These, each weighing about 3100 lb., were lifted 2 ft. by the waves about eleven times per minute, and drove a horizontal shaft by means of chains and ratchets, developing but 12 h.p., steadiness being obtained by the use of heavy flywheels. The fixed charges on the excess cost of wave motors thus far proposed over steam-power plants of equal capacity, have been more than sufficient to care for the fuel and other additional costs necessitated by the use of the latter.

COST OF POWER

By L. S. MARKS

The cost of producing power is made up of two classes of costs—**fixed charges** and **operating costs.** The former are those dealing with the plant itself, practically regardless of its use, and consist of interest on the capital invested, rental of premises or an equivalent allowance, depreciation of the machinery, apparatus and buildings, taxes, insurance, etc.; also, in the case of companies engaged in the sale of power, office rental, salaries of officers and assistants, and all expenses not directly chargeable to the power plant. In addition to interest allowance, central-station engineers maintain that a *profit* charge should be made when costs of central-station power and isolated-plant power are compared; and that this profit charge should be the amount that could have been earned (over and above interest) by the capital invested in the plant had it been employed in extending the most profitable part of the business which was capable of further development. The rate of **interest** varies, but is usually taken as 5 per cent. in calculations. **Taxes** range from 0.1 per cent. to 2.0 per cent. of the investment, depending on location; for estimating purposes 1 per cent. of actual value may be assumed. **Insurance** against loss by fire or explosion may be roughly covered by an allowance of 0.5 per cent. There is little agreement among engineers on the subject of **depreciation** charges, or the amounts which should be set aside annually in an interest-bearing **amortization fund** to provide for the purchase of new apparatus, etc., to replace that worn out. Estimates of the **useful life** of the different parts of a plant vary within wide limits, one published list being as follows:

	Years		Years
Buildings, brick or concrete	50	Motors	20
Buildings, wooden or sheet-iron	15	Pumps	25
Chimneys, brick	50	Condensers, surface	20
Steel stacks, self-supporting	25	Condensers, jet	35
Sheet-iron stacks, guyed	10	Feed-water heaters	20–30
Boilers, water-tube	25	Economisers	20
Boilers, fire-tube	15	Wiring	20
Engines, slow-speed	25	Belts	7
Engines, high-speed	15	Piping	12–20
Steam turbines	25	Coal-handling machinery	10–15
Generators	25–30	Transformers	25–30

Due to obsolescence or inadequacy of apparatus, however, these periods are in practice very much shorter; the **average life** of a plant is probably but from 12 to 18 years. The average life of central power plants is still less as a consequence of the rapid developments in generating units. The **percentage to allow for depreciation,** according to eleven published estimates, varies as follows (a rough approximation would be 2 per cent. for buildings and 5 to 6 per cent. for other items):

	Min.	Max.	Avg.		Min.	Max.	Avg.
Buildings	1.0	2.5	1.9	Wires and cables	2.0	6.6	4.4
Boilers	2.5	10.0	6.2	Switchboards	2.0	10.0	5.1
Steam piping	2.5	10.0	5.5	Rotary converters	4.0	10.0	5.4
Auxiliaries	3.0	10.0	6.1	Motors	4.0	10.0	4.6
Steam engines	2.5	10.0	5.1	Transformers	3.0	6.6	5.0
Generators, belted	3.3	10.0	6.1	Shop equipment	3.0	15.0	7.4
Generators, direct-connected	3.3	8.0	5.3	Supplies and misc.	1.5	7.5	4.9

Inclusive allowances for fixed charges vary from 10 to 14 per cent.

Scrap Values in per cent. of the original cost may be assumed to average as follows: Buildings, 5; boilers, stokers and furnaces, 5; conveyors, elevators and hoists, 1; turbines, complete, 10; engines and condensers, 10; piping, valves and traps, 3; pumps, 5; synchronous converters, transformers and exciters, 10; switching apparatus and instruments, 5; alternators and motors, 10; storage batteries, 10; tools and sundries, 3.

Operating Costs include labor or attendance; supervision; fuel and water; oil, waste and other supplies; and repairs. It is difficult to give adequate information regarding **labor** costs. Generally, it may be assumed that plants of under 100 h.p. capacity can be attended to by one man for each shift of 8 or 10 hr. When the fuel consumed in one shift exceeds 2 tons, a fireman will be needed; where it exceeds 3 tons, a fireman should be employed for every 3 tons burnt or fraction thereof. Published data on the labor costs in street-railway power plants (continuous operation, 8760 hr. per annum) are as follows:

Capacity, kw.	100	300	500	1000	3000	5000	10,000	20,000
Labor cost per kw-year	$27	9.20	8.52	6.96	4.98	4.10	3.76	3.56

Estimates of labor cost are also given in Tables 3 and 4. Oil, waste and supplies form from 2 to 10 per cent. of the total operating costs, inversely as the capacity of the plant.

Load Factor. The load factor of a power plant is the ratio of the average power to the maximum power during a certain period of time. The average power is taken over a certain period of time, such as a day, a month or a year, and the maximum is taken over a short interval of the maximum load within that period. In each case both should be specified. The **plant or capacity factor** is the ratio of the average load to the rated capacity of the plant. The **demand** of an installation or system is the load which it puts on the source of supply, as measured at the receiving terminals. The **maximum demand** is the greatest demand, as measured over a suitable and specified interval (as a "5-min. maximum demand"). The **demand factor** is the ratio of the maximum demand to the total connected load. The **diversity factor** is the ratio of the sum of the maximum power demands of the subdivisions of any system to the maximum demand of the whole system, measured at the point of supply. The **connected load** is the combined continuous rating of all the receiving apparatus on consumers' premises connected to the system. [From A. I. E. E. Standardization Rules, 1914.] Few industries have a load factor as high as 80 per cent. In machine shops it is stated to range from 40 to 50 per cent.

Costs of Steam-power Plants. Tables 1 and 2 give approximate costs of the various items entering into the construction of steam-power plants. According to the authorities of Table 2, power-plant buildings contain from 50 to 100 cu. ft. per kw. of capacity and require a ground area of from 0.8 to 2 sq. ft. per kw.; buildings cost from 8 to 12 cents per cu. ft., and foundations from $1.50 to $4.00 per sq. ft. of building area. The cost of turbo-generators is given on p. 1006. Costs of completed plants, exclusive of land, are also given in Tables 3 and 4.

Table 1. Cost of Equipment of Isolated Power Plants

(P. R. Moses, *A. I. E. E.*, Jan. 12, 1912)

	Cost per kw. of capacity		Cost per kw. of capacity
Boilers (erected and set in masonry):		Gas producers	15–20
Horizontal-tube	$14–18	Electric generators:	
Water-tube	16–20	Direct-connected to high-speed engines	13–16
Steam engines:		Belt-connected to engines	12–15
High-speed, simple, direct-connected	20–25	Direct-connected to Corliss engines	16–20
Medium-speed, compound, non-condensing, direct-connected	28–35	Switchboards	5–10
Low-speed, compound, condensing, belted	20–25	Foundations	5–10
Low-speed, simple, belted	25–30	Steam fitting, including feed heater, separator, exhaust heads, tanks, pipe covering, etc.	20–30
Gas engines	50–60		
Oil engines (Diesel)	75–85		

Cost of Steam Power. Plant, fuel and labor costs, as well as estimates of fixed charges, vary so widely that it is impossible to predict power costs with any degree of accuracy. The estimates in Table 3 are for mill or factory power plants, the first five items being taken from tables devised by W. O. Webber (*Eng. Mag.*, July, 1908). They are for plants running 10 hr. a day, 308 days in the year, and at from 80 to 100 per cent. of their rated capacity. The figures for fuel consumption are based on steam consumptions ranging from 34 lb. to 14 lb. per h.p-hour, according to size and type of plant, and on evaporations of from 6 to 9 lb. of water per lb. of coal burned. With high-grade equipment, good fuel and efficient attendance, as good, or even better, results can be obtained. Very low fuel consumptions are reported for **locomobiles** (p. 961), or semi-portable engines mounted on internally fired tubular boilers with short steam connections and built-in superheaters. Such units, built in sizes from 100 to 1000 h.p., develop under test conditions a brake horse power on less than 1 lb. of coal, and should operate regularly on a consumption of 1.5 lb.

Table 2. Cost of Steam-Electric Power Stations, 2000–20,000 Kw. Capacity

(O. S. Lyford, Jr. and R. W. Stoval, *Elec. Jour.*, 1912, vol. 9, p. 322. Based on maximum continuous capacity of generators at 50 deg. cent. temperature rise)

	Dollars per kw. High	Dollars per kw. Low
Preparing site (dismantling and removing structures, making construction roads, tracks, etc.)	$0.25	0.00
Yard work (intake and discharge flumes for condensing water, railway siding, grading, fencing, sidewalks)	2.50	1.00
Foundations (including foundations for buildings, stacks and machinery, together with excavation, piling, waterproofing, etc)	6.00	1.00
Boiler-room equipment (including boilers, stokers, flues, stacks, feed pumps, feed heater, economizers, mechanical draft and all piping and pipe covering except for condenser water)	24.00	12.00
Turbine-room equipment (including steam turbines and generators, condensers, condenser auxiliaries, water piping, oiling system, etc.)	22.00	12.00
Electric switching equipment (including exciters, masonry switch structure with all switchboards, switches, instruments, etc., and all wiring except for building lighting)	5.00	2.00
Service equipment (including cranes, lighting, heating, plumbing, fire protection, compressed air, furniture, permanent tools, coal and ash-handling machinery, etc.)	5.00	2.50
Building (including frame, walls, floors, roofs, windows and doors, coal bunkers, but exclusive of foundations, heating, plumbing, etc.)	12.00	4.00
Starting up (comprising labor, fuel and supplies for getting plant ready to carry useful load)	1.00	0.50
General charges (such as engineering, purchasing, supervision, clerical work, construction plant and supplies, watchman, cleaning up, etc.)	6.00	3.00
Total, except for land and interest during construction	$83.75	38.00

Table 3. Annual Cost of One Horse Power in Factory Steam-Power Plants*

	Simple non-condensing engines			Compound condensing engines				
Rated capacity of plant, h.p.	20	40	80	100	300	500	1000	2000
Cost of plant per h.p.†	$200	190	175	170	126	96	60	56
Fixed charges at 14 per cent	$28.00	26.60	24.50	23.80	17.65	13.45	8.40	7.85
Attendance	$30.00	20.00	13.00	12.00	8.60	6.20	3.50	3.00
Oil and other supplies	$6.00	4.00	2.60	2.40	1.72	1.24	0.70	0.60
(a) Cost per horse power less fuel	$64.00	50.60	40.10	38.20	27.97	20.89	12.60	11.45
(b) Lb. steam per h.p-hour	34	32	30	20	18	16	15	14
(c) Lb. steam per lb. coal burnt	6	7	7	8	8	9	9	9
(d) Lb. coal per h.p-hour = b/c	5.67	4.57	4.29	2.5	2.25	1.78	1.67	1.56
(e) Coal per h.p-year at $1 per ton	$7.79	6.28	5.90	3.44	3.09	2.45	2.30	2.15
Cost of 1 h.p-year $(a + e)$‡	$71.79	56.88	46.00	41.64	31.06	23.34	14.90	13.60

* Plants operating 10 hours a day, 308 days in the year, at 80 to 100 per cent. of rated capacity; boilers hand-fired.

† Includes buildings, entire equipment, and erection.

‡ Cost with coal at $1 per ton. For any rate x (dollars) of fuel cost per ton, cost of 1 h.p-year = $a + ex$.

Where the load factor is low, the cost of a horse power actually delivered is higher than given in Table 3. For example, if it is necessary to have a capacity of 500 h.p., but the average load is only 250 h.p., the total cost will be made up of the cost less fuel, $20.89 × 500 = $10,445, plus the cost of the coal burned [= 250 × 1.78 × 3080 (hours) × $1/2240 (lb.)], or $612, making $11,057 per annum for 250 h.p., or $44.23 per h.p-year as against $23.34 when the plant is working at 100 per cent. capacity.

One fireman could be dispensed with, but the saving due to this would probably be counterbalanced by the increased fuel consumption at half load. In industries requiring a supply of heat as well as power, and where this heat may be obtained from the exhaust steam of a non-condensing engine, it is proper to deduct the cost of independently developing this heat from the gross power cost.

Table 4. Costs and Operating Expenses of Steam-Electric Power Plants*

	Capacity of plant, kilowatts			
	4000	8000	15,000	30,000
Cost of Plant:				
Boiler-room equipment and piping	$21.50	19.50	16.75	15.00
Generating equipment	22.50	20.50	18.25	15.50
Electric control equipment	5.00	5.00	4.50	4.00
Service equipment	5.00	5.00	4.50	4.00
Buildings, foundations and yard work	17.50	14.00	11.75	9.25
Engineering supervision	9.50	8.00	6.25	5.25
Total cost per kw. (except for land and interest during construction)	$81.00	72.00	62.00	53.00
Operating Cost:				
Labor	0.22	0.15	0.123	0.095
Water, supplies and repairs	0.14	0.09	0.073	0.050
Coal at $1.00 per 10,000,000 B.t.u. (= $3 per ton, approx.)	0.42	0.36	0.329	0.300
Total, cents per kw-hr	0.78	0.60	0.525	0.445

* From curves in the "American Handbook for Electrical Engineers," embodying average results from a large number of plants operating with load factors ranging from 25 to 33 per cent.

The **total cost of a kilowatt-hour** of electric energy at the switchboard terminals may be calculated approximately from Table 4. Assume a plant of 15,000 kw. rated capacity. According to a preceding paragraph (taking average values), such a plant would occupy a ground area of 15,000 × 1.5 = 22,500 sq. ft. which, at $2 per sq. ft. (value assumed only for purpose of calculation) would cost $45,000. The cost of the plant (Table 4) = 15,000 × $62 = $930,000. Interest on average investment during construction would probably be covered by $25,000, making a total investment of $1,000,000. Fixed charges on this amount at 12 per cent. = $120,000. The rated output of such a plant would be 15,000 × 8760 = 131,400,000 kw-hr. per annum. Assuming the load factor to be 30 per cent., the actual output would be 39,420,000 kw-hr., whence the fixed charges per kw-hr. would be $120,000/39,420,000 = 0.304 cent. Adding this to the operating cost from Table 4 (0.525 cent), gives the total cost of 1 kw-hr., with coal at $3 per ton, as 0.829 cent. The actual power costs in large plants are frequently much lower than this figure.

Cost of Water Power. Water-power plants cost from $20 to $200 per h.p., depending on the capacity, the head employed, whether or not a dam is required, difficulties of construction, etc. Ordinary low-head plants cost from $60 to $100 per h.p. The cost of power per h.p-year ranges from $10 to $30, being usually under $15 for ordinary low-head plants. For costs of hydro-electric machinery, see p. 1097.

Cost of Gas Power. See p. 1065.

HOISTING AND CONVEYING

BY

C. KEMBLE BALDWIN

HOISTING MACHINERY

TYPES OF DRIVES

Hand Power is applied by crank, lever, chain or rope, and is used where an apparatus is required intermittently for short periods. Hand-power drives are limited to short-lift, slow-speed hoisting. They are of low efficiency, owing to the large speed reduction required.

Transmission Drives are applied by means of belts, ropes or friction wheels, and are used only where power is already installed for other purposes. The capacity of a transmission drive is limited by the connecting member. The maximum power for belt drives is about 15 h.p.; for friction drives, about 5 h.p.

Compressed-air Drives are applied in two ways: (1) By direct-lift apparatus in which the air acts on a piston to which the load is attached directly or through intermediate pulley blocks. (2) The air is used in engines of either the reciprocating or rotary type, to which the load is connected by gearing, drum and cable. Compressed-air hoists are used where air supply has been installed for other purposes. Their radius of action is relatively small, being limited by the flexible connection to the source of air supply.

Combustion-motor Drives are used for operating small or medium-capacity hoists in locations where steam or electric power is not available. Combustion motors must be started without load, therefore clutches are required to connect the load after the engines are up to speed. They are not satisfactory under fluctuating load.

Hydraulic Drives are applied by water under pressure acting on a piston, to which the load is attached directly or through intermediate pulley blocks. They were formerly used universally for heavy lifting in steel mills, for elevators, cranes, etc. Electric drives have practically replaced hydraulic drives in all hoisting machinery except in the case of elevators. The radius of action is limited by the flexible connection where hoist is movable, and where stationary by the cost of installation and maintenance of pumps, piping, etc.

Steam Drives are used principally where a central steam supply is available, as in the case of mine hoists, and on portable hoists where the engine and boiler are mounted on the same base. By the simple manipulation of throttle and brakes, heavy loads may be hoisted and lowered very rapidly and smoothly, the steam cushion absorbing the shocks of sudden starting and stopping. Stationary hoists are limited only by their distance from the source of steam supply. Portable hoists are limited by the weight of boiler and engine to about 50 h.p.

Electric Drives are now used where transmission, compressed-air, hydraulic and steam drives were formerly employed. The economy, ease of transmission and flexibility of electricity and the great improvement of the control apparatus have resulted in the general adoption of the electric drive for all types of hoisting apparatus.

PARTS OF HOISTING APPARATUS

Drums are made with smooth surfaces on hand-power hoists and on power hoists where the rope speed is low; and with grooved surfaces when the rope speed is over 1000 ft. per min. Up to about 4 ft. diameter they are usually made of cast iron in one piece. Larger drums have cast-iron or cast-steel spiders with either smooth wooden lagging or grooves attached as cast-iron or hard-wood segments. To reduce weight, large high-speed drums are built with cast-iron hubs, channel spokes and steel-plate outer surface reinforced with angles. Conical grooved drums are used on mine hoists to equalize the work on the engine. The diameter of the drums is fixed by the diameter and construction of the hoisting ropes (see p. 844). The face of a drum is made wide enough to hold the required amount of rope plus three or four holding turns. The hole in the drum face through which the end of the rope passes to be secured should be as shown in Fig. 1, in order to prevent excessive bending.

Fig. 1.

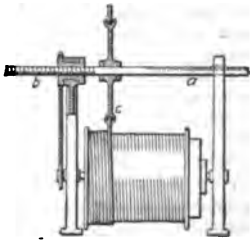

Fig. 2.—Hoisting Drum.

Where there is side draft on the rope, movable **idlers** are provided to align the rope with groove. The idlers may be moved parallel to the face of the drum by the side pressure of the rope or driven positively sideways, thus eliminating friction and increasing the life of rope. In Fig. 2, the idler sheave *c* revolves between fixed collars on shaft *a*, which is connected to the drum shaft by sprocket and chain. The shaft is prevented from rotating by a feather key. The sprocket *b* being a nut held from moving sideways by flanges, the shaft *a* with the sheave *c* is moved in the direction of its axis. In an alternative construction the idler shaft is threaded but held stationary, and the sheave hub is a nut. The sheave is turned by the friction of the rope, which causes it to travel back and forth. Fig. 3 shows construction used when the side draft is excessive. The upright rollers *a*, *a* are moved sideways by screw *b* driven by sprocket and chain *c* from the drum shaft. Where necessary to wind the rope on the drum in several layers, a clutch is provided to reverse the direction at the end of the travel.

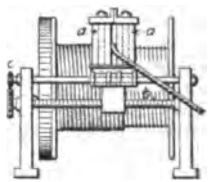

Fig. 3.—Hoisting Drum.

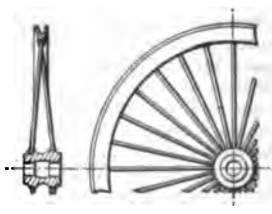

Fig. 4.—Rope Sheave.

Sheaves (see p. 741) should be grooved to fit the rope as closely as possible, to prevent the rope from assuming an oval or elliptical shape under heavy stress. They should be balanced and properly aligned to prevent swaying of the rope and its consequent abrasion against the sheave flanges. When the tension is great and speed high, the grooves are filled with renewable hardwood blocks. Sheaves up to 5 ft. pitch diameter are cast in one piece in iron or steel, Fig. 157, p. 741. Sheaves up to about 10 ft. diameter, Fig. 4, are made with cast-iron hubs and rims with round steel spokes cast in. Sheaves larger than 10 ft. are built as shown in Fig. 5, with cast-iron or steel segmental rims, cast hubs and steel spokes bolted with turned and fitted bolts.

Counterweights are used with elevators, skip hoists, mine hoists and the like, to equalize the engine load. The engine or motor is thereby smaller, as it must only accelerate the total mass and overcome friction. The brakes of a counterbalanced system must be more powerful than for the same hoist without counterweights, as they must retard greater masses. Skip and mine hoists are counterbalanced by means of duplicate cars, one traveling up while the other goes down. The effective load is the difference between the weights of a full and empty car, corrected for the weight of the rope. Elevators are usually overbalanced, *i.e.*, the counterweight exceeds the light weight of the car by the average expectation of load. With high lifts, the weight of rope is neutralized by compensating chains hung from the top of the shaft and attached to the bottom of car, producing no pull when the car is down and the maximum when at the top.

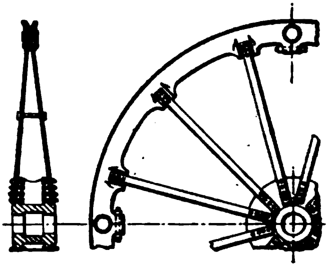

Fig. 5.—Segmental Rope Sheave.

Brakes (see p. 700). The smaller hoists are provided with band brakes, usually hand-operated, and the larger hoists with post brakes, mechanically operated. On electric hoists, it is usual to apply the brake with a weight or spring and remove it by a solenoid. Should the current fail, the brakes are automatically applied. A dash pot is sometimes used to avoid shock. On steam hoists, the brake is taken off by a steam piston and cylinder instead of a solenoid. On overhead cranes, load brakes are used to sustain the load automatically at any point and to regulate the speed when lowering.

In one type of load brake (Fig. 6), the motor *A* drives drum *B* through the load brake on the intermediate shaft *D*. This consists of a spider *C* keyed to shaft *D*, its inner end supporting one end of a coiled bronze spring of square section *E*. The opposite end of spring is fixed in the flange *F* loosely fitted to shaft *D* and directly attached to pinion *G*. Any relative angular motion of flange *F* and spider *C* alters the closeness of the coiling of spring *E*, consequently also altering its outside diameter considered as a drum. This outer surface is one of the friction surfaces of the brake, the other being provided by the internal face of drum *H*, which revolves loosely on the shaft *D* at one end and on flange *F* at the other. It is restrained from moving in one direction by ratchet *I* and pawls *J*. The exterior of drum *H* is grooved for heat dissipation.

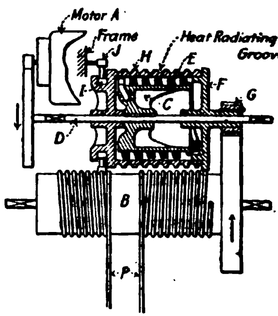

Fig. 6.—Load Brake.

The action of the load brake in Fig. 6 is as follows: When hoisting, the brake revolves as shown by the arrow. Pawls *J* permit drum *H* to revolve, consequently the whole mechanism is locked and revolved as one piece. When stopping the load, the downward pull of the load reacts so as to drive drum *H* against pawl *J*. Flange *F* therefore moves slightly in an angular direction relative to spider *C*, and spring *E* consequently untwists until it grips interior of drum *H*, thus locking the load. The action is such that the grip is slightly more than necessary to hold the load. Reversing the motor for lowering the load drives the interior of brake surface against drum *H*, so that the power consumed is the amount necessary to overcome the excess holding power of the brake over the load reaction.

Load brakes of the disk type and cone type (see pp. 702, 703) are also used, which embody the same principle of pawl locks and differential action. The type should be chosen with a view to smoothness of working and lack of chatter, as well as to the power required for lowering at different values of load within the range of the crane.

LOAD SUSPENSION

Wire Rope (see p. 843). For **hoisting** devices, where flexibility is the chief consideration, the rope generally used is made of 6 strands of 19 wires each on a hemp core (Fig. 1, p. 845). Extra pliable ropes are made with 6 strands, 37 wires each, or 8 strands, 19 wires each, on a hemp core. These ropes, while more flexible and permitting of the use of smaller drums and sheaves, are made of smaller wire, and hence are less durable. For **haulage**, where resistance to abrasion is the determining consideration, the rope is made of 6 strands of 7 wires each on hemp core (Fig. 4, p. 846). This construction presents heavier wire to resist the wear of cable grips, etc.

Fig. 7.—Haulage Rope.

Fig. 8.—Lang Lay Rope.

Hoisting ropes are constructed with the relative twist of the wire in the strands the reverse of the twist of the strands about the core, Fig. 7, and should not be spliced. Haulage ropes are of the same construction or of the Lang lay type, Fig. 8 (twist of wire and strand in the same direction), which construction increases the distribution of the surface wear and also the life. Lang lay ropes have a tendency to untwist, so should not be used when the load is in free suspension. They are difficult to splice.

Reverse bends should be avoided in hoisting ropes, and all drums and sheaves should be of the same diameter to obtain the maximum service from the ropes. Hoisting and haulage ropes should be frequently greased to prevent corrosion; boiled linseed oil is used on ropes subjected to atmospheric action, and crude petroleum and graphite on haulage and hoisting ropes in wet places. The greatest wear on ropes is at the points of attachment to the load, which should be frequently inspected and new connections made at the first sign of wear. Sufficient extra rope is usually coiled up inside the drum to be paid out to make these connections. For **strength** and working loads of wire ropes, **sizes of drums** and sheaves, etc., see pp. 843–851.

Fig. 9.

Hoisting Chains are used for handling very heavy loads through short distances and also in cases where abrasion would destroy ropes. Chains require greater drum faces than ropes. For light loads, plain welded link chain is used (Fig. 187, p. 761); for heavy loads, stud link chain (Fig. 9), the stud preventing the link from distorting. Chains should be frequently inspected and annealed. For weights, dimensions and safe loads, see Table 95, p. 760.

Hooks for cranes, etc., are usually made with swivel, on the larger sizes with ball, bearings, as in Fig. 10. Fig. 11 shows a safety hook, the sliding collar *a* on the shank locking the safety lever *b*. Fig. 12 shows a hook with a safety handle to protect the workman when guiding the hook. For design of hooks, see p. 761.

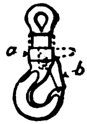

FIG. 10. FIG. 11. FIG. 12.
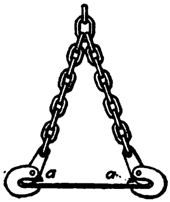
Crane Hooks.

Lifting Tongs. Fig. 13 shows the type used for lifting plates. The cams *a* grip the plate when the chains tighten, preventing slipping. They are safer than plain hooks. Self-closing tongs, Fig. 14, are used for handling logs, manure, straw, etc. The rope *a* is attached to and makes several turns around drum *b*; chains *c* are attached to the bucket head *e* and to drum *b*. When power is applied to rope *a*, drum *b* is revolved, winding itself upon chains *c* and closing the tongs. To open, slack off on rope *a*, holding tongs on *d* attached to head *e*.



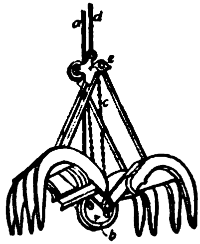


FIG. 13. FIG. 14.
Lifting Tongs.

Lifting Magnets (see also p. 1600) are used for handling pig iron, scrap iron, castings, billets, tubes, rails, plates and other finished materials; also used to handle skull-cracker balls in scrap yards, and in some localities for handling magnetic iron ore. They are of two **types**: circular magnets, for handling pig iron, scrap and similar detached material; and bi-polar, for handling rails, beams and similar products of fairly heavy section and considerable length. Rectangular magnets are used to some extent in handling plates which are flexible and tend to pull away from the magnet face by their deflection. Circular magnets are the most rugged and rectangular the least rugged.

Lifting magnets should not be used for carrying material over the heads of workmen, as failure of current will drop the load. Safety tongs are sometimes used in connection with magnets, but they are cumbersome and limit output. If 10 tons or more of material is to be handled per day and a crane is available for service, the installation of a magnet will be profitable.

Circular magnets, Fig. 15, consist of a steel casing *a* having an annular slot in its lower face in which the magnetizing winding *b* is placed. Strap copper windings are usually employed, permitting a greater number of ampere-turns in the same space than circular wire. The slot is covered by a non-magnetic plate *c* of manganese steel held in position by removable pole shoes *d*. Circular magnets are usually suspended by three chains. The headroom required is given in Table 18, p. 1601. Bi-polar magnets, Fig. 16, have a horizontal core *a* enclosed by a magnetizing winding *b*. The core has poles *c* which project below the clearance line of the winding.

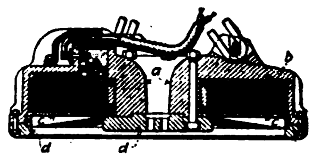

FIG. 15.—Lifting Magnet.

Lifting magnets are operated on 220-volt direct-current circuits. The magnet controllers automatically shunt a discharge resistance across the magnet terminals just prior to the opening of the magnet circuit, and automatically disconnect it just prior to the re-establishment of the circuit. This renders harmless the strong inductive reaction when the circuit is suddenly opened and protects the magnetizing winding. To release the load instantly, the current in the coil is reversed, overcoming the residual magnetism that causes the load to cling after the circuit is opened.

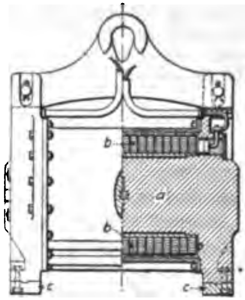

Fig. 16.—Bi-polar Lifting Magnet.

Cable take-ups, Fig. 17, are usually used to keep cable taut. Special types are used on locomotive cranes. The diameter of sheaves should be at least 30 times the diameter of cable. **Capacity** depends on the nature of the material handled (see p. 1601). When handling heavy steel scrap, the capacity will be about 10 per cent. greater than with pig iron. In figuring the kw.-hours required per ton of material handled, assume the magnet energised but 50 per cent. of the time when in continuous service.

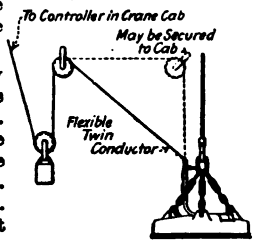

Fig. 17.—Cable Take-up for Lifting Magnet.

Tubs. Self-dumping tubs, Fig. 18, are rapidly being superseded by self-filling buckets. Tubs are mounted on steel rollers and filled by hand. When empty, the center of gravity is back of the trunnions; when filled, it is in front, so that the tub will dump itself when trip bar *a* is raised. They are also made with trip levers on the bale. By raising the tub until the levers come in contact with a stop on the trolley, the latch is released. To prevent breakage of material, the latch is arranged so that tub may be lowered on to pile, automatically releasing the latch. When the the tub is raised, it dumps. Tubs are made in sizes of from 10 to 20 cu. ft. for hand filling, and up to 140 cu. ft. for spout filling. Bottom-dump tubs are used when the load must be accurately placed in such work as charging furnaces, placing concrete, etc. Various types of bottom doors are used, Fig. 19 showing a single door with hand-operated latch.

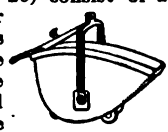

Fig. 18.

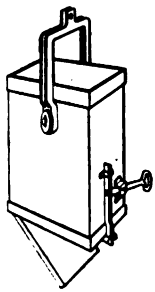

Fig. 19.

Self-filling Drag-line Buckets (Fig. 20) consist of a scraper bowl which is drawn by rope *b* over the material to be handled. The shackles of *b* are so attached that the cutting edge will penetrate the material. When the bucket is filled, it is raised by rope *a* and carried to the dumping position, when rope *b* is released, allowing the load to dump. These buckets are built with capacities from 1½ to 3½ cu. yd. Their design is determined by operating conditions.

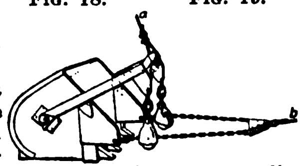

Fig. 20.—Self-filling Drag-line Bucket.

Grab Buckets. The more important **types** of grab buckets described below have their approximate **weights, capacities** and **dimensions** given in Table 1. The **Hayward** type, Fig. 21, is used for handling coal, sand, gravel, etc., and for other materials which do not pack tightly and which may be easily dug. The holding rope *a* is made fast to the head of the bucket. The closing rope *b* makes several wraps around and is made fast to drum *d* mounted on the shaft to which the scoops are pivoted. The chains *c* are made fast to the head of the bucket

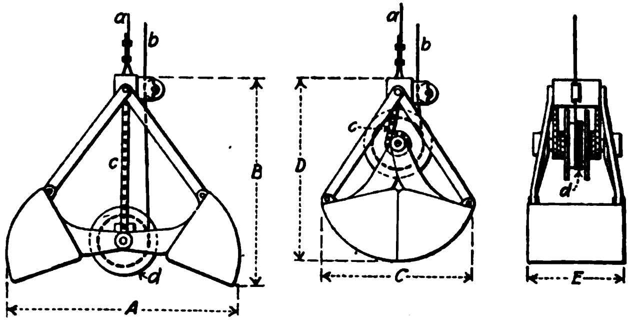

Fig. 21.—Hayward Grab Bucket.

and to the small diameter of drum *d*. When power is applied to rope *b*, it causes the drum to wind itself up on chain *c*, raising the drums and closing the bucket. To dump, hold rope *a* and slack rope *b*. The digging power of the bucket is determined by the weight and the ratio of the diameters of the large and small parts of the drum. In the **Williams** type, Fig. 22, used for the same service as the Hayward, the holding rope *a* is attached to the head

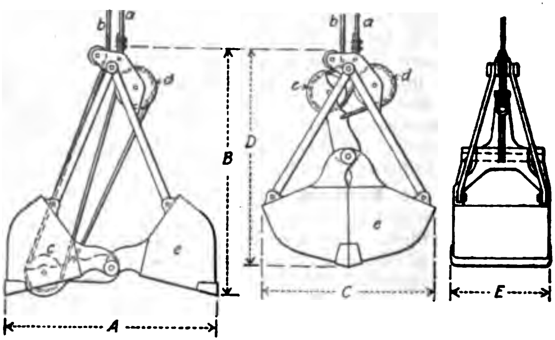

Fig. 22.—Williams Grab Bucket.

of the bucket. The closing rope *b* passes around a bend sheave in the head of bucket, over sheaves *c* and *d*, and is made fast to the arm carrying sheave *c*, which is attached to shell *e*. To close the bucket, rope *a* is slacked and power applied to *b*, drawing sheaves *c* and *d* together. To open the bucket, the weight is carried on rope *a*, rope *b* is slacked and the bucket then opens automatically. The **Andresen-Evans** type, Fig. 23, is used for handling coal, stone and (in the heavier types) ore. The hold rope *a* is attached to the bucket arms by chain shackles to open the bucket. The closing line *b* is made fast to and makes several wraps around the large-diameter drum *c*, which is mounted on a shaft carried by the frame of the bucket to which the scoops are pivoted. The four chains *f* are made fast to the small diameter of the drum *e*, the other ends being made fast to the bent strut *d* above the drum *e*. When power is applied to rope *b* it re-

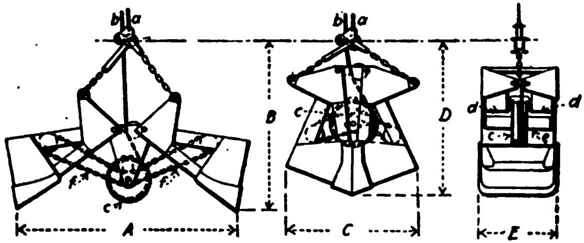

FIG. 23.—Andreesen-Evans Grab Bucket.

volves drums *c* and *e*, causing chains *f* to wind upon the small-diameter drum *e*, closing the bucket. To dump bucket, the weight is held by rope *a*, and rope *b* is slacked, allowing the bucket to dump automatically.

In the **Brownhoist** type, Fig. 24, used for handling coal, ore and similar materials, the path of the bucket gives a true scraping motion and the bucket head does not lower when opening, as is the case with other types. The hold rope *a* is made fast to the trolley above and passes over sheave *c* in the head of the bucket, the other end of the rope going to the hoisting drum. The

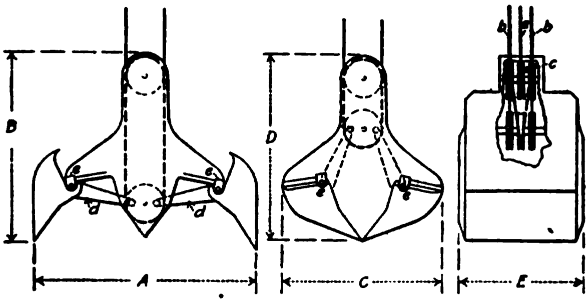

FIG. 24.—Brownhoist Grab Bucket.

speed of hoisting can be doubled by leading both ends of rope *a* to the drum. Rope *b* passes over the two sheaves in the head of the bucket and the three sheaves in the sliding cross head. When power is applied to rope *b*, the sliding cross head is raised. The arms *d* of the scoops are pivoted to the sliding cross head and a sliding connection *e* pivoted to the scoop causes the scoops to be drawn in as the cross head is raised. To dump the bucket, the weight is carried by ropes *a* and rope *b* is slacked, allowing the bucket to dump automatically.

The **Hulett** type, Fig. 25, is used for handling coal, ore and **similar materials**. The scoops are pivoted at points *c*, from quadrants on shaft *d*, and on links

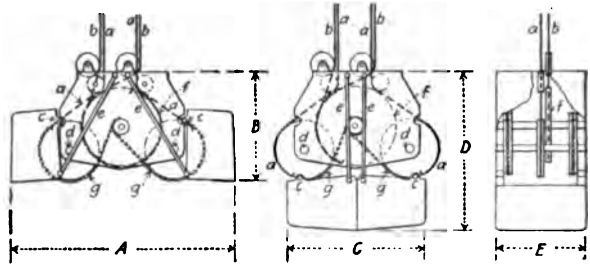

Fig. 25.—Hulett Grab Bucket.

e, so as to give a scraping motion to the bucket. These buckets are operated by four ropes, except in the smaller sizes. The holding ropes *a* pass around sheave on shaft *d* to open the bucket. The closing lines *b* pass around sheave *f*, and the chains *g* fastened to quadrants on shaft *d* are made fast to small diameter of drum *f*. To open the bucket, slack cables *b* and hold cables *a*. To close the bucket, slack cables *a* and pull in on cables *b*.

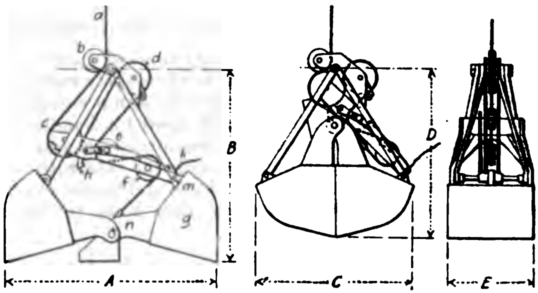

Fig. 26.—Williams Single-rope Grab Bucket.

The **Williams** single-rope type, Fig. 26, is used for handling coal, sand in foundries, and in other places where the digging is not difficult and where but a single-drum engine is available, or where it is desirable to hook the bucket on a derrick or crane hook. Rope *a* passes around sheave *b*, around sheaves *c* (carried by the latching arm), *d* (carried by the head of the bucket), *e* and *f* (carried by the latching arm), and is made fast to the arm of scoop *g*. The open view of Fig. 26 shows the latching arm when the bucket is resting on the material and rope *a* is being slackened. The latching arm, pivoted at point *m*, is lowered until latch *h* engages a projection on extended arm of scoop *g*. When power is applied to rope *a*, the latch *h* raises the shaft *n*, closing the bucket. To discharge, the trip rope *k* releases latch *h*, allowing the bucket to

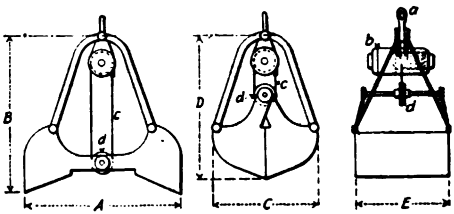

Fig. 27.—Hayward Electric Single-rope Grab Bucket.

open automatically. The **Hayward electric** single-rope type, Fig. 27, is used for handling coal, sand in foundries, and in other places where it is desirable to hook the bucket on a derrick or crane hook. The bucket is hung from the crane or derrick hook by the eye *a*. The four bucket arms are pivoted on this head, and suspended therefrom is a self-contained electric hoist *b*, consisting of motor, gear-reduction box and drum. One end of the rope *c* is made fast to the casing of the hoist, and the other to the hoist drum. When current is turned on, the drum revolves, winding up the rope, thus

* Dimensions and weights given are for coal buckets.

raising sheave d and closing the bucket. To dump the bucket, the hoist is reversed. The hoist is provided with a disk clutch, which is adjusted to slip should the bucket be prevented from closing by a large lump. This clutch also slips if the motor is not stopped when bucket is entirely open or closed. This prevents overloading the motor. The ¾-cu. yd. bucket is provided with a 4-h.p. motor. The 1-, 1¼- and 1½-cu. yd. buckets have motors of from 6 to 10 h.p., according to the duty. The **orange-peel bucket,** Fig. 28, used for digging material which cannot be dug with grab buckets, consists of four blades pivoted to a moving cross head. The operation of the bucket is the same as that of the Hayward type, Fig. 21.

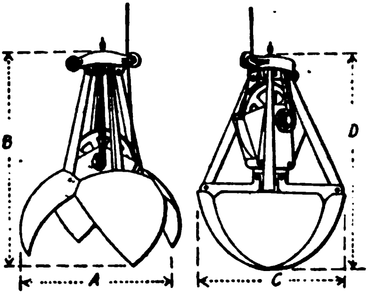

FIG. 28.—Orange-peel Bucket.

HAND-POWER HOISTING APPARATUS

Winches and Crabs are hand-power hoisting devices used with ropes and sheaves. (Called crabs when mounted on skids as independent hoists, and winches when attached to cranes, derricks, etc., forming their hoisting mechanism.) They are limited to short lifts, slow speeds, and intermittent hoisting. They consist of a rope drum geared by one or more reductions to hand cranks, and are usually provided with a band brake for lowering and ratchet and pawl for holding the load. Fig. 29 shows a double-purchase crab; Fig. 30 a double-purchase winch. Cranks may be used on intermediate or drum shafts to handle lighter loads quickly. Winches and crabs are built in capacities up to 5,000 lb. on a single rope. By the use of block and tackle heavier loads may be handled at corresponding slower speeds.

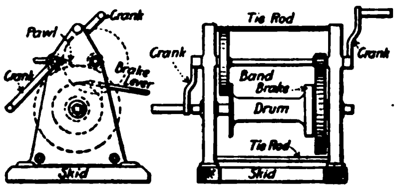

FIG. 29.—Double-purchase Crab.

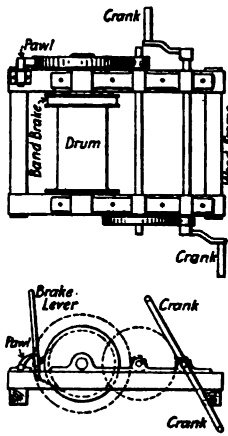

FIG. 30.—Double-purchase Winch.

Capstans, Fig. 31, are used mainly on shipboard for applying power to Manila rope. The base a is bolted to the deck and carries shaft b. Base a has recesses to receive pawls c and d. The gear plate e carried the pawls d and three pinions, f, meshing with

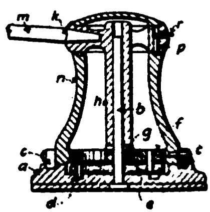

FIG. 31.—Capstan.

with the center gear *g* which is attached to the head *h* by a jaw clutch. The head *h* has holes *k* to receive the capstan bars *m*. The barrel *n* carries the pawls *c*, also the annular gear at the lower part, meshing with pinions *f*. When the head *h* and barrel *n* are attached by pin *p*, light loads are lifted by giving the rope several turns about the barrel *n*, the pawls *c* keeping the barrel from reversing. When hoisting heavier loads at a slower speed, the release pin *r* disengages the head *h* from the barrel *n*, and the motion from the head is transmitted through the center gear *g*, the pinions *f*, to the annular gear of *n*, thus increasing the power, due to the gearing. The pawls *d* and *c* hold the barrel from reversing. A capstan may be operated by a steam engine or electric motor placed below deck and geared to shaft *b*.

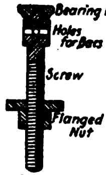

FIG. 32. House-raising Screw Jack.

Jacks are portable tools used for lifting heavy loads through short distances. There are three types in common use: Screw jacks, used in house raising, shoring, etc,; rack-and-lever jacks, for light work; and hydraulic jacks, for very heavy work. Owing to the large reduction, the lifting speed is slow. Their range is limited by weight of the jacks, which must be portable. **House-raising screw jacks**, Fig. 32, consist of a heavy screw threaded into a flanged nut. The screw head is fitted with a ball with socket in the bearing plate. The screw is turned by a bar passing through holes in the screw head. Fig. 33 shows a bell-base screw jack sometimes fitted with a ratchet head in place of the bar, thus increasing the speed. **Rack-and-lever jacks**, Fig. 34, consist of a cast-steel or malleable-iron base and post to which is pivoted the lever and pawl. The rack-toothed bar passes through the hollow post and is raised by the pawls actuated by the lever. The load is both raised and lowered by the lever. **Hydraulic jacks** are made in a great variety of forms according to service. Fig. 35 shows the common type, consisting of a base or cylinder and a head or piston. The head serves as a reservoir for the fluid and contains also the pump rods. At the lower end is the pump piston which draws the fluid from the reservoir and forces it through the valve in the bottom of the head into the base, thus forcing the piston or head up. The operating lever is so constructed that during pumping the travel is limited, but by reversing the lever the pump piston travels beyond the pumping position, touching the check-valve stem and allowing the fluid to pass back through a by-pass into the reservoir in the head, thus lowering the load. House-raising jacks are made with lifts up to 50 in. and are used in multiple, thus raising any desired load. Bell-base screw jacks have a maximum lift of about 30 in. Lever-and-rack jacks will lift 15 tons through 19 to 20 in. Hydraulic jacks of the type illustrated are made to lift 50 tons 18 in. Special types will lift 250 tons 18 in. Bridge jacks are built to lift 600 tons 12 in.

FIG. 33. Screw Jack.

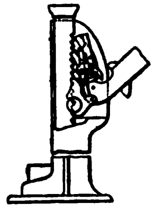

FIG. 34. Rack-and-lever Jack.

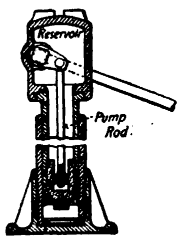

FIG. 35. Hydraulic Jack.

Chain Hoists are portable lifting devices suspended from a hook and operated by hand chain. They are used for short lifts and for intermittent service on loads up to 20 tons. The limit of weight of hoist is about 1400 lb. and that of the maximum practical downward pull on the operating chains is about 500 lb. Three types are in common use, each being provided with a hook to suspend the hoist from the overhead member, hook and chains for supporting the load, and hand chain for imparting power. The **differential hoist** (see Fig. 36, p. 658) consists of three chain sheaves with an endless chain for lifting and operating. One of the upper sheaves is constructed with an extra link pocket. The difference in diameter being too small to overbalance the friction of the parts, the load is automatically sustained at any point, making the hoist self-locking. The **worm-gear hoist**, Fig. 36, consists of an operating chain *a* passing over pocket sheave *b* mounted on worm shaft *c*. The worm imparts motion to the two load sheaves *d*. The load chain is attached to the swivel hook and passes over the load sheaves, the slack hanging in a loop. The worm gear makes the hoist self-locking. Separate chains are used for hoisting and operating. The **spur-gear hoist** (see Fig. 38, p. 658) has a higher efficiency than the other types, as it does not depend on friction of the mechanism to sustain the load. A mechanical brake, consisting of a ratchet and pawl and friction plate, sustains the load. To lower, the hand chain is pulled, overcoming the friction of the friction plates and revolving the ratchet. Table 2 gives **capacities**, weights and general data of the three types.

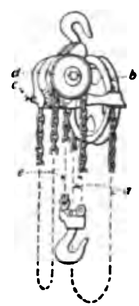

FIG. 36. Worm-gear Hoist.

* Spur-gear hoists—12-, 16- and 20-ton—have 2 operating chains. The pull on chains and the amount of chain overhauled is the total for the 2 chains.

POWER HOISTS

Pneumatic Hoists are used for short lifts in places where compressed air is already installed. The movable hoist is limited by the flexible air connection to a radius of about 25 ft. The direct-acting hoist is made with stroke from 4 to 10 ft. or more, but with rope and sheaves may be geared up to 6 : 1 or more. Fig. 37(*a*) shows the direct-acting hoist, consisting of a cylinder *d*, piston *e* and piston rod *f*, on the end of which is a hook for the attachment of the load. This hoist is made both single- and double-acting. The single-acting hoist is hung vertically, the upper end of the cylinder being open to the atmosphere, and air under pressure admitted at the lower end, lifts the piston and load. The double-acting or balanced-pressure hoist has the motive end of the cylinder under constant air pressure and the balancing end subject at will to a variation of from full to no pressure. The force exerted by the hoist is due to the difference in pressure on the two sides of the piston. As the area of the piston rod makes the effective area on the two sides unequal, the piston is forced toward the stuffing box when the air pressure is equal on the two sides. The double-acting hoists may be used vertically or horizontally. Fig. 37(*b*) shows the reeving for a horizontal cylinder lifting its load vertically. Fig. 37(*c*) shows a rope-geared hoist which may be reeved 2, 4 or 6 to 1. The hoist is operated by chains *h*, controlling valve *g*. Special automatic attachments are supplied when the load is to be suspended for a period of time, and speed boxes are used to govern the speed of stroke independent of the operator. Check valves are placed in the supply pipe to maintain pressure in case of failure of air supply. Lubrication is admitted through the air supply. Table 3 gives clearance dimensions, capacities and air consumption,

The **motor hoist** consists of a small-cylinder air engine driving a hoisting drum through a spur-gear or worm reduction. Where spur gears are used, an automatic brake must be employed to hold the load. Fig. 38 shows the worm-gear type. The air engine *a* drives drum *b* through worm-gear and spur-gear reductions *c* and *d*. The hoist rope is made fast to the drum and carries a hook at the lower end for attachment of the load. Lever *e* attached to the motor coming in contact with the top of the hook, stops the motor, acting as an automatic limit stop. The hoist is operated by chains from the floor. Table 4 gives clearance dimensions.

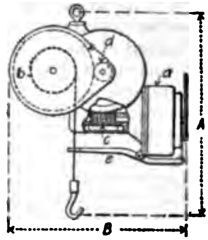

FIG. 38.—Air-motor Hoist.

Electric Hoists are used where rapid and frequent hoisting is required. When attached to a trolley, they are used for moving material in shops, yards, etc., and largely on small cranes as the power unit. They are very flexible and well adapted

to expansion, as each hoist being an independent unit, several may be used on the same trackage. They are limited in capacity to about 6 tons, and can be operated by chains from the floor. If the hoist is to be moved frequently over a considerable distance, it is built in the form of a telpher, the man riding with the hoist. (See p. 1155.)

Fig. 39 shows one of the many types of electric hoists. The motor *a* drives the drum *b* through the gear reductions *c* and load brake *e*. The hoisting cable is made fast to the hoist, passes around the sheave *f*, and is made fast to the drum. The solenoid brake *g* on the motor stops the motor when the current is shut off, thus enabling the operator to place the hook accurately. The type shown in Fig. 39 is carried by the four wheels *h*, moved by the hand wheel *k* and chains *m* through a spur-gear reduction. Current is brought to the hoist by conductors on either side of the rail through the sliding shoes or trolleys *n*. The controller is operated from the floor by chains *p*. These hoists are arranged for hook suspension where used in a stationary position. Other types of electric hoists employ a worm-gear reduction between motor and drum, this type not requiring the load brake, but depending on the worm gear to hold the load. All types are provided with an arm attached to the hoist, so that when the sheave *f* approaches the hoist it will come in contact with arm, throwing out the circuit breaker. Capacities are given in Table 5, together with speeds, sizes of motors, weights and clearance dimensions.

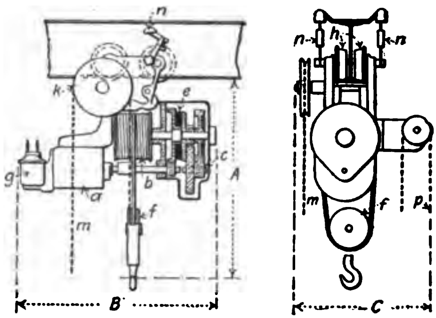

FIG. 39.—Electric Hoist.

PLATFORM ELEVATORS

Platform elevators are used for raising and lowering freight and passengers between the various floor levels in buildings. Five types are in general use: Hydraulic plunger, low-pressure hydraulic cylinder rope-geared, high-pressure cylinder rope-geared, electric drum, and electric traction. The hydraulic plunger type is limited to speeds of 400 to 600 ft. per min., due to difficulty in making accurate stops at higher speeds, and also by the cost of sinking deep wells for plunger cylinders. The low-pressure cylinder type is limited by the space required for cylinders. The efficiency is less and the cost of installation greater than for the high-pressure type. The high-pressure cylinder type is used for high speeds and lifts. The electric drum type is limited to medium lifts, owing to the width and diameter of drums on which cable must be coiled. The traction geared type is used for speeds up to 350 ft. per min. and long lifts. The traction gearless type is used universally for high speeds and long lifts.

Hydraulic Plunger Type, used with water pressure from 140 to 200 lb. per sq. in. In this type the car is lifted by a steel tube plunger, working in a pipe cylinder set in the ground in an outside steel casing. The plunger must be several feet longer than the travel of the car. The cylinder is supplied with water through an operating valve of the balanced-piston type, this valve being controlled from the car by a rope. Limit valves in the supply line and in the exhaust line are operated automatically by ropes when the car reaches the upper and lower limits. Buffers of the spring or oil type attached to the head of the cylinder protect it from shock due to excess speed. A counterweight attached by ropes to the top of the car counterbalances the weight of the car and part of the plunger. The car is raised by the water pressure in the cylinder, assisted by the counterweight, and the descending car must exert sufficient pressure to force the water out of the cylinder. To maintain the lifting pressure of the plunger constant, the weight of the counterweight rope is made to counterbalance the water displaced by the plunger. The plungers are from 5 to 7 in. in diameter, depending on the length. Water pressure may be obtained from city mains or from closed steel pressure tanks six-tenths full of water and four-tenths full of air. The capacity of tank is from ten to twenty times the volume of water used per trip. The pumps are either steam- or electrically driven and provided with automatic regulators to stop or start the pumps when the pressure in the tank reaches its maximum or minimum.

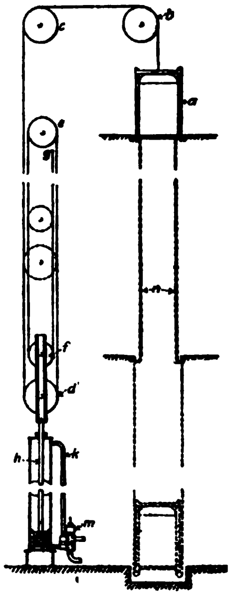

Fig. 40.—Hydraulic Rope-geared Elevator.

Vertical Hydraulic Cylinder Rope-geared Type (Fig. 40). This consists of car *a* suspended by ropes passing over sheaves *b*, *c*, *d*, *e* and *f* and made fast at *g*, near the fixed sheave *e*. Sheaves *d* and *f* are carried by a traveling frame attached to the end of piston rod *h*. To raise the car, water is admitted to the cylinder at the top through pipe *k*, forcing the piston down. To lower, water is allowed to escape from the bottom of the cylinder, the flow being controlled by valve *m*, operated by a running or standing rope from the car. Uniform working stroke is secured by circulating the water from the upper to the lower end of the cylinder and discharging from the latter into an overhead tank or through a suitable valve. This maintains a constant back pressure under the piston and gives better control. Automatic top and bottom limit stops are provided to shut off the water when the limits are approached. Relief valves are placed in the exhaust to allow water to pass to the upper part of the cylinder from the lower part, if the stop is too sudden. The cage is counterbalanced by the heavy piston and traveling sheave, and, if necessary, by a separate weight. The chains *n* attached to the bottom of the cage or counterweight and midway in the elevator shaft, balance the weight of the lifting cables.

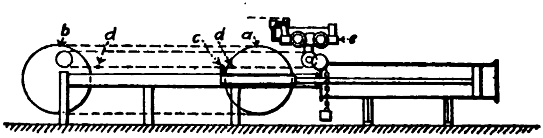

Fig. 41.—Hydraulic Rope-geared Elevator.

Fig. 41 shows the **horizontal cylinder pulling type**, which is located in the basement. The operation is similar to the vertical type, except that a separate counterweight is required to take the place of the traveling sheaves, piston and rod. To raise the car, sheaves *a* are pulled away from sheaves *b*, the reeving being sufficient to give the desired lift. The fork *c* attached to the cross head carrying sheaves *a* automatically limits the length of travel by coming in contact with the stops *d* attached to rope which closes the valve *e*. The **horizontal cylinder pushing type** is similar to the pulling type, except that the fixed sheaves are supported on the back head of the cylinder and the piston connected to the traveling sheave so as to push them apart. Limit stops similar to the pulling machine are used, and rubber-buffers on the piston and on the cross head coming in contact with a projection of the cylinder head reduce shock in case of overtravel. Either of these types may be mounted in double or single deck to economize floor space. The usual reeving is 8 to 1, although this may be made as low as 4 to 1 or up to 12 to 1.

High-pressure Elevators, Fig. 42, are similar in operation to the low-pressure type, but designed for water pressures of from 700 to 800 lb. per sq. in. This reduces the size of piping and cylinders and makes them suitable for high-speed equipment. The elevator is shown with a 6 to 1 reduction, but this may be from 4 to 1 to 8 to 1. Rope *a*, attached to the car, passes around the traveling sheaves *b*, *c* and *d* and the fixed sheaves, *e* and *f*, and is made fast at *g*. The cylinder *h* is inverted, the piston *k* being forced down by the pressure. The required counterweight is attached to the frame of the moving sheaves. The pump *m* forces the water into the accumulator *n*, from which it passes to the cylinder *h* through high-pressure valve *p*. The discharge water passes from the cylinder to the main discharge reservoir *r* through valve *p*. Valve *p* is operated by the low-pressure valve *s*, which in turn is controlled by the pilot valve under pressure from the water from reservoir *r*. The plunger operates under a pressure of from 700 to 800 lb., but the valve *s*, which is controlled by rope from the car, operates under a pressure of from 80 to 100 lb. The discharge from the pilot valve is piped to open reservoir *t* and returned by pump *v* to the main discharge system.

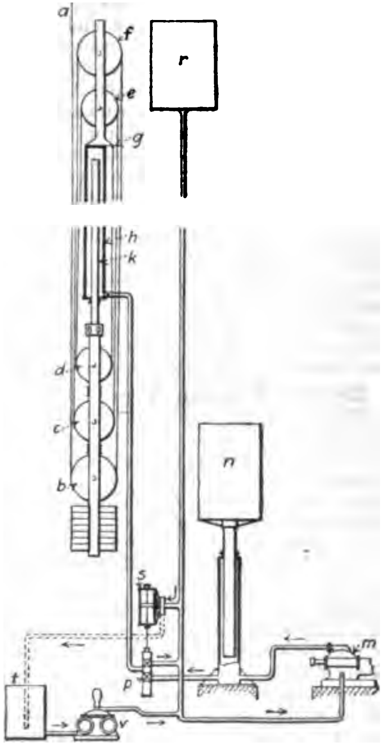

FIG. 42.—High-pressure Hydraulic Elevator.

Electric Drum Type. This type may have hoists mounted at the top of the shaft or in the basement. They may be single- or double-geared. In the double-worm-gear machine the motor drives a shaft carrying a right- and a left-hand worm; these worms mesh with worm gears, which also mesh with each other. This arrangement eliminates the end thrust due to the worms. The drum is driven from one of the gears by arms extending from the gear engaging similar arms on the drum, thus applying power to the drum near its face without torsional strains in the shaft. A solenoid brake on the worm shaft is applied by a spring and held off by a magnet operated by the line current. A magnet control system is used automatically to accelerate and retard the car, so that the brake is not used until the car has come nearly or quite to a stop. Compound-wound direct-current or slip-ring alternating-current motors may be used. The cars are overbalanced by a counterweight attached to cables made fast to the drum on the opposite side from the hoisting rope. For very heavy service, where the tooth pressure becomes excessive, the hoists are driven by two motors. Limit stops of a mechanical type attached to the winding drum limit the travel of the car. Additional limit switches placed in the hatchway are operated by the car itself or the counterweight, should they run beyond their limits. These switches cut off the current and apply the brake. Potential switches cut off the current in case of failure of the supply. Slack cable switches cut off the current and apply the brake, should the car or counterweight be arrested in their travel by the regular safety devices or by obstructions, thus preventing the cables from unwinding on the drum. The hand-operated emergency switch in the elevator cuts off the current to the motor independent of all the automatic devices.

Electric Traction Type. This latest development in elevator construction, shown in Fig. 43, is used for very high lifts and high speeds. It consists of a slow-speed motor *a*, connected to traction sheave *b* through a rigid form of connection described under the drum type. The ropes from car *d* pass over sheave *b*, over sheave *c*, back over *b*, and are made fast to counterweight *e*. The solenoid brake *f* is attached to the shaft of the motor and sheave. The motor is of the special slow-speed shunt-wound direct-current type, with magnet controller for the variable speed and electric braking so that the brake *f* acts only after car stops. An inherent safety feature is due to the reduction in the tractive effort of the sheave when car or counterweight reach the end of travel and the cables become slack. On very-high-lift elevators, such as used in the Woolworth Building, New York City, elevators of this type may have the bottom of the hatchways enclosed in air-tight chambers to act as a cushion to prevent a rapid drop. Traction-type elevators for car speeds approximately 450 ft. per min. are also used rope-geared 2 to 1 for both car and counterweight. Traction types are built with worm-gear drive for car speeds of 350 to 400 ft. per min. This type uses a high-speed motor with drive similar to the drum machine.

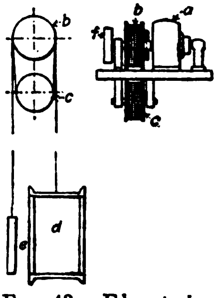

FIG. 43.—Electric Traction Elevator.

Efficiencies. The approximate efficiency of hydraulic apparatus is as follows: E_1, hydraulic cylinders, 75 to 90 per cent.; E_2, friction loss in piping and valves, 5 to 6 per cent. for high pressure and 10 to 30 per cent. for low pressure; E_3, the load efficiency of elevators, which depends upon the unbalanced weight of the car, etc. $= eL/(L + U)$, where L = live load, U = unbalanced weight, e = mechanical efficiency of elevators, sheaves, etc. = 90 to 95 per cent. The total efficiency from pump to work done $= E_1 \times E_2 \times E_3$. Some comparative total percentage efficiencies are as follows: Vertical high-pressure, 55 per cent.; vertical low-pressure, 52 per cent.; horizontal low-pressure, 44 per cent.; plunger low-pressure, 40 to 45 per cent.

For electric elevators of the drum or geared traction type, the mechanical efficiency will range from 60 to 72 per cent.: for the direct-connected gearless type, about 75 to 85 per cent. The total efficiency of drum geared electric elevators is from 50 to 55 per cent., and of the gearless traction type, 55 to 65 per cent. Average motor efficiencies given by T. E. Barnum, *Proc. A. I. E. E.*, vol. 30, are as follows (per cent.): ½ load and maximum speed, geared traction, 90 per cent.; gearless traction, 76 per cent. ½ load and normal speed, geared traction, 78 per cent.; gearless, 58 per cent. ¾ load and maximum speed, geared traction, 91 per cent.; gearless, 80 per cent. ¾ load and normal speed, geared traction, 81 per cent.; gearless, 67 per cent. Normal speed = ½ maximum speed.

Speeds. Hydraulic plunger elevators have a range of speed of from 300 to 600 ft. per min., but are not well suited to high speeds. Hydraulic cylinder elevators operate up to 600 ft. per min., for both the high- and low-pressure types. Electric elevators of the drum type travel as high as 400 ft. per min. but usually from 250 to 350 ft.; worm-geared traction type up to 400 ft. per min. and rope-geared up to 450 ft. per min.; gearless traction type, from 400 to 700 ft. per min. Elevators running at from 600 to 700 ft. per min. are express elevators, while those making frequent stops run from 400 to 600 ft. For ordinary freight service the speed is from 50 to 250 ft. per min.

Loads and Weights. The live load for passenger elevators is usually from 75 to 80 lb. per sq. ft., and the **weight of** the **car** itself from 100 to 125 lb. per sq. ft. of platform. For hydraulic elevators of the plunger type, the **counterweight** is usually taken equal to 75 or 80 per cent. of the weight of the car and plunger. For the cylinder type machines, the unbalanced weight is from 500 to 1500 lb., depending on the speed of operation required and ease of handling; for freight service, 500 lb. up, and for passenger service, 800 to 1500 lb. For electric elevators, the counterweight is usually equal to the weight of the car plus 40 to 50 per cent. of the live load.

Capacity of freight elevators, from 1000 to 10,000 lb.; of passenger elevators, from 2000 to 4000 lb. **Power** requirements depend upon the speed, capacity, etc. Power is usually required for motion in one direction only for hydraulic elevators, but for electric it may be required in both directions. Let L = weight of live load, lb., U = unbalanced weight of car, lb., S = speed of car, ft. per min., and e = efficiency of complete elevator, per cent. Then h.p. $= 100(L + U)S/33{,}000\,e$. In determining the horse power required to operate hydraulic elevators, allow for power on upward trip only, and for an approximate result compute ⅔ of the amount required to operate all elevators at one time under full load. For electric elevators, power may be required in both directions, depending on direction and amount of travel. Compute power for 70 per cent. of amount required to raise all elevators at the same time, assuming 70 per cent., as they will not all be running all the time. Operation may be such that they will all lift full loads and return empty, depending on the time of day. For hydraulic elevators, the steam required per car-mile, using a flywheel type pump, ranges from 150 to 250 lb., based on 25 lb. of steam per i.h.p. of the pumps. Other types of pumps in proportion. For electric elevators, the car-mile energy consumption ranges from 3.5 to 8 kw.-hr., depending on the frequency of stops.

TRAVELING CRANES

A traveling crane consists of a steel bridge carried by wheels on the ends, traveling on elevated track. The bridge carries the hoisting unit which may be hand power, pneumatic or electric. The hand-power crane is limited to a capacity of 50 tons and a span of 40 ft., where the duty required is slow and infrequent. The pneumatic crane is used for short lifts where electricity is not available and where air is already installed for other purposes. The electric crane is built in capacities up to 200 tons and with spans up to 125 ft. Larger capacities and longer spans may be built, but are seldom required in present engineering practice.

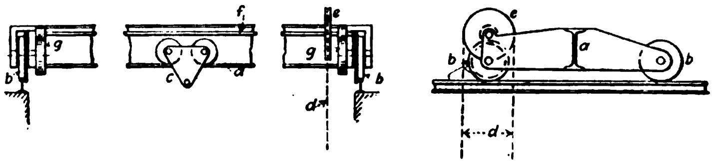

Fig. 44.—Hand-power Crane.

Hand-power Crane (Fig. 44). In its simplest form this consists of an I-beam *a* supported by four wheels *b*. The trolley *c* traveling on the lower flanges carries the chain hoist forming the lifting unit. The crane is moved by hand chain *d* turning pocket wheel *e* keyed to shaft *f*. The pinions on shaft *f* mesh with the gears *g* keyed to the axles of the two wheels. For heavier duty and longer span, the bridge is constructed of two I-beams side by side, a four-wheel trolley running on rails secured to the upper flanges. Fig. 45 shows a crane of this type operated by a winch supported by a structural frame hung from the bridge. One end of the hoisting chain is made fast to the end of the bridge, passes over sheave *a* in the trolley, around the pendant sheave *b* carrying the swivel hook, over sheave *c* in the trolley, around *d* on the end of bridge, and is then made fast to the drum of the winch. The trolley is moved by a separate winch.

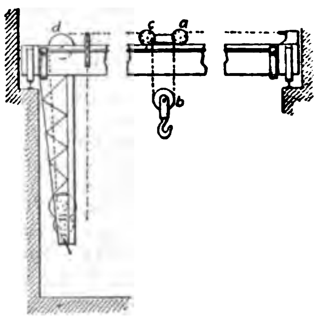

Fig. 45.—Heavy-duty Hand-power Crane.

Electric Traveling Crane (Fig. 46). This consists of two bridge girders *a*, on top of which are rails on which travels the self-contained hoisting unit *b*. The girders are supported at the ends by trucks with two or four wheels, according to the size of the crane. The crane is moved along the track by motor *c*, through shaft *d* and gearing to the truck wheels. Suspended from the girders on one side is the operator's cab *e*, containing the controller and operating levers. The resistance boxes are usually suspended under the floor of the cage. The bridge girders for small cranes are of the I-beam type, but on the longer spans box girders are used to give lateral stiffness. The girders are rigidly attached to the end truck framing, which carries the double-flanged wheels for supporting the bridge. The end frames project over the rails so that in case of a broken wheel or axle, the frame will rest on the rail, preventing the crane from dropping. One wheel axle on each truck is fitted with gears for driving the crane. A powerful foot brake on shaft *d* enables the operator in the cab to stop the crane.

The self-contained hoisting unit consists of a motor-driven truck carried by double-flanged wheels geared direct to the moving motor. This truck carries the hoisting drums which are geared direct to their motor, being provided with solenoid brake, together with a load brake to hold the load, should the current fail. The larger sizes of cranes have auxiliary hoists of smaller lifting capacity carried by the truck of the main hoist. The drums are spiral-grooved, the rope being made fast at each end of the drum and passing around sheaves in the pendant block and on the trolley truck. As the load is lifted, the ropes wind on the drum toward the center so that the load on each of the bridge girders is the same. Limit switches are provided to stop the motors when the limits of travel are reached. Current is brought to the crane by sliding contacts from trolley wires strung along the runway girders on the cab side. Current from the cab to the hoisting truck is carried by wires attached to the girders with sliding contacts carried by the truck.

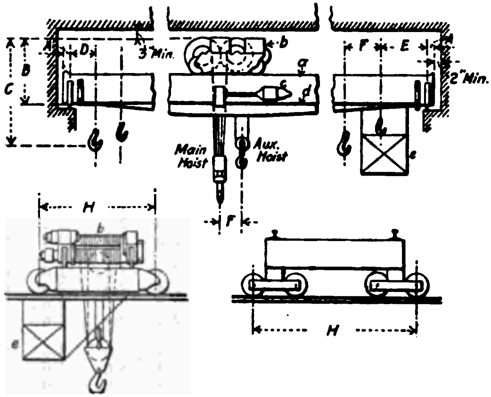

Fig. 46.—Electric Traveling Crane.

Table 6. Typical Capacities and Speeds of Electric Traveling Cranes for General Service

Capacity, tons (2000 lb.)	Hoisting speed, ft. per min.	Bridge travel speed, ft. per min.	Trolley travel speed, ft. per min.	Capacities of auxiliary hoists, tons	Speed of aux. hoists, ft. per min.
5	25-100	300-450	100-150	....	....
10	20-75	300-450	100-150	3	30-75
15	17-60	300-400	100-150	3 or 5	40-125

50	8-30	200-300	100-150	5 or 10	25-100
60	8-30	200-300	100-150	10 or 15	20-60
75	6-25	200-250	100-150	15	20-50
100	5-18	200-250	100-150	20	20-50
125	5-15	200-250	100-150	25	20-50
150	5-15	200-250	100-150	25	20-50

Electric cranes are built for either alternating current or direct current. The motors for both kinds of current are of special slow-speed types designed particularly for crane service. Direct-current motors are series-wound and alternating-current are of the slip-ring type. The usual voltage is 220.

* 60-ton cranes (over 60-ft. span) and larger have 4-wheeled trucks; smaller sizes have 2-wheeled trucks.

The **efficiency** of electric cranes ranges for **the motor** from 65 to 90 per cent., and for the mechanical part from 70 to 80 per cent., giving a combined efficiency of from 45 to 72 per cent. between the crane hook and the switchboard. The **lifting speed** for hand-power cranes is from 2 to 25 ft. per min.; for pneumatic cranes, from 5 to 35 ft. The speeds of electric cranes, for general service, are given in Table 6. The speed of bridge travel in ft. per min. should not exceed the length of the runway plus 100 ft. The **capacities**, clearance dimensions, wheel loadings, etc., for standard electric cranes are given in Table 7. These figures should be used for preliminary work only, as the data vary with different manufacturers.

BRIDGE CRANES

Gantry Cranes are modifications of traveling cranes used out of doors where it is not convenient to erect an overhead runway. The bridge, Fig. 47, is carried at the ends by the legs *a*, which may be bolted to foundations or mounted on wheels so that the crane may travel. The bridge carries a hoisting unit, the same as the traveling crane, but covered to protect the machinery from the weather. The crane is driven by motor *b* through a gear reduction to shaft *c*, which drives the vertical shafts *d* through bevel gears. Bevel-gear and spur-gear reductions connect the axles of the wheels with shafts *d*. Gantry cranes are made in the same sizes as standard traveling cranes. They are, however, usually built to suit local conditions.

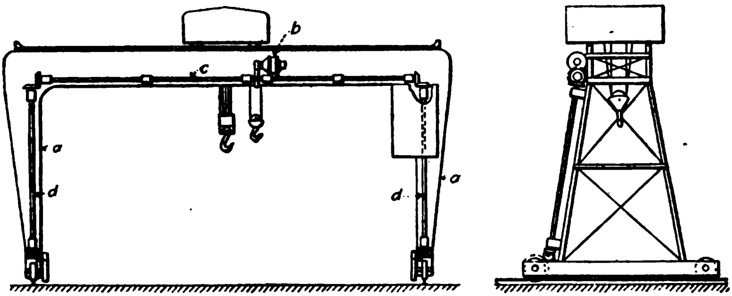

FIG. 47.—Gantry Crane.

Bridge Storage Cranes are used to unload material in bulk, such as coal, ore, stone, gravel, sand, etc., from open-top cars and vessels and to place it in open storage piles; also to reclaim material from storage piles and deposit it in cars or vessels. Their capacity is limited by the size and speed of the self-filling grab bucket carried by the bridges. These buckets are from 2 to 10 tons capacity, the average being from 2 to 5 tons. The span of the bridges varies with local conditions, one in use being 500 ft. from c. to c. of supporting towers.

Storage bridges consist of a trussed steel span with a cantilever at one or both ends, as required by local conditions. When used for unloading material from vessels, the cantilever end is hinged so that it may be raised to clear the masts of vessels and be housed inside of the dock line. The bridge span is flexibly mounted on the supporting towers to prevent distortion, should one end run ahead of the other. Fig. 48 shows a bridge with an inverted tower. A king pin is provided at *a*, and sliding contacts, well greased, between the span and the tower, to carry the load. The other end is carried by the A-frame, the span being hung by the links *b* from the lower chord, a pin being provided to take the wind load. The hoisting unit is carried by wheels resting on tracks *c*, and is usually of the man-trolley type consisting of a carriage containing the hoisting drum, motors, controlling apparatus and the operator for the grab bucket. The trolley is propelled by motors geared to the truck wheels. The hoisting unit may also be of the rope-driven type, in which the hoisting drums with their motors and other apparatus are fixed in one of the towers, the bucket and trolley being moved by wire ropes.

Fig. 49 shows a bridge in which the tower spans one or more railroad tracks, giving it a wide base. It is connected to the bridge span through a king pin, the load being carried by well-greased bearing plates. The other end is carried by an A-frame, the bridge being provided with a girder and socket resting on the ball on top of the A-frame. The bridges are mounted on wheels, the trucks being pin-connected so as to take up inequalities in the

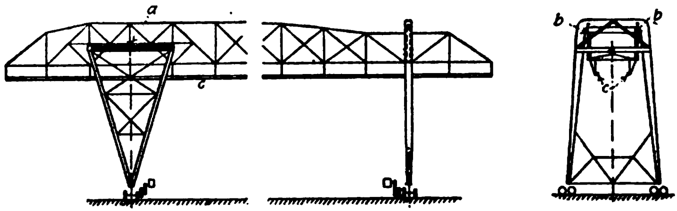

FIG. 48.—Bridge Crane with Inverted Tower.

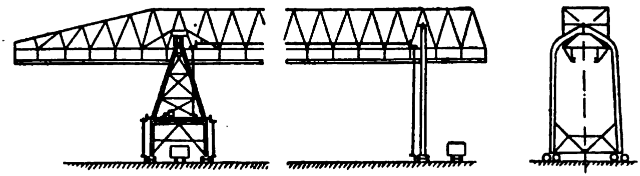

FIG. 49.—Bridge Crane with Shaft-driven Trucks.

tracks. They are propelled in various ways, the most usual drive consisting of motors geared to the truck-wheel axles. Two drum-type controllers are used, each controlling the motors at one end of the bridge. Indicators are provided so that the operator at all times knows the relative position of the two ends, and the two controllers enable him to move the ends of the bridge at the same speed. One manufacturer gears the motors to the axles of the truck wheels by worm-gear and spur-gear reductions, the worm gears acting as an automatic lock when the bridge is stationary.

Fig. 49 shows the shaft-driven bridge, in which the truck-wheel axles are driven through spur-gear and bevel-gear reductions by a vertical shaft from a motor at the tower end. The shear-leg end of the bridge is propelled by a shaft (carried by the bridge span) through bevel gears. Universal joints are used in the shaft at the tower and shear-leg ends to compensate for the movement at these points. A jaw clutch is provided so that the bridge may be lined up by moving one end while the other end is stationary. One manufacturer employs cables anchored at the ends of the bridge travel, passing over motor-driven drums on the bridge trucks. This method pulls the bridge along independent of the friction of wheels on rails, solenoid motor brakes locking the bridge when not in motion. The two ends are handled by separate controllers.

Capacity of storage bridges, from 100 to 500 tons per hour, depending on the size of the buckets, motor equipment, etc. **Speed** of bridge traverse, from 50 ft. to 200 ft. per min., depending upon the service; speed of the man trolley, from 500 to 1500 ft. per min.

ROTARY CRANES

Rotary cranes are used for lifting material and moving it to points covered by a boom pivoted to a fixed or movable structure. Derricks are used out of doors, in quarries, for construction work, etc., being built so that they may be easily moved. Pillar cranes always are fixed and used for light, infrequent service. Jib cranes are used in manufacturing plants. Locomotive cranes mounted on car wheels are used to handle loads by hook, or bulk material in tubs or grab buckets. Wrecking cranes are of the same general type as locomotive cranes and are used for handling heavy loads on railroads.

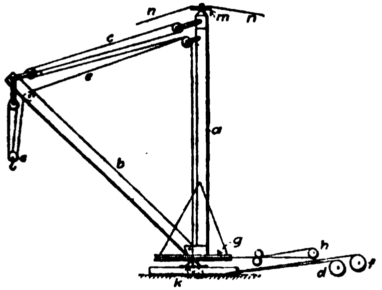

Fig. 50.—Guyed Wooden Derrick.

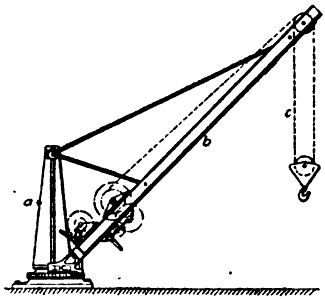

Fig. 51.—Pillar Crane.

Derricks are made with either wood or steel masts and booms of the guyed or stiff-leg type, and are either self-slewing or swung with a bull wheel. Fig. 50 shows a guyed wooden derrick of the bull-wheel type. The mast *a* is carried at the foot by pivot *k*, and at the top by pivot *m*, held by rope guys *n*. The boom *b* is pivoted at the lower end of the mast. The rope *c*, passing over sheaves at the top of the mast and at the end of the boom and through the pivot *k*, is made fast to drum *d*, and varies the angle of the boom. The hoisting rope *e*, from which the load is suspended, is made fast to drum *f*. The bull wheel *g* is attached to the mast and swings same by a rope made fast to the bull wheel and passing around the reversible drum *h*. In derricks of the self-slewing type the engine is mounted on a platform attached to the mast and the derrick is swung by a pinion meshing with a gear attached to the foundation. Either the bull-wheel or self-slewing type may be made of steel or wood construction and of the guyed or stiff-leg type.

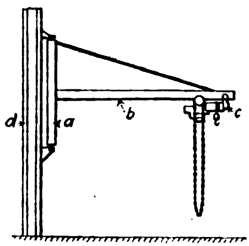

Fig. 52.—Column Jib Crane.

Fig. 51 shows a fixed-radius **pillar crane**, largely used for unloading cars in railroad yards, and usually of the hand-power type. It consists of a pillar *a*, bolted to a foundation, carrying the boom *b*, which may be swung around a full circle. The load is lifted by ropes *c* operated by a hand winch. Fig. 52 shows a **column jib crane** consisting of pivoted post *a*, carrying boom *b*, on which travels the hoist *c*. The post *a* is attached to column *d* so that it may swing through approximately 270 deg. The **yard jib crane**, illustrated in Fig. 53, consists of mast *a*, carrying fixed boom *b*, on which travels the hoist *c*. The mast is carried by a pivot bearing *d* at the bottom, and bearing *e* at the top, held by guys *f*. The crane is swung by gear *g* attached to the foundation through pinion *h* from motor carried by the mast.

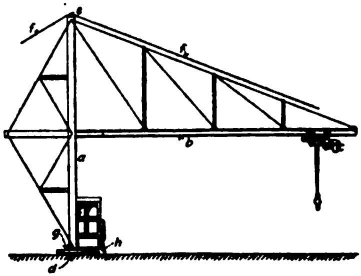

FIG. 53.—Yard Jib Crane.

Fig. 54 shows a **locomotive crane** traveling on standard-gage track and self-propelled by bevel gears from the crane engine. These cranes require but one operator and are usually steam-driven, the boiler, engine and boom being carried by a turntable so that they may turn through a full circle. A two-drum engine is used when lifting loads with a hook, one drum raising and lowering the boom, the other lifting the load. When a two-rope grab bucket is used, an extra drum is provided on the engine. These cranes propel themselves at about 7 or 8 miles per hour, and in addition to handling the material are used for shifting cars. Table 8 gives general data on locomotive cranes. Fig. 55 shows a **wrecking crane** which travels on standard-gage track, the engine, boiler and boom being mounted on a turntable so that they may swing through a full circle. Two hoists are

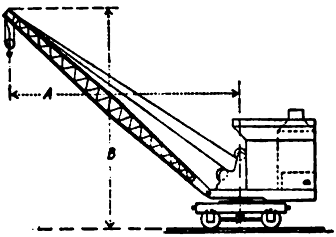

FIG. 54.—Locomotive Crane.

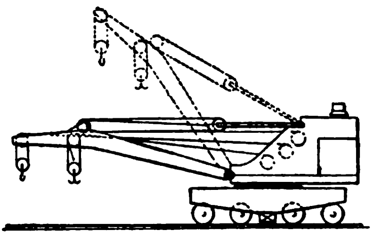

FIG. 55.—Wrecking Crane.

usually provided, one in the end of the boom and one midway between the pivot and end. These cranes are provided with outriggers so that very heavy loads may be handled without overturning the cranes. Table 9 gives general data on this type of crane.

Capacities of Rotary Cranes. Wooden derricks are made with booms from 24 to 80 ft. in length and from 3 to 20 tons capacity. Steel derricks are made with booms from 50 to 100 ft. long and from 5 to 50 tons capacity. The booms operate at an angle of 15 deg. to 45 deg. from the horizontal. Fixed-radius pillar cranes are made with 15-ft. radius to handle from 1 to 30 tons; 20-ft. radius, 2 to 20 tons; 25-ft. radius, 2 to 15 tons. Column jib cranes are made up to 20-ft. radius for 3-ton loads. Yard jib cranes are designed especially for the work to be done. Capacities of locomotive and wrecking cranes are given in Tables 8 and 9. Wrecking cranes are built with booms up to 40 ft. radius.

EXCAVATING MACHINES

Steam Shovels are used for excavating on dry land such loose material as sand, earth, ore, blasted rock, etc., and placing it in cars or wagons so that it may be moved to the dumping point. Shovels are also used to deposit excavated material directly on dikes, waste piles, etc. They are made in two types: the revolving-shovel, in which the dipper and machinery revolve 360 deg. on a turntable, and the railroad type, where the dipper and boom alone revolve through approximately 180 deg. The smaller machines may be mounted on traction wheels for use in cellar excavation, road grading, trench work, etc.. Larger sizes travel on standard-gage track or are equipped with caterpillar traction, and are used in railroad construction, in stripping overburden from coal or ore mines, loading material into cars, canal construction, etc. Shovels discharging to spoil banks are provided with booms 60 to 75 ft. long. Steam shovels cannot excavate under water, as they stand below the level of the material they are digging. Except in the case of long-boom shovels, they are dependent upon some method of transportation to move the excavated material. Steam shovels consist of a structural-steel frame, similar to that of a car, which is supported on traction wheels, caterpillar traction, or railroad trucks, as the size and use determines. This frame supports the power plant and the boom for carrying the dipper and dipper beam. Fig. 56 shows a typical shovel of the railroad type. The cutting edge of the dipper is usually provided with teeth, and is pulled through the material by a rope or chain passing over end of the boom and operated by a drum, driven by double-cylinder engine *a*. The double-cylinder thrusting

engine *b*, mounted on the boom and operated independently, forces the beam, to which the dipper is attached, in or out. In this way the dipper is held into the work while the cutting edge is being pulled through the material by engine *a*. When the dipper is filled, the swinging engine, attached by chains to the turntable *c*, swings the dipper over the wagon or car to be loaded. Two operators are required, one to control the hoisting and swinging engine, the other located on a platform attached to the boom to operate the thrusting engine and to trip the latch of the door on the bottom of the dipper, which

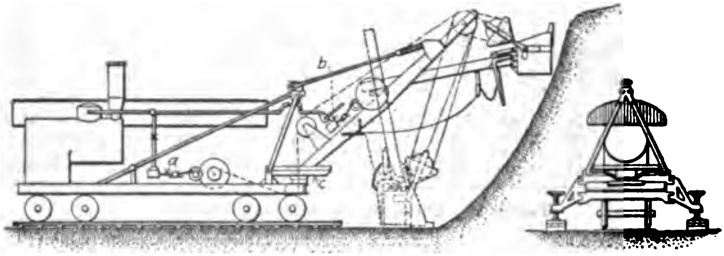

FIG. 56.—Steam Shovel.

allows the material to be discharged by gravity. The revolving shovel consists of the upper frame carrying the boom, boiler, engines, etc., mounted on a turntable so that it may turn through a full circle. The hoisting of the bucket is usually accomplished by chain, but wire rope is used where the digging is comparatively easy and where high speed is desired. Table 10 gives capacity and general data for shovels of different sizes of the chain-hoist type. These shovels make from 3 to 4 cycles per min. when operating at full speed. The wire-rope type will make from 3 to 5 cycles per min. The hoisting and thrusting engines are usually under steam from one-quarter to one-third of the time, and the swinging engine about one-half the time, when operating steadily. The engines are of the high-speed type and the determining factor in their size is not the horse power they develop, but the amount of pull they can exert on the dipper when moving it about 100 ft. per min. The working boiler pressure is about 125 lb. Electric shovels are used to some extent.

Table 10. Data on Steam Shovels
[Chain-hoist (Bucyrus) type]

Type of shovel	Weight, tons	Capacity of dipper, cu. yd.	Size of engines in in.			Boiler		Effective pull on dipper, lb.	Capacity, cu. yd. per hour

	116	3½-6	13 ×16	9 ×9	9 ×9		58×18-3	98,000	150-550

Dipper Dredges are used for excavating material from the beds of harbors, rivers, canals, etc. The excavated material is discharged either on to the bank or on to scows which carry it to the dumping point. The water must be deep enough to float the dredge. Depth of digging limited to approximately 55 ft. The operation of dipper dredges is similar to that of railway-type steam shovels, except the apparatus is mounted on a scow instead of a car, and held in its operating position by spuds. Dredges of this type are built with dippers from 1 to 15 cu. yd. capacity, and are designed especially for the work to be done.

Ladder Dredges are used for excavating sand, gravel, etc., especially gold-bearing gravel in placer mining. They are built to dig to a depth of 75 ft. below water line, and will dig through soft rock. The digging unit consists of an endless chain of buckets passing over tumblers at each end of a ladder pivoted at its upper end, and driven by the upper tumbler; speed, from 12 to 18 buckets per min. Dredges are made with buckets having a capacity of from 3 to 16 cu. ft. each. Table 11 gives the average monthly capacities of placer dredges in the California gold fields.

Table 11. Capacity and Operating Costs of Ladder Dredges

Size of buckets, cu. ft.	3	4	5	7	7½	8	13	13½
Capacity, 1000 cu. yd. per month	34	40	74	81	101	149	230	255
Cost of handling, cents per cu. yd.	8.0	6.5	5.3	4.85	4.34	3.58	2.91	2.41

Drag-line Excavators are used for digging open cuts, drainage ditches, canals, sand and gravel pits, etc., where the material is to be moved from 20

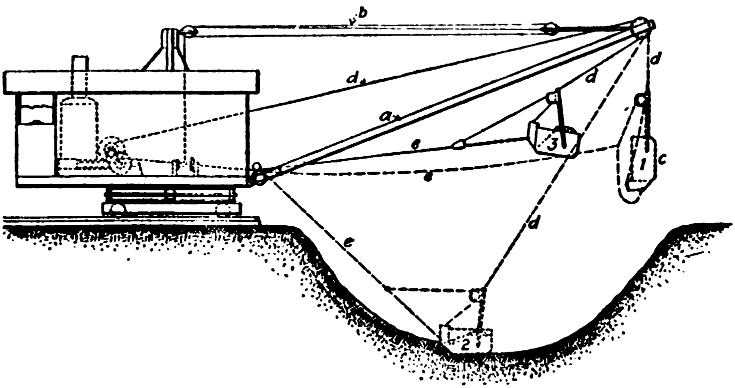

FIG. 57.—Drag-line Excavator.

to 200 ft. before dumping. They cannot handle rock unless blasted. Being provided with long booms and mounted on turntables, permitting them to swing through a full circle, these excavators may deposit material directly on the spoil bank farther from the point of excavation than any other type of machine. While a steam shovel stands below the level of material it is digging, a drag-line excavator stands above, so it may be used to excavate material under water. The bank on which it operates must have sufficient bearing value to support the weight of the machine. Fig. 57 shows a drag-line excavator consisting of a turntable mounted on skids, trucks or caterpillar traction. The turntable supports the boiler and engine. The boom *a* is pivoted at its lower end to the turntable, the outer end being supported by cable *b* so that it may be raised and lowered to the desired angle. The scraper bucket *c* is supported by cable *d* attached to a bale on the bucket, passing over a sheave at the head of the boom and made fast to the engine. A second cable, *e*, is attached to the front of the bucket and made fast to the second drum of the engine. The bucket is shown in three positions. Position 1 is the dumping position, the bucket being suspended from cable *d*, *e* being slack. The bucket is dropped and dragged along the surface of the material by cable *e* until filled (position 2). It is then hoisted by rope *d*, drawn back to its dumping position, *e* being kept tight until the dumping point is reached, when *e* is slacked, allowing the bucket to dump by gravity. After the bucket is filled, the boom is swung to the dumping position, while the bucket is being hauled out. **Speed,** about 1 bucket per min.; under favorable conditions, 2 or even 3 trips per min. are possible. Table 12 gives general data and **capacities** of the various sizes.

Table 12. Data on Drag-line Excavators
(Lidgerwood Type)

Weight, tons	Capacity of bucket, cu. yd.	Working radius of boom elevated 25 deg., ft.	Size of engines		Boiler		Capacity, cu. yd. per hour

VESSEL-UNLOADING MACHINERY

Bucket-operating machines used to unload bulk material such as coal, ore, stone, etc., from the holds of vessels, have their bucket capacity fixed by the dimensions of the vessel hatches. Mine-run material may be handled, provided the lumps do not exceed about 24 in. in size. The type of unloading device is determined by the nature of the material to be handled and the capacity desired.

Mast and Gaff Unloader (Fig. 58). This is the simplest type of unloader, consisting of a mast *a* set in the ground and supported by stiff legs *b*, and rope guys, where possible. The gaff *c* is pivoted at its lower end to the mast above the crosstrees *d*. The outer end of the gaff is supported by rope *e*, and the angle may be adjusted. The clos-

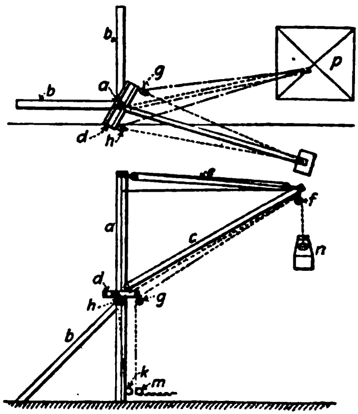

FIG. 58.—Mast and Gaff Unloader.

ing rope from one of the drums of the engine passes over sheave *m*, sheave *g* attached to the crosstrees, and sheave *f* suspended from the end of the boom, and is made fast to the closing drum of the bucket. The hold rope from the other drum of the engine passes over sheaves *k*, *h* and *f*, and is made fast to the head of the bucket *n*. After the bucket is closed, the operator hoists on the closing line, slacks on the hold line, raising the bucket and swinging the gaff over the hopper *p*. After the bucket is empty, the gaff is swung out by putting greater tension on the hold line than on the closing line. These unloaders are used mainly on coal, sand, gravel, crushed stone, etc., and handle from 50 to 60 tons per hour. They cannot unload from boats wider than from 25 to 30 ft.

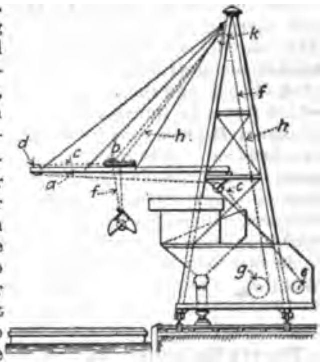

FIG. 59.—Boston Tower Unloader.

Boston Type Tower. The Boston or two-man tower (Fig. 59) consists of a tower of steel or wood, carrying the boom *a*, on the upper flanges of which travels the trolley *b*. The closing line *f* attached to the closing drum of the bucket passes over one sheave of the trolley, over sheave *k* at the head of the tower, and is attached to one of the engine drums *g*. The hold line *h*, secured to the head of the bucket, passes over a sheave of the trolley, over a sheave at the head of the tower and is attached to a drum on the same shaft as *g*. The trolley rope *c* is secured to the front of the trolley, passes over sheave *d* on the end of the boom and is attached to drum *e* of the trolley engine. Two operators are required, one controlling the raising, lowering, opening and closing of the bucket, the other the movement in and out on the boom. The drums of the hoisting and closing engine are provided with frictions. After the bucket is closed, it is raised on the closing and hold lines, the trolley operator slacking on rope *c*, allowing the bucket to run in over the hopper. After the bucket is dumped, the trolley is hauled out by rope *c* and the bucket is lowered into the vessel. Capacity, 75 to 300 tons per hour, depending on size of bucket (rarely over 2 cu. yd.).

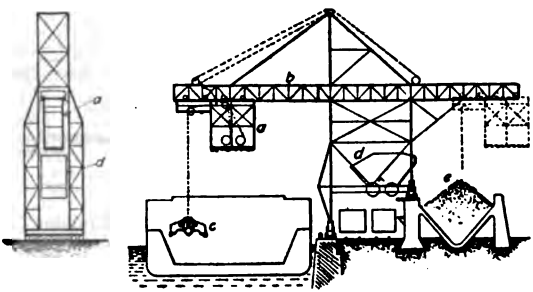

FIG. 60.—One-man Unloader.

One-man Type Unloaders (Fig. 60) are used for the rapid unloading of coal, ore, etc. The steel-frame tower carries a self-contained hoisting unit or man trolley, *a*, which may be moved along the boom *b*. The trolley carries the drums, motors, controllers and operator required for the grab bucket *c*. After the bucket has been filled and hoisted, the trolley is moved along the boom, discharging the material into the hoppers *d*, from which it may be fed to railroad cars; or to the trough *e*, back of the unloader, from which it will be moved to the storage pile by the storage bridges. This constitutes the Hoover & Mason method of handling ore. The boom *b* is hinged so that it may be raised to clear the masts of vessels. Towers of this same general form are used with rope-operated buckets, the drums, motors and controlling apparatus being located in the tower. Fig. 61 shows one method of reeving the ropes for such a tower. The reeving of the closing line is shown at *A*, the bucket being attached to *a*, sheave *b* being on the end of the boom, and sheave *c* carried by an auxiliary trolley which may be moved by rope winding on drum *d*. Diagram *B* shows the holding line which is attached to the head of the bucket, these ropes being reeved the same as the closing line. To close the bucket, drum *d* is revolved, pulling sheave *c* back, closing the bucket without movement of the trolley, as it is in balance. When the bucket is closed, drums *d* and *f* are revolved at the same speed, raising the bucket. To move the trolley, the endless rope, Diagram *C*, is attached to the two ends of the trolley, making several wraps around drum *g*. The trolley is therefore hauled in either direction. Capacity, 100 to 1000 tons per hour, depending on size of bucket (2 to 10 tons for coal, up to 10 tons for ore).

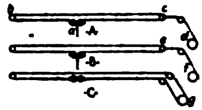

FIG. 61.

Hulett Unloader (Fig. 62). This consists of a bucket *a* attached to arm *b* which is pivoted with a parallel motion from beams *c* and *d*. The bucket is opened and closed by drum *e* on arm *b*, and the arm is raised and lowered

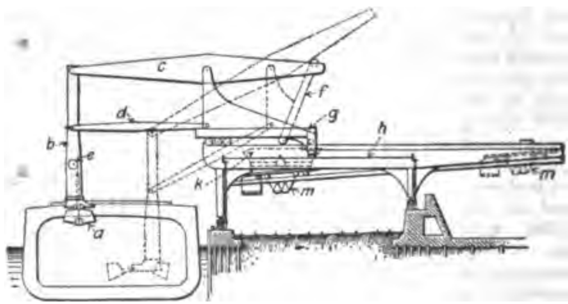

FIG. 62.—Hulett Unloader.

by cable *f* attached to the arm and drawing down the extended end of lever *c*. Levers *c* and *d* are pivoted on traveler *g* so that the whole device may be moved on the framework *h*, permitting the bucket to discharge into hopper *k*. The material from hopper *k* is discharged to the motor-driven car *m*, which travels on the inclined track, carrying the material to the storage back of the machine, where it may be reached by the storage bridges. The car *m* may also discharge into railroad cars running under the unloader. Capacity, 500 to 1000 tons per hour with buckets of from 10 to 15 tons capacity.

Self-unloading Vessels are made having a hopper bottom with a series of gates discharging to two pan or belt conveyors which elevate the material, feeding an elevator which lifts the material above the deck line and discharges to a belt conveyor carried by a swinging boom. The boom carrying the conveyor may be elevated to an angle of 18 deg., and is made from 100 to 150 ft. long. From 500 to 2000 tons may be unloaded per hour.

CONVEYING MACHINERY

General. Conveyors are devices for moving material from one point to another at the same or a different elevation. In **intermittent conveying** the material is moved in a succession of separate loads; in **continuous conveying** the material is delivered in a practically steady stream.

The **angle of repose** of any material is the angle with the horizontal at which material will stand when piled. For anthracite coal it is about 27 deg.; for coke of the same size, about 40 deg. The percentage of fine material in the mass has a decided influence on the angle, as the fines carry the bulk of the moisture. Screened material has an angle of repose of from 35 to 40 deg., depending on the shape, smoothness and method of storing. Thirty-seven degrees has been found to be the average angle for crushed and screened limestone, iron and copper ore, and similar materials. Mine-run soft coal will stand at from 35 to 37 deg.

The **angle of slide** is the angle at which material will flow on an inclined surface. Anthracite coal will flow on steel plate inclined at about 20 deg., coke at about 25 to 30 deg. Ore, stone, etc., will slide at about 30 deg. where the fine material is removed, and at 35 to 40 deg. for mine-run material. It is customary to build chutes on an angle of 45 deg. for such material as coal, stone, ore, etc., this angle being increased when there is a large percentage of fine, damp material. Where gentle handling is required to prevent breakage, special tests should be made to determine the minimum angle of slide.

The **weights of loose materials** commonly handled by conveying apparatus range approximately as follows:

	Lb. per cu. ft.		Lb. per cu. ft.		Lb. per cu. ft.
Ashes	45–50	Coke	26–30	Ore	105–215
Barley	37–40	Earth	75–115	Rye	44–50
Cement	90–118	Gravel	90–135	Sand	75–120
Charcoal	17–27	Lignite	31–47	Slag, blast-furnace	37–63
Clay	95–169	Lime	50–80	Stone, broken	90–120

TRANSPORTATION BY DIRECT-IMPELLED VEHICLES

Loading, Hauling and Dumping Material with Carts and Wheelbarrows (Condensed from Taylor and Thompson's "Concrete Costs"). Capacity of double carts, 33⅓ cu. ft.; single carts, 16 cu. ft. Let g = time of shoveling per cu. yd. in minutes per one man (for gravel, 29.5 min.; sand, 19.7 min.); c = time of changing carts at face per cu. yd. in minutes per team (for double carts, 2 min.; single carts, 3.5 min.); d = time of dumping per cu. yd. in minutes per team (for double carts 1.4 min.; single carts, 1.5 min.); n = number of men shoveling; m = ratio of cost of team and teamster to cost of labor of one man (for double carts, 3; single carts, 1.5). Then, **time per cu. yd. loading** material when teamster does not help load =

$$T = (g + nc) + m[(g/n) + c + d],$$

where $(g + nc)$ = time of loading gang reduced to time of one man, and $m[(g/n) + c + d]$ = time of team and teamster waiting during loading, changing carts and dumping.

When teamster helps loading, the time per cu. yd. loading and dumping

$$T = (g + nc) + [(m - 1)\,g/(n + 1)] + m(c + d)$$

On short hauls, the amount of work done depends on the time of loading, as the horses have ample resting time.

Let l = distance hauled one way in hundreds of feet or miles; t_s = actual time of hauling 100 ft. or per mile and return per cu. yd. (= 0.9 min. for 100 ft. and 47.5 min. per mile). Then, **time per cu. yd. loading, hauling and dumping** (for short hauls) when teamster does not load =

$$T_1 = (g + nc) + m[(g/n) + c + d] + m(l \times t_s)$$

When teamster helps load, $T_1 = (g + nc) + [(m - 1)\,g/(n + 1)] + m(c + d) + m(l \times t_s)$.

When teamster loads alone, $T_1 = m(g + c + d) + m(l \times t_s)$

On long hauls, the work a team can do is limited by the distance a horse can travel. The average horse can travel per day 17 miles, 8½ miles hauling a load and 8½ miles with empty cart.

The loading time is not enough to give the horses rest, so that the time of changing carts, loading and dumping does not enter the formula. Let l = distance hauled one way in miles; t_l = time of team per cu. yd. per mile of actual hauling and return plus required time to rest (=56.9 min. based on 17 miles in 10 hr.; 48.35 min. based on 20 miles in 10 hr.; 45.5 min. based on 17 miles in 8 hr.) Then, **time per cu. yd. loading and hauling** where teamster does not help load = $T_2 = (g + nc) + m(l \times t_l)$

When teamster helps load, $T_2 = \left(\dfrac{ng}{n + 1} + nc\right) + m(l \times t_l)$

When teamster loads alone, $T_2 = m(l \times t_l)$

In **transporting by wheelbarrows**, gangs should be arranged to give room for the wheeler to load his own barrow. Should two men load with the wheeler idle, add 35 per cent. to the time and cost of loading; when one man loads with the wheeler, add 25 per cent. In carrying loads up or down a slope, add 5 per cent. for each 4 deg. of slope. Hauling by wheelbarrows is

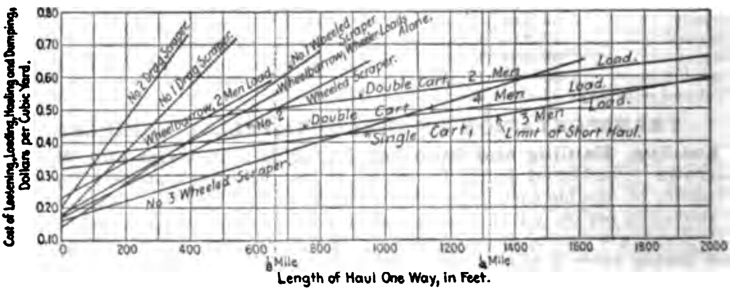

Fig. 1.—Cost of Loading and Hauling Gravel.

more economical than by carts up to a distance of about 250 ft. The capacity of a wheelbarrow is 3 cu. ft. Fig. 1 gives costs of loading and hauling gravel by double carts and wheelbarrows, based on wages of 20 cents per hour.

Scrapers. Drag scrapers are used for excavating and hauling plowed earth or sand when the haul is short. Wheeled scrapers are used for longer hauls where the quantity is greater and in cases where it would be impossible to use dump carts. Fresno or Buck scrapers are used for leveling land and roads, for thin cutting and spreading, and also for dragging dirt down hill, pushing material ahead of the pan, filling ditches, etc. Scrapers should be used in gangs, the number depending on the length of haul and local conditions. Either one or two men are required to load, depending upon the capacity of scraper and material handled. The driver usually dumps without help, but for larger capacities, a helper is frequently used. Drag scrapers are limited to hauls of 400 to 500 ft.; wheeled scrapers to hauls of 800 to 900 ft., but may be used up to 1600 ft. where impossible to use dump carts. Fresno scrapers are limited to short hauls and leveling. All scrapers are limited to easy-cutting material, unless it is plowed first.

The **drag scraper** (Fig. 2) consists of a steel pan *a*, bent from one piece, the bottom being reinforced by a hard-steel wearing plate. The hardwood handles *b* are attached to the pan and the bale *c* is pivoted at the sides and carries a swivel eye, to which the team is attached. To load the scraper, the handles are raised until the cutting edge gathers the load, when they are lowered and the scraper is dragged along the ground. To dump, the handles are raised until the cutting edge catches the ground and the pull of the team throws the pan over.

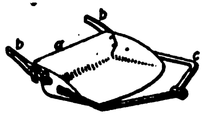

Fig. 2.—Drag Scraper.

The **wheeled scraper**, Fig. 3, consists of an arched axle *a* carrying two wheels of steel or wood with wide tires. The lever *c* is attached to the axle and the scraper pan *d* is hung from lever *c* by straps *e*. The tongue is attached to the pan and carries a pair of hooks *f* connected to lever *c* by straps *g*. To load the pan, lever *c* is raised until hooks *f* engage the lugs at the front of the pan so that the pull is applied to the cutting edge. After the pan is filled, lever *c* is lowered, which lifts the front end of the pan, releasing the hook *f*. The latch *h* engages the back end of the pan, holding it several inches above the ground, in which position it is moved to the dumping point. To dump, the back end of the pan is raised until the cutting edge catches the ground, when the pull of the team turns the pan over. The hook *k* pivoted to the draft gear holds the pan in its dumped position during the return trip. When handling sand, gravel or other loose material, automatic end gates are used to prevent leaking of material from the pans.

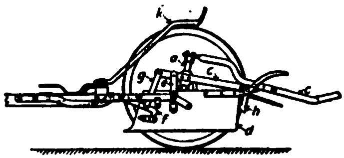

Fig. 3.—Wheeled Scraper.

The **Fresno or Buck scraper**, Fig. 4, consists of pan *a* carrying the runners *b* and lever *c*. The draft attachment *d* is attached to the pan by links. To load, the lever *c* is raised until the cutting edge gathers the desired load. The scraper is then dragged along the ground until the dumping point is reached, when lever *c* is raised until the cutting edge catches the ground, throwing the pan over on the runners. When empty, it travels on the runners.

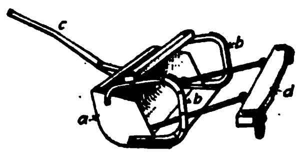

Fig. 4.—Fresno or Buck Scraper.

The speed of scrapers depends on the nature of the ground. For continuous operation, a team of horses can travel about 17 miles per day or about 2¼ miles per hour. Table 1 gives capacities and weights of the various types of scrapers. Fig. 1 gives costs of handling material by drag and wheeled scrapers. Two horses are required for drag and wheeled scrapers, with a snap team to help load large wheeled scrapers. Four horses are required for sizes Nos. 1 and 2 Fresno scrapers and two horses for No. 3.

Industrial Cars. Various types of narrow-gage cars are used for handling bulk and package material inside and outside of buildings. Those used for bulk material are usually of the dumping type, the form of the car being determined by the duty. They are either pushed by men or drawn by mules, locomotives or cable. The **rocker side-dump car,** Fig. 5, consists of a truck, on which is mounted a V-shaped steel body supported on rockers so that it may be tipped to either side, discharging material. Largely used on con-

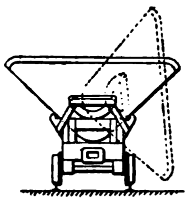

Fig. 5.—Rocker Side-dump Car.

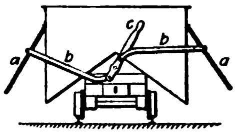

Fig. 6.—Gable-bottom Car.

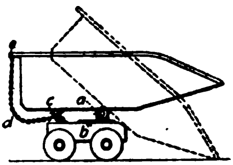

Fig. 7.—Scoop Dump Car.

struction work. Table 2 gives capacities, weights and general dimensions of standard sizes. In the **gable-bottom car,** Fig. 6, the side doors *a* are hinged at the top and controlled by levers *b* and *c* which lock the doors when closed. As this type of car discharges material close to the ground on both sides of the track simultaneously, it is used mainly on trestles, as described under "Endless Rope System," p. 1152. Table 3 gives capacities and general dimensions of various sizes. The **scoop dump car,** Fig. 7, consists of a scoop-shaped steel body pivoted at *a* on turntable *b* carried by the truck. The latch *c* holds the body in a horizontal position, being released by chain *d* attached to handle *e*. The body being mounted on a turntable, the car is used for service where it is desirable to discharge material at any point in the circle. Made with capacities from 12 to 27 cu. ft., to suit local requirements. The **hopper-bottom car,** Fig. 8, consists of a hopper on wheels, the bottom

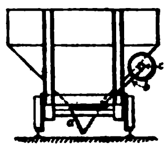

Fig. 8.—Hopper-bottom Car.

opening being controlled by door *a* operated by chain *b* winding on shaft *c*. The shaft is provided with hand wheel and ratchet and pawl. The type of door or gate controlling the bottom opening varies with different materials.

36	1,220	1,970	2,760	3,550	4,630	7,100	8,280
42	1,050	1,690	2,360	3,040	3,970	6,080	7,100

The **box-body dump car**, Fig. 9, consists of a rectangular body pivoted on the trucks at *a*, and held in horizontal position by chains *b*. The side doors of the car are attached to levers so that the door is automatically raised when the body of the car is tilted to its dumping position. The cars may be dumped to either side, and on the large sizes, where rapid dumping is required, this is accomplished by compressed air. This type of car is largely used in excavation and quarry work, being loaded by steam shovels. The greater load is placed on the side on which the car will dump, so that dumping is automatic when operator releases the chain or latch. The car bodies may be steel or wood, steel-lined. Table 4 gives capacities, weights and general dimensions of standard sizes. **Mine cars** are usually of the four-wheel type with low bodies, the doors being at one end, pivoted at the top, with latch at the bottom. Industrial **tracks** are made with rails from 12 to 45 lb. per yd., gage from 24 in. to 4 ft. 8½ in. Either steel or wooden ties are used. The steel tie is preferred where tracks are frequently moved, owing to lighter weight, the track being made up in sections. Table 5 gives wheel loadings for different weights of rail with various tie spacings. It is not economical to move material over 200 ft. in industrial cars pushed by men. Industrial cars are frequently built with one wheel attached to the axle, the other wheel loose to enable the car to turn on short-radius tracks. The frictional resistance per ton (2000 lb.) for different types of mine-car bearings is as follows:

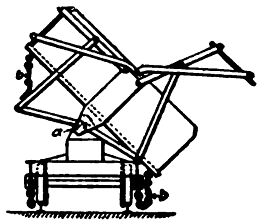

FIG. 9.—Box-body Dump Car.

Type of bearing	Drawbar pull, lb. per ton: Level track	2 per cent. grade	4 per cent. grade
Spiral roller	13	15	46
Solid roller	14	18	53
Self-oiling	22	31	..
Babbitted, old style	24	40	..

Motor Haulage

Electric Locomotives are used for hauling industrial cars in mines, quarries, yards, etc., taking the place of mules, steam locomotives and rope haulage. On standard-gage railroads, electric locomotives of 130 tons or more are used on passenger and freight service and for yard shifting. They are also largely used in mines, the locomotives being provided with cable and reel for hauling cars from side entries not equipped with trolley wire. Electric locomotives consume power only when in use. They have large momentary overload capacity, easy control, low maintenance cost and produce no smoke or fire.

Their use is limited to grades of approximately 10 per cent. for traction, and 16 per cent. for rack, locomotives. The size of track limits the weight of the locomotive, but for heavy service two locomotives are frequently used in tandem. The voltage is limited in many states by law to 275 volts for mine work; the usual gathering locomotive weighs from 5 to 6 tons, for haulage from 10 to 30 tons. Fig. 10 shows an electric locomotive of the mine type. The motors *a* are pivoted on the axles, the back end supported by rods *b*. The axles are driven through pinions and gears running in dust-tight cases. The motors are usually direct-current 250-volt. They are of the rugged enclosed type, designed for sparkless operation under any load, with capacity usually sufficient to drive the wheels to the slipping point. One motor is usually provided for each axle. Controllers are usually of the drum type with magnetic blow-out for series-parallel operation, and may be located at both ends or one end of locomotive, as required. Trolley poles are used to take current from the overhead wire, double poles being used where it is not possible to bond the rails. **Gathering locomotives,** used in mines and yards for collecting cars from tracks not equipped with trolley wire, are supplied with reel *c*, carrying conductor cable *d*. This reel is positively driven from the axle of the locomotive through sprocket chain and gears so that the cable will be paid out or drawn in as the locomotive moves. The carriage *e*, carrying horizontal and vertical rollers, guides the cable on the drum, being driven by screw *f* through sprocket chain *g* from the reel shaft. When the locomotive leaves the main track, the conductor *d* is attached to the trolley wire and to the track if the siding is not bonded. The cable is automatically paid out and taken up as the locomotive moves. The reel may be motor-driven, predetermined tension being maintained in the cable. This arrangement is used where steep grades are encountered. Locomotives may be equipped with a motor-driven winch on which is coiled a wire cable. In this case the locomotive stays on the main track, the cable being carried out and attached to the cars by an attendant. The winch pulls the cars out to the main track. This type requires an extra man; it cannot return cars up grade on entries, but can haul cars out on tracks not strong enough to support the locomotive. Locomotives may be equipped with either or both devices for gathering cars. Special locomotives equipped with powerful winches are frequently used for gathering only.

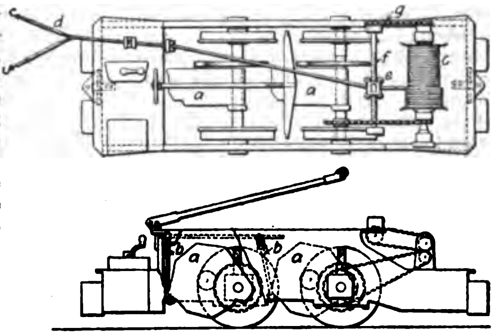

Fig. 10.—Electric Mine Locomotive.

The **Goodman rack-rail locomotives** are used on grades up to 16 per cent. A rack rail is mounted between the T-rails so the teeth of the sprocket wheel on the locomotive axle will engage therewith. With this system, locomotives may be operated by traction on level track, using the rack only on grades, or may operate on rack at all times. The rack may be used as a conductor if properly insulated and protected. Locomotives may be equipped with hand- or motor-driven winches for loading and unloading material.

Table 6 gives the minimum and recommended weights of rail for different locomotives, the size depending on the character of roadbed, spacing of ties, etc. The rail gages are from 18 in. to 4 ft. 8½ in. The electrical efficiency is from 70 to 85 per cent., depending on the size of motors and load factors. Total efficiency ranges from 60 to 75 per cent. The **weight** and **drawbar pull** for standard-size locomotives are given in Table 6 and are based on a train resistance of 30 lb. per ton for friction and 20 lb. per ton for each per cent. of grade. For cast-iron wheels and clean, dry rails, the drawbar pull is taken at 20 per cent. of the locomotive weight, and 25 per cent. with steel wheels. For sanded rails, the starting drawbar pull is 25 to 30 per cent. with cast-iron, and 30 to 33 per cent. with steel, wheels. Table 6 is based on locomotives with steel wheels. If cast-iron wheels are used, take 80 per cent. of the values given in the table. If roller-bearing cars are used, larger gross train loads may be handled.

Table 6. Standard Electric Locomotive Performances

Loco. weight, tons	Drawbar pull, lb.	Speed, miles per hour	Gross train load in tons for a resistance of 30 lb. per ton								Minimum weight of rail per yd., lb.	Recommended weight of rail per yd., lb.
			Per cent. of grade

20	10,000	7.2	333	192	131	98	76	61	51	42	50	60
25	12,500	7.1	417	240	164	122	95	77	63	53	60	80

Storage-battery Locomotives are used for hauling industrial cars where it is impossible or not economical to install trolley wires and bond the rails. They are largely used in storage yards and in buildings of manufacturing plants; also to some extent in mines for gathering cars. Their first cost is frequently less than that for trolley installation. They possess many of the advantages of the trolley locomotive but eliminate the danger and obstruction of the trolley wire. Being charged at night, they make no demand on the day load, as do trolley locomotives. Storage-battery locomotives are limited by the energy which may be stored in the battery. They should not be used on steep grades or where large continuous overloads are required. They give best results where light and medium loads are to be handled intermittently over short distances with a grade of not over 3 per cent. against the haul. The general construction and mechanical features are similar to those of the trolley type, Fig. 10, with battery boxes located either on top of the truck or between the frames, according to the type of service. Motors are of the special low-voltage vehicle type with drive to the axle of spur gears, or special high-efficiency worm gears. For light work the batteries may run several days on a single charge, but are usually charged every night. The charging may be done from existing generators in the power house where the voltage is sufficiently constant, but a separate generator set is usually employed.

The **efficiency** of batteries varies from 50 to 75 per cent., under average working conditions. The motor efficiency is from 65 to 80 per cent. The **speed** varies from 3 to 7 miles per hour, the average being from 3½ to 4½ miles. Table 7 gives the **weight and drawbar pull** of standard locomotives.

Table 7. Performances of Typical Battery Locomotives

Weight, tons	Drawbar pull, lb.	Miles per hour at rated draw-bar pull	Min. gage, in.	Wheel base, in.	Approx. total ton-miles on one charge, assumed friction = 30 lb. per ton.	Battery capacity, amp-hr.
2½	400	3	18	30	66	126
3	500	4	24	34	200	220
4	700	5	30	36	280	270
4	1000	3½	18	34	230	225
4	1000	3½	24	44	300	300
5	2000	3½	30	36	265	300
7	2400	3½	36	66	320	450

In determining the capacity of the **battery**, both the current and the energy factors must be considered. The speed at which the nominal drawbar pull is developed forms one basis for estimating the size of the battery. Assuming the overall efficiency of locomotives to be 60 per cent., I = the current discharge of the battery, amperes; E = voltage of battery; D = drawbar pull, lb.; M = speed, miles per hour, then $I = 3.32DM/E$. If the current is required almost continuously, the battery selected should have a normal discharge rate of $0.5I$ to $0.67I$; for intermittent service, from $0.25I$ to $0.2I$. Generally, $0.33I$ is used. If the current discharge for a required drawbar pull is not in excess of the normal discharge rate, then the size of the battery will be determined by the energy which must be stored to perform the desired work between charging periods. Assuming the efficiency of the locomotive at 60 per cent., rolling friction of locomotive 20 lb. per ton and of cars 30 lb. per ton, each per cent. of grade adding an additional 20 lb. per ton for both locomotive and cars, the kilowatt-hours required for handling locomotives and cars during the day is determined. This result is multiplied by 1.35 to allow for loss of greater than normal discharge, switching, excessive starting and stopping, etc. The result is the kilowatt capacity at a normal discharge rate required of the battery.

Gasoline Locomotives, being self-contained units, are used where it would not be economical to use electric or steam locomotives and in localities where the cost of oil is less than that of coal. They require no external charging station or licensed engineer. The first cost and maintenance are low. They are limited to hauls up grade of from 10 to 12 per cent., and used to some extent in mines (which must be well ventilated, due to exhaust gases and danger from fire). Mine-type locomotives are of the same general form as the trolley and storage-battery locomotives, the power unit being a four-cylinder four-cycle water-cooled engine. Power is transmitted to the axles by bevel and spur gears or by sprocket chains. The transmission provides two or three speeds both forward and reverse. The low speed is used for starting and pulling heavy loads and the high speed for long-distance runs. The engine runs in one direction and is provided with friction clutches for the forward and reverse motion and jaw-type clutches for shifting from high to low speed. The clutches are interlocking so that the jaw clutches cannot be thrown until the friction clutches are thrown out in the neutral position. For mine work, the gasoline tanks are filled outside the mine and attached to the locomotive through connections which prevent leakage during the change. The intake and exhaust of the engine and the magneto are screened with safety gause to prevent sparks igniting gas in the mine. For surface haulage, the same type of motor is used, but the gasoline tanks are attached to the frame and filled while in place. The method of transmitting power from engine to axles varies with different makers, but the general principles are as described under mine types. Gasoline locomotives operate at speeds from 3 to 15 miles per hour, and require from ¼ to ⅒ of a gallon of gasoline per h.p.-hour. Table 8 gives approximate performances of Milwaukee type locomotives.

Table 8. Performance of Gasoline Locomotives
(Train loads in tons of 2000 lb.)

Brake horse power	Weight, tons	Drawbar pull, lb.	Gear	Speed, miles per hour	Gross train load in tons (exclusive of locomotive) that may be hauled on level track and different grades with train resistance of 20 and 30 lb. per ton.

Motor-driven Cars and Trucks are used for moving material in bulk or packages, where it is not possible or convenient to lay tracks. **Electrically driven cars** used in industrial establishments are generally designed for special conditions. Self-discharging cars may be provided with scale beams mounted on the truck to weigh the charge. They are driven by railway-type motors, the operator riding with the car. **Electric automobiles** for freight and package handling are built with chassis of pressed steel and provided with solid-rubber-tired wheels. The motor is of the low-voltage vehicle type, driving the rear axle through gears or chain. The controller is of the drum type. The batteries are arranged in trays so they may be removed when discharged and charged batteries substituted, giving continuous operation of the truck; or batteries may be charged at night without being removed. Capacities range from 500 lb. (delivery wagons) up to 10 tons (trucks). Speeds range from 8 to 15 miles per hour for wagons up to 1000 lb. capacity and 4 to 8 miles for larger sizes; average speed, from 5 to 6 miles.

The average mileage is from 15 to 20 miles per charge on city streets where hills are encountered, and 20 to 30 miles on level streets. Cost of operation, from 25 to 40 cents per ton-mile.

In the transportation of package material in industrial plants, freight houses, stations, etc., **electric baggage and freight trucks** are extensively used. Fig. 11 shows the drop-frame truck, consisting of a steel frame carried by four wheels, provided with solid rubber tires. One pair of wheels is driven from the motor through a gear reduction, the storage battery being located at the other end of the truck. A hinged driver's platform is provided at each end, so arranged that when the operator steps on the platform, he releases the brakes and closes the main circuit between the battery and controller. He may then insert the controller handle. The steering bars are connected to all four wheels so the truck may turn in a radius of 15 ft. As controllers and steering bars are provided at each end, the truck may run in either direction without turning. The drop-frame type of truck is about 12 ft. in length and 45 in. wide, has a capacity of about 4000 lb. and a speed of 4 to 6 miles an hour, loaded; weight, about 3000 lb. Freight trucks are made with large driving wheels at one end, small wheels at the other end. They are about 7 ft. long and 42 in. wide, the platform being 10½ in. above the floor. Weight, about 1900 lb.; capacity, 4000 lb. A 30-day record of an Elwell-Parker drop-frame truck handling baggage showed an average daily service of 11 hours, mileage of 13½ miles, handling 225 tons. The truck was moving one-third of the time and loading and unloading the balance. A gang of eight men was employed and the cost of handling was 10.4 cents per ton.

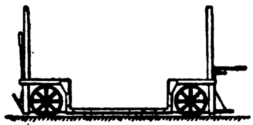

Fig. 11.—Electric Freight Truck.

For heavy haulage both on country roads and city streets **gasoline trucks** are rapidly supplanting horses. They are made with capacities from 1000 lb. up to 10 tons, and run at speeds varying from 16 miles per hour for the 1000-lb. truck to 5 miles for the 10-ton truck. In the tractor type the motor unit, either of the three- or four-wheel type, is not provided with a body for receiving the load. The load is carried in a separate body, one end of which is attached to the tractor. The tractor pulls the load instead of pushing it, and time is saved, as the tractor does not have to remain idle during the loading and unloading period. Fig. 12 gives the cost per ton-mile of hauling material with two-horse teams and trucks and tractors of various sizes, as compiled by the New England Audit Company.

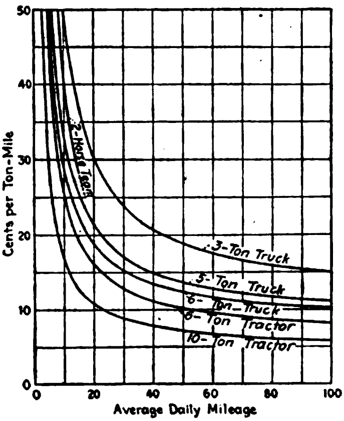

Fig. 12.—Costs of Hauling by Horse Teams, Trucks and Tractors.

Automatic Electric Haulage. The Woodford system of central control (patented) is used in quarries, surface mines, brickyards, excavation work, etc., where cars are to be moved within sight of operator in a central tower. As operators may be placed at intervals, the length of haul is without limit. The minimum gage is 36 in., owing to the motor equipment of cars. Maximum grade, about 15 per cent. It is not economical on capacities of less than 10 tons per hour. The system consists of a series of motor-driven cars, each provided with a selector switch. Between the T-rails there is located a third rail insulated by wooden blocks. It is made in sections that may be energized through feeder wires at two different voltages, under control of operator in central tower. The lower voltage operates the brakes on the car and the higher voltage the motor. The operator may thus either apply the brakes or move the car or cars in any of the sections at will. 220-volt direct current is generally used. Where the feeders are longer than 1½ miles, 550 volts is used, necessitating standard insulators on the third rail. When running down grade, the cars are retarded by the motors which run in the opposite direction, generating energy which is dissipated by resistance coils in the circuit. Should the circuit breaker be thrown out, a loaded car would back down the grade at a predetermined speed depending on the resistance and capacity of coils. The system may be applied to any size or type of car and the cars may be dumped at any desired point by the central-station operator. For spotting cars at the loading point, if at a long distance from the central station, a sub-controlling lever is installed to enable a local operator to spot the cars and when loaded to move them on to the main line. The operating speed varies from 4 to 12 miles per hour, depending upon local conditions.

CARS DRAWN BY CABLE

The haulage of cars by cable is divided into five general systems: Gravity inclined planes, engine inclined planes, tail-rope systems, endless-rope systems and the Hunt automatic railway. Their use is limited to mine and industrial cars.

Gravity Inclined Planes are used for lowering material in cars down an inclined plane. The grade must be sufficient for the loaded car to haul the empty car up the incline, overcoming the frictional resistance of cars, rollers supporting the rope, etc. If too steep the cars will attain too much velocity, causing excessive work on the drum brake. The system includes a drum located at the top of incline under which the cars may pass, the drum being provided with a brake which puts the speed of the cars under the control of operator. Fig. 13 shows four arrangements of track. Arrangement *A* consists of two tracks, one for empty and one for loaded cars, joined by switches at top and bottom. In *B*, three rails are used with turnouts in the middle of the plane. *C* requires still less rail, but involves a self-acting switch at the lower end of the parting. *D* has but a single track with a counterweight running on a separate track of narrower gage than the car track and under same for hauling empty cars to the top of the incline. The capacity of arrangement *D* is one-half that of *A*, *B* and *C*, as loaded and empty cars cannot be handled simultaneously.

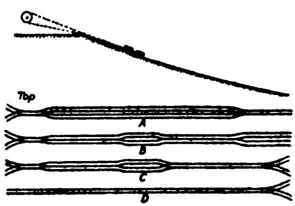

FIG. 13.

In all of these arrangements, the cable may wind on a drum at the top of the incline, or pass over a grip wheel at the same place. Where a single drum is used, one rope leads off the top and one off the bottom of the drum. Two drums are frequently used geared together and rotating in opposite directions, both ropes leading from the under side of the drums, preventing the tendency to lift the cars when at the top of the plane. The grip wheel is used only for light service. The ropes are supported by rollers between the track, and derailing switches and safety devices are provided in case the rope breaks. The proper grade for the incline depends on the length, the number and weight of the cars handled each trip. For ordinary inclines up to 2000 ft. in length, it varies from 4.8 to 10 per cent. To give the car an initial velocity, the top of the incline is steeper for a short distance, called the "knuckle." Operating speeds, 7 to 15 miles per hour.

Engine Inclined Planes are used for raising material in cars up an incline where the empty cars will return by gravity. The plane must have sufficient grade to allow the empty cars to descend the full length by gravity, hauling the rope after them. Long, straight grades will operate on $2\frac{1}{4}$ per cent. or even less, under the best conditions. Curved inclines should have steeper grades. The construction consists of a single or double track with an engine-driven drum at the top; or the engine may be at the bottom with a return sheave at the top. This requires twice the length of rope, therefore greater friction must be overcome by the descending car. The road may be straight or curved and the grade uniform or varying, if all one way, and sufficient for the empty cars to descend hauling the rope. An example of a plane with engine at the top is a 4600-ft. incline, $72\frac{1}{2}$ ft. total fall, with 3 per cent. grade for 200 ft., 2 per cent. for 100 ft. and $1\frac{1}{2}$ per cent. for the remainder. The train, consisting of 25 to 30 cars, is hauled by $\frac{9}{16}$-in. steel rope, a round trip occupying 9 min. The empty cars, weighing 15 to 18 tons, descend at a velocity of about 15 miles per hour. The cars are usually provided with brakes, and a derailing bar pivoted and dragged behind the last car sticks into the ground, derailing the train in case it starts backward, due to a broken rope. Operating speeds, 7 to 15 miles per hour.

The Tail-rope System is used principally for collecting and moving cars in mines. As the cars are pulled in both directions, this system does not depend on grades for its operation, so the road may be straight, curved, level or undulating. It is frequently used in connection with gravity and engine planes in large mines but is being replaced by electric-locomotive haulage, except on steep grades. Fig. 14 shows a two-drum engine, one for the main rope, the other for tail rope, both drums being provided with brakes and clutches.

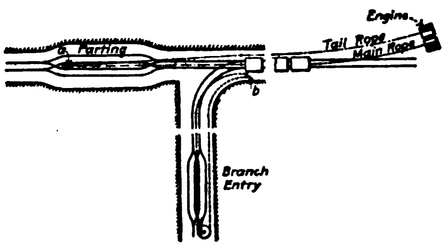

Fig. 14.

The main rope hauls the loaded cars in one direction, the tail rope pulling the empty cars back. The main rope is attached to the front of the train; the tail rope is carried over sheave *a* at the parting and attached to the rear. As the train is hauled out, the tail rope is dragged after it. To return the empty cars, the operation is reversed, the main rope being dragged in by the train. Either rope may be used for braking the speed of the train through brakes and clutches on the engine drum. The tail ropes are usually smaller than the main rope, but local grade may be such as to reverse this condition. For handling branch entries by power, a rope twice the length of the branch is laid in it with ends *b* in the main entry. Shackle connections are placed in the main and tail ropes, which are stopped opposite the branch. When the ends of the branch rope are connected to the main and tail ropes, the cars may be drawn in and out of the branch entry. As many connections of this kind as necessary may be provided. Operating speeds, 7 to 15 miles per hour.

The Endless-rope System is used for moving material in cars on level

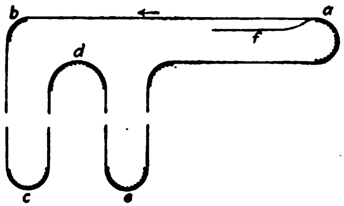

Fig. 15.

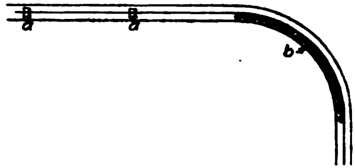

Fig. 16.

or inclined tracks. It is employed to some extent in mines, but its most frequent use is on elevated structures, forming storage piles where cars run continuously from the loading hopper over the circuit of track back to the loading point. The length of the system depends upon the grade, number of curves, weight, capacity and number of cars used, all of which determine the stress in the rope. Systems of this type have been installed with the circuit over a mile in length. The system consists of a constantly running endless steel rope traveling in the middle of a narrow-gage track. Fig. 15 shows a typical plan of road, the cars being loaded on the straight section between *a* and *b* and discharged on the sections, *bc*, *cd* and *de*. The section of track *f* is provided for spare cars. The driving mechanism is located at point *a*. The rope is supported on the straight section, Fig. 16, by cast-iron rollers, *a*, spaced 18 to 20 ft. apart, and guided around the curves by a series of rollers, *b*, about 7 in. in diam., set on vertical spindles and having concave faces. Fig. 17 shows one type of driver located beneath the track. The rope passes over sheave *a*, makes several wraps over the grooved drums *b* and *c*, passes over tension sheave *d*, guide sheave *e*, and

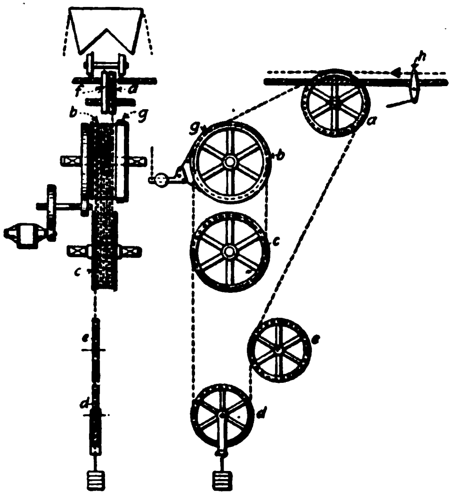

Fig. 17.—Driver for Cable with Endless-rope System.

over sheave *f*, which is on the same shaft as sheave *a*. Drum *b* is driven from the engine or motor by gears, and drum *c* has its shaft tilted so as to lead the rope to the grooves of drum *b*. The tension sheave *d* is provided with a weight to keep the rope at the proper driving tension. It is necessary to ungrip the cars where the rope passes over sheave *a* to the driver, which is done by hand. Should the operator fail to do this, the car will strike the trip bar *h*, which is connected by levers to the band brake *g* by a latch. When the car strikes the trip *h* it stops the motor and applies the brake. The rope cannot be started until the operator resets the trip, releasing the brake.

The cars are usually of the gable-bottom type with side doors hinged at the top and opened automatically by movable stops at the desired dumping point. The cars are attached to the rope by grips as shown in Fig. 18. These grips consist of a casting *b*, forming the upper jaw of the grip, with a sliding piece *c* guided by *b* and forming the lower part. The casting *b* is pivoted around point *e* by the bar *d*, and slides on the curved supports *h*. This enables the car and grip to make the turns. The moving section of the grip *c* is threaded at the top and raised and lowered by the shaft *f* and hand wheel *g*. To attach the grip to the rope, the operator swings the grip against the rope and turns the hand wheel *g* until the lower half of the grip raises the rope against the upper half. The cars are from 1 to 5 tons in capacity. The ropes are from ⅝ to ⅞ in. in diameter. The curves have a minimum radius of 15 ft. The speed of the endless-rope system is from 1 to 3 miles per hour. The **capacity** of gravity and engine planes depends on the length of haul, number of cars per train and the amount of time consumed in shifting, making fast and releasing the cars from the cable. Endless-rope systems will handle up to 250 tons per hour.

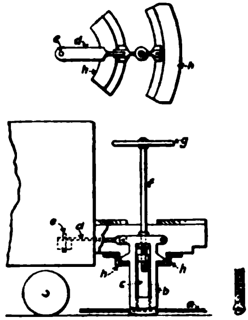

FIG. 18.

The Hunt Automatic Railway is used for moving bulk material on elevated track which may be placed on a down grade from the loading point. Its use is limited to a length of 600 ft. and curves may be placed only at the loading end. Fig. 19 shows the general form. The cars are loaded at *a*

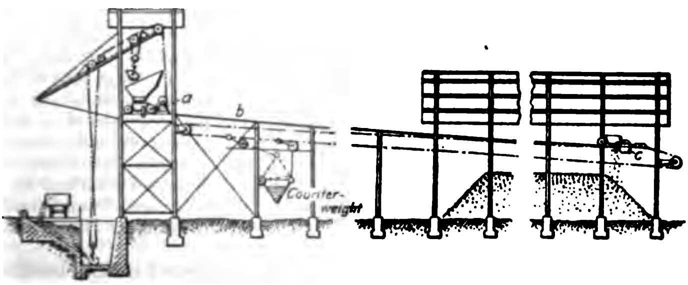

FIG. 19.—Hunt Automatic Railway.

and started by the operator down the first section of track inclined on about a 10 per cent. grade. The balance of the track is on from 2½ to 3 per cent. grade so that the car will travel the length of the track by gravity. The car is of the gable-bottom type (see Fig. 6) with the back inclined so that the discharging material will assist in starting the car backward. The side doors are hinged at the top and are controlled by a wire rope made fast to one door passing through ties on the end of the car, the other end being made fast to a toggle lever. Attached to this lever is an extension carrying a roller so arranged that when it strikes the dumping board on the stringers of the runway it will break the toggle, allowing the doors to open. The car is stopped by contact with a block attached through a spring and a cable to a counterweight which is lifted by its momentum; the falling of this counterweight imparts sufficient impetus to the car to return it up the grade to the loading point. The dumping block on the cable must be moved when the dumping point is changed; its movement is about 40 ft. The gage of the track is 21 in. outside and the curves at the loading end must have a radius of 30 ft. or over. The counterweight may be located at any point under the track. The cars are made in one- and two-ton capacities and a round trip on a 300-ft. track can be made in about 1 min. Only one man is required to operate the device and no power is required.

OVERHEAD TRACKAGE

Light Rigid Trackage consists of tracks of various forms suspended from overhead structures, for carrying trolleys to which loads are attached by hooks or chain blocks. Fig. 20 shows the **bar type** of track, consisting of a steel bar *a* with rounded edges carried by hangers *b* from the structure above. The trolley consists of four wheels *c* provided with roller bearings, each pair of wheels being carried by frame *d*, pivoted at points *e*, enabling the trol-

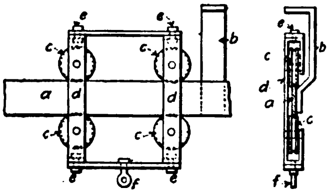

Fig. 20.—Bar Track.

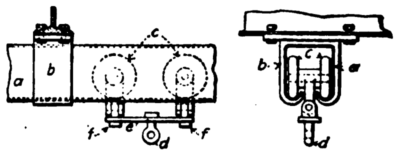

Fig. 21.—Coburn Track.

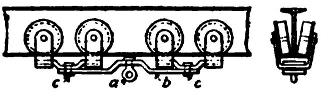
Overhead Trackage.

ley to turn on track of small radius. The load is attached to eye *f*. This construction is used for loads up to 4000 lb., the hangers being spaced from 2 to 5 ft. apart. In its simpler form, it is largely used for handling meat in packing houses. The **Coburn type** track, Fig. 21, consists of a rolled-steel track *a* supported by cast brackets *b* bolted to the overhead structure. The trolleys consist of four wheels *c* with rounded treads, provided with roller bearings. The load is suspended from the swivel eye *d* attached to bar *e*, which is pivoted at *f* so that the trolley may turn on track of small radius. This type is used for loads from 300 to 4000 lb., the hangers being spaced from 20 in. to 5 ft. apart.

The **single I-beam track** and trolley (Fig. 22) consists of an I-beam suspended from the overhead structure, with trolley wheels running on the lower flange. The type shown has eight wheels, the load being suspended from the swivel eye *a* attached to bar *b*, which is pivoted at *c* so that the trol-

ley may turn on track of small radius. This type of trolley is used in capacities of from 1 to 10 tons. Fig. 23 shows a double I-beam track used for the heavier work, the trolley wheels running on the lower flanges. The trolley is driven by a hand chain *a* through chain wheel *b*, pinion *c*, and gear *d*, the latter being keyed to the axle of one pair of wheels. Capacity, from 10 to 20 tons. The types shown in Figs. 20 and 21 are also made with a greater number of wheels, spreading the load over a greater length of track by the use of equalizing bars, such as shown in Fig. 22. They are usually moved along the track by hand, while those



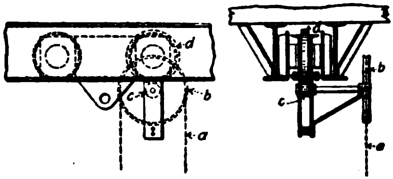


Fig. 22.—Single I-beam. Fig. 23.—Double I-beam.
Overhead Trackage.

shown in Figs. 22 and 23 may be moved either by hand or by chain wheel.

Telphers. **The telpher is a form of electric hoist which not only lifts the load but transports it on overhead track from one portion of an industrial plant to another, the operator riding on the telpher and controlling all operations. It is used to lift and transport material which may be suspended from a hook, such as pieces of machinery, trucks or boxes containing merchandise, lumber on skids, and bulk material such as coal, ore, etc., in tubs or grab buckets; also for great variety of service in industrial plants both in-**

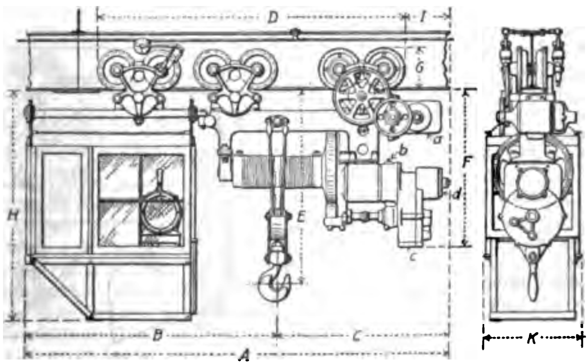

Fig. 24.—Hook Type Telpher.

side and outside of buildings, handling freight, etc., in freight houses and warehouses, unloading open-top cars and carrying the material to storage piles, bins, etc., as well as handling lumber, pipe, structural steel, etc., on skids. The length of haul is limited only by the length of the runways, the apparatus being used principally within the limits of a manufacturing plant. The minimum radius of track is 15 ft. when telphers are provided with swivel trucks. The load is limited to about 5 tons on standard machines.

A typical arrangement of track consists of an I-beam suspended from the overhead structure, the telpher wheels running on the lower flanges. The

switches consist of a pivoted section of beam supported by rollers at the moving end from a curved track above, and provided with a system of levers to enable the operator to throw the switch from the cab and to lock it in position. Turntables also operated from the cab enable the telpher to be turned at right angles. Fig. 24 shows the general form of a telpher of the **hook type.** The trucks are pivoted to the telpher frame to enable them to turn on short radius. The telpher is propelled by motor *a* geared to four wheels of the forward truck. The hoisting drum is driven by gears from motor *b*, provided with load brake *c* and solenoid motor brake *d*. Multi-speed controllers are used on both hoist and travel, limit switches being provided to prevent overhoisting. Table 9 gives general data on this type of hoist. When used to handle skids of lumber the same type is used, except that the drum is made longer and two hoisting ropes are used—winding on the same drum. The **lumber grapple hook,** Fig. 25, carried by turntable *a*, is suspended from the drum by ropes *b*. The hooks *c* take hold of the sticks under the pile of lumber, being controlled through lever *d* by the operator in the cab. The timbers *e*, to which are attached the pipes *f*, form a fork to hold the pile together. This system handles lumber in units of about 1500 ft. B. M. each, and is largely used to transport material between the storage yard, kilns, cars and boats.

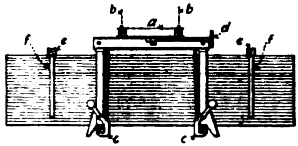

FIG. 25.—Lumber Grapple Hook.

Fig. 26 shows a telpher of the **grab-bucket type.** The closing rope of the bucket is attached to the closing drum *a*, and the hold rope to the hoist drum *b*. Each of the drums is driven by its own motor through spur-gear reductions, each being provided with solenoid brakes. The two motors are controlled by one drum controller. The telpher is moved by one or more motors geared to the truck wheels, operated by a drum-type controller. Table 10 gives general data on this type of hoist. Telphers may be operated by either direct or alternating current. The hoisting **speeds** vary from 25 to 200 ft. per min., and the travel speeds from 250 to 700 ft. per min., depending upon local conditions.

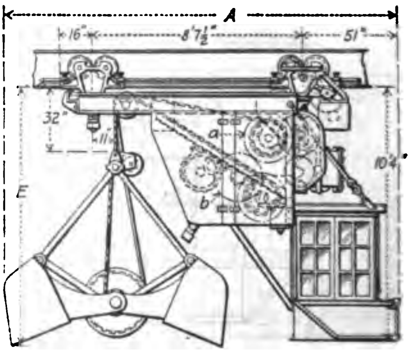

FIG. 26.—Grab-bucket Telpher.

Cableways are aerial hoisting and conveying devices using suspended steel cable for track, the loads being suspended from carriages and moved by gravity or power. The most common uses consist in transporting material from open pits and quarries to the surface, handling construction material in the building of dams, docks, etc., where the construction of tracks across rivers or valleys would be uneconomical, loading logs on to cars, coaling vessels at sea, etc. The maximum clear **span** is from 2000 to 3000 ft.; usual spans, 300 to 1500 ft. The gravity type is limited to conditions where at least a 20 per cent. grade is obtainable on the track cable. **Transporting**

cableways move the load from one point to another. Hoisting-transporting cableways hoist the load as well as transport it. A **transporting cableway** may have one or two fixed track cables, inclined or horizontal, on which the carriage operates by gravity or power. The gravity transporting type, Fig. 27(*I*), will either raise or lower material. It consists of one track cable *a*, on which travels the wheeled carriage *b* carrying the bucket. The traction rope *c* attached to the carriage is made fast to the power drum *d*. The inclination must be sufficient for the carriage to coast down and pull the traction rope after it. The carriage is hauled up by the traction rope *c*. Drum *d* is provided with brake to control the lowering speed, and material may be either raised or lowered. When it is not possible to obtain sufficient fall to operate the load by gravity, the traction rope *c*, Fig. 27(*II*) is made endless so that the carriage *b* is drawn in either direction by the power drum *d*. Another type of inclined cableway, shown in Fig. 27(*III*), consists of two track cables *a*, *a*, with an endless traction rope *c* driven and controlled by drum *d*. When material is being lowered, the loaded bucket *b* raises the empty carriage *bb*, the speed being controlled by the brake on the drum. When material is being raised, the drum is driven by power, the descending

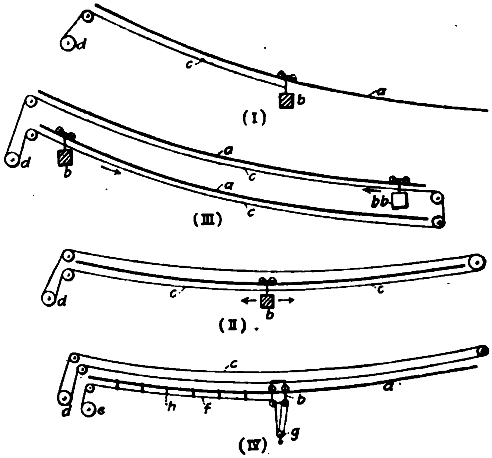

Fig. 27.—Cableways.

empty carriage assisting the engine in raising the loaded carriage. This type has twice the capacity of that shown in Fig. 27(*I*).

A **hoisting and conveying cableway,** Fig. 27(*IV*), hoists the material at any point under the track cable and transports it to any other point. It consists of a track cable *a* and carriage *b* moved by the endless traction rope *c* and by the power drum *d*. The hoisting of the load is accomplished by the power drum *e* through fall rope *f* raising the fall block *g* suspended from the carriage. The fall-rope carriers *h* support the fall rope, otherwise the weight of this sagging rope would prevent the fall block *g* from lowering when without load. Where it is possible to obtain a minimum inclination of 20 deg. on the track cable, the traction-rope drum *d* is provided with a brake and is not power-driven. The carriage then descends by gravity, pulling the fall and traction ropes to the desired point. Brakes are applied to drum *d*, stopping the carrier. The fall block is lowered, loaded and raised. If the load is to be carried up the incline, the carriage is hauled up by the fall rope. With this type, the friction of the carriage must be greater than that of the fall block, or the load will run down. The most recent development is the use of self-filling grab buckets, operated from the carriages of cableways, which are lowered, automatically fill themselves, are hoisted, carried to dumping position and discharged.

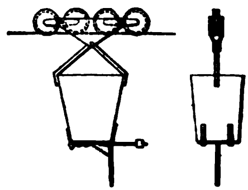

Fig. 28.—Bucket Carriage.

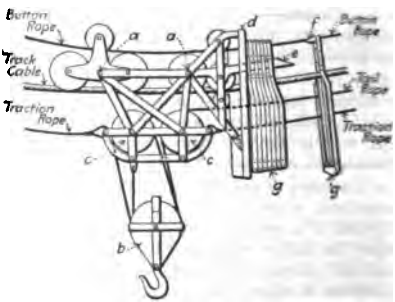

Fig. 29.—Lidgerwood Carriage.

Fig. 28 shows one type of bucket **carriages** used on transporting cableways. It consists of a four-wheeled carriage, from which is suspended an automatic bottom-dumping bucket. These carriages may also be provided with hooks or slings to which loads of various types may be attached. Fig. 29 shows the Lidgerwood type of carriage used on hoisting-transporting cableways. The trucks are pivoted at *a*, so as to distribute the load equally on the wheels. The fall block *b* is suspended from the carriage by sheaves *c*. At the back of the carriage is the pivoted frame *d* carrying the horn *e* for picking up the fall-rope carriers *g*. As the carriage runs out, the buttons *f* on the button rope distribute the fall-rope carriers at intervals, and as the carriage returns these carriers are picked up by the horn *e*. The button rope is made fast to one tower and kept tight by the counterweight at the other tower. Fig. 30 shows the Roebling type of carriage, in which the fall hook *a* is carried by a flat steel rope winding like a watch spring on drum *b*. The fall rope *c* is endless and wound around the two multiple-grooved sheaves *d* in the carriage, driving the drum *b* through pinions *e* and gear *f*, thus raising or lowering the load. This type does away with fall-rope carriers.

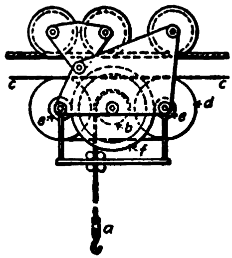

FIG. 30.—Roebling Carriage.

The **fall-rope carriers** are light steel frames for carrying the traction and fall ropes. In the Lidgerwood system these are distributed by the button rope above the track cable. The buttons are about 100 ft. apart and of different diameters, the eyes of the carriers being made to correspond to the buttons, so that as the carriage moves out the carriers are distributed by their respective buttons. Other types of carriers are carried by wheels on the track cable and attached to the carriage, to each other and to the tower by chains or rods which space them along the track cable as the carriage moves out. **Supporting towers** may be of steel or wood, fixed or movable. For short spans, simple A-frames are used, while on the long spans they are made with four posts. The movable towers are made with four or more posts securely braced and mounted on wheels. Both towers may move longitudinally or one may be fixed, the other moving on curved tracks. Fixed towers have been built as high as 235 ft. and traveling towers 125 ft. The towers are sometimes provided with propelling mechanisms where the cableways are frequently moved. The movable towers must be provided with counterweights to keep them from overturning. The engines and boilers serve this purpose at one end, the other end being weighted down with the required quantity of rock.

Table 11. Typical Installations of Gravity Transporting Cableways for Handling Coal (Roebling)

Type	Span, ft.	Diam. of track cable, in.	Type of carriage	Time of round trip, min.	Capacity per day of 10 hours, tons
Gravity incline, Fig. 27(*I*)	500	2	1½-ton bottom-dump bucket	2	500
Gravity 2-rope, Fig. 27(*III*)	1190	2¼	3½-ton bottom-dump bucket	4	1000
Gravity 2-rope, Fig. 27(*III*)	2077	2	2-ton bottom-dump bucket	2	1200

The carriage **speed** is from 300 to 1000 ft. per min. (in special cases up to 1800 ft.); average hoisting speed, from 100 to 300 ft. per min. The **average loads** for coal, earth, etc., are from 1 to 5 tons, for rock from quarries, 5 to 20 tons. Cableways have been built to handle loads of 50 tons on short spans. Tables 11 and 12 give data of typical installations. Steam-driven cableways require one fireman and one engineer; electric cableways, one engineer. Traveling and radial cableways require, in addition, one rigger, and all types require a signalman if it is not possible for the engineer to see the carriage and load at all times.

Table 12. Typical Installations of Hoisting and Conveying Cableways (Lidgerwood)

Service	Type	Material handled	Span, ft.	Load, tons	Diam. of track cable, in.	Diam. of conveying rope, in.	Diam. of hoisting rope, in.	Ht. head tower, ft.	Ht. tail tower, ft.
Building concrete bridge	Stationary	Concrete materials, forms, etc.	2038	6–10	2½, plow steel	¾, plow steel	¾, plow steel	165	165
Excavating and building dam	Stationary	Grab bucket and concrete materials	1436	10	2¼, patent locked steel	¾, Hercules steel	¾, Hercules steel	80	125
Building power house	Stationary	Building materials and machinery	1100	10–30	2¼, special patent locked steel	¾, special plow steel	¾, special plow steel	45	60
Quarry	Stationary	Stone	525	5	1¾, patent locked steel	⅝	⅝	50	50
Logging	Traveling	Logs	800	3–4	1½, patent locked steel	⅝	⅝	74	74
Clay pits	Radial traveling	Clay in skips	975	10	2¼, patent locked steel	¾	¾	74	80

The **deflection of** the **track cable** with its maximum gross load at mid-span is usually taken as one-twentieth of the span. Let S = span between supports, ft., l = one-half the span, ft.; w = weight of rope, lb. per ft., P = total concentrated load on rope, lb.; h = deflection, ft.; H = horizontal tension in rope, in lb. at one-fourth breaking strength. Then $h = S/20 = (wl + P)l/2H$, $P = (2hH - wl^2)/l = (8hH - wS^2)/2S$.

For track cables, a factor of safety at least of 4 is advised. The traction and fall ropes should have the sum of the load and bending stress well within the elastic limit of the rope, or for general hoisting about two-thirds of the elastic limit (which is taken at 65 per cent. of the breaking strength). Let P = load on the rope, lb.; A = area of metal in rope section, sq. in.; E = 29,500,000; R = radius of curvature, in.; d = diam. of individual wires in rope, in. (For 6-strand 19-wire rope, $d = 1/15$ rope diam.; for 6-strand 7-wire rope, $d = 1/9$ rope diam.) Then, load stress per sq. in. = $T_l = P/A$, and bending stress per sq. in. = $T_b = Ed/2R$. In determining the horse power required, the load on the traction or on the fall ropes will govern, depending upon the degree of inclination.

Cable Tramways are aerial conveying devices using suspended cables, carriages and buckets for transporting material over level and rough, mountainous country, across rivers, valleys, hills, etc. They are used for handling small quantities over long distances, and their construction cost is insignificant as compared with railroads and bridges. Two types are in use, single-rope, which both supports and propels the carriages; and double-rope, where one rope supports and the other propels the carriages. Table 13 gives data on typical installations of cable tramways. Single-rope tramways must run in a straight line but may have vertical curves. Owing to the high ratio of the weight of the moving parts to the weight of material carried, they are adapted only to short lengths ($\leq$ 1000 ft.), short spans and small capacities. They are not extensively used. The double-rope tramways are made in two types. The underhung type handles large capacities at high speeds and over long lengths, but must be in a straight line, although vertical curves are allowable. The overhead type is adapted to almost any requirement, with lateral as well as vertical curves. It is the best type for large capacity, but the spans must be shorter. The stress in the traction rope limits the length of tramways. For small capacity on level ground, 7 to 10 tons per hour may be carried 6 miles in one section. For 60 tons per hour the limit is about 3 miles. Larger capacities and steep inclines require shorter sections. Tramways are in operation 22 miles long, made in eight sections, the carriages being transferred from one section to the other.

Table 13. Typical Installations of Cable Tramways

Total length of tramway system, miles	Number of sections	Tramway elevates or lowers	Vertical distance between terminals, ft.	Material handled	Capacity of each carriage, lb.	Capacity, tons per hour	Speed of carriages, ft. per min.
1	1	Lowers	400	Ore	750	10	300
2	1	Lowers	812	Ore	1,200	50	333
2¼	1	Lowers	600	Rock	1,000	60	300
2½	1	Lowers	1,150	Ore	1,000	40	300
4	1	Lowers	200	Coal	1,250	50	500
12	3	Lowers	650	Log wood	300	10	300
22	8	Lowers	11,500	Ore	1,000	40	500

The **single-rope type**, Fig. 31, consists of an endless cable *a* passing over horizontal sheaves *d* and *e* at the ends and supported at intervals by towers. This cable is moved continuously and both supports and propels the carriages *b* and *c*. The carriages are either attached permanently to the cable, in which case they must be loaded and dumped while in motion, or they are attached by friction grips so that they may be connected automatically or by hand at the loading and dumping points. When the tramway is lowering material from a higher to a lower level, the grade is frequently sufficient for the loaded buckets *b* to raise the empty buckets *c*, operating the tramway by gravity, the speed being controlled by brake on grip wheel *d*.

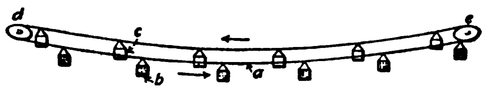

Fig. 31.—Single-rope Cable Tramway.

The **double-rope type**, Fig. 32, consists of two stationary track cables *a*, on which the wheeled carriages *c* and *d* travel. The endless traction rope *b* propels the carriages, being attached by friction grips. Fig. 33 shows the arrangement of the **overhead type**. The track cable *a* is supported at intervals by towers *b*, carrying the saddles *c*, in which the track cable rests. Each tower also carries the sheave *d* for supporting the traction rope *e*. The self-dumping bucket f is suspended from the carriage g. The grip h which attaches the carriage to the traction rope e is controlled by lever k. In the **underhung type,** shown in Fig. 34, the track cable a is carried above the traction rope e. The saddle c on top of the tower supports the track cable, and sheave d the traction cable. The sheave is provided with a rope guard m.

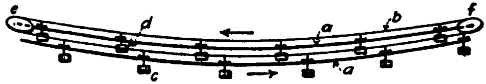

FIG. 32.—Double-rope Cable Tramway.

The lever h with roller on the end automatically attaches and detaches the grip by coming in contact with guides at the loading and dumping points. The carriages move in one direction only on each track. On steep downgrades, special hydraulic speed controllers are used to fix the speed of the carriages.

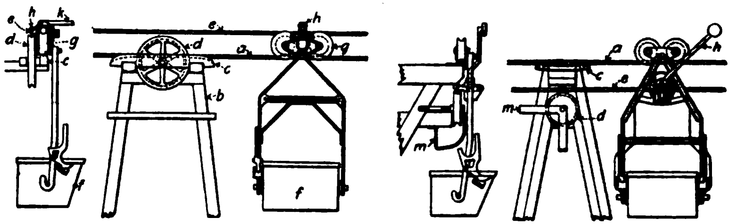

FIG. 33.—Overhead Type. FIG. 34.—Underhung Type.
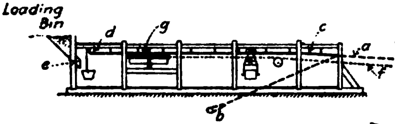
Double-rope Cable Tramways.

The **track cables** are of the special locked-joint smooth-coil or tramway types. Cast-steel ropes are used for short spans and plow-steel for long spans. The usual spans for level ground are from 200 to 300 ft., and in rough country as required. One end of the track cable is anchored, the other end counterweighted to one-quarter the breaking strength of the rope so that the horizontal tension is a known quantity. Special couplers of machine steel are used to splice the rope, designed to develop the full strength of the rope and to have as small a diameter as possible to allow the carriage wheels to roll over them. The **traction ropes** are made 6-strand 7-wire, or 6-strand 19-wire, of cast or plow steel on hemp core. The maximum diameter is 1 in., which limits the length of the sections. The traction rope is endless and is driven by a drum or grip wheel at one end, passing over a counterweighted sheave at the other end.

Fig. 35 shows a **loading terminal.** The track cables a are anchored at b. The carriage runs off the cable to the fixed track c, which makes a 180-deg. bend at d. The empty buckets are loaded by the chute e from the loading bin, continue around the track c, are automatically gripped to the traction cable f, and pass on to the track cable a. The traction cable f passes around and is driven by the grip wheel or drum g. When the carriages are permanently attached to the traction cable, they are loaded by a moving hopper which is automatically picked up by the carriage and carried with it a short distance while the bucket is being filled. Fig. 36 shows a **discharge terminal.** The carriage rolls off from the track cable a to the fixed track c, being automatically ungripped. It is pushed around the 180-deg. bend of track c, discharging into the bin underneath, and continues on track c until it is automatically gripped to the traction cable *f*. The counterweights *h* are attached to the track cables *a*, and the counterweight *k* is attached to the carriage of the traction-rope sheave *m*. The **supporting towers** are A-frames of steel or wood. At abrupt vertical angles the supports are placed



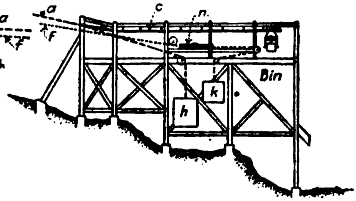


FIG. 35.—Loading Terminal. FIG. 36.—Discharge Terminal

Cable Tramway.

close together and steel tracks installed in place of the cable. The best practice spaces the towers, where possible, approximately the same as the carriages, so that but one carriage will be on a span at a time.

The operating **speed** for single-rope tramways is from 100 to 200 ft. per min., for double-rope tramways, from 200 to 550 ft. Single-rope tramways have a **capacity** of 5 to 15 tons per hour. Double-rope systems, up to 200 tons per hour, and under extremely favorable conditions, 300 tons. The standard buckets are made with capacities up to 1 ton.

Fig. 37 shows the **Lawson type tramway,** in which the car *b* is carried by the two track cables *a*. These cables rest at the towers on the pivoted saddles *c*. The cars are attached to traction rope *d*. The cars are loaded by a special traveling hopper filled from bin above and traveling with the car a short distance while it is being filled. They are discharged as they pass around the drum at the dumping end.

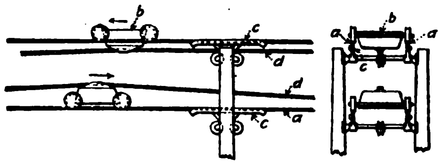

FIG. 37.—Lawson Cable Tramway.

STRESS IN ROPES (Roebling). The **deflection** for track cables of tramways is taken as 1/40 to 1/50 of the span to reduce the grade at the towers. Let S = span between supports, ft.; h = deflection, ft.; P = gross weight of buckets and carriages, lb.; Z = distance between buckets, ft.; W_1 = total load per foot of rope, lb.; H = horizontal tension of rope, lb. The best condition is when $S = Z$, with only one bucket in the span. The formulæ given under Cableways (p. 1160) then apply. When several buckets come in the span at the same time, special treatment is required for each span. For large capacities the buckets are spaced close together, and the load may be assumed as uniformly distributed and the live load per lineal foot of span $= P/Z$. Then $H = W_1S^2/8h$, where W_1 = weight of rope per ft. $+ (P/Z)$. When the buckets are not spaced closely, the equilibrium curve can be plotted

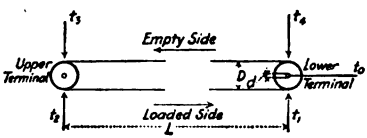

FIG. 38.

with known horizontal tension and vertical reactions at points of support.

For figuring the traction rope, t_0 = tension on counterweight rope, lb., t_1, t_2, t_3, t_4 = tensions (lb.) at points shown in Fig. 38; n = number of carriers in motion; a = angle subtended between the line connecting the tower supports and the horizontal; W_1 = weight of each loaded carrier, lb.; W_2 = weight of each empty carrier, lb.; w = weight of traction rope, lb. per ft.; L = length of tramway of each grade a, ft.; D = diam. of end sheave, ft.; d = diam. of shaft of sheave, ft.; f_1 = 0.015 = coefficient of friction of shaft; f_2 = 0.025 = rolling friction of carriage wheels. Then, if the loads descend, the maximum stress on the loaded side of traction rope is

$$t_2 = t_1 + \Sigma\,[L\,w \sin a + \tfrac{1}{2}nW_1 \sin a] - f_2\,\Sigma\,[Lw \cos a + \tfrac{1}{2}nW_1 \cos a]$$

where $t_1 = \tfrac{1}{2}t_0[1 - f_1(d/D)]$. If the load ascends, there are two cases: (1) driving power located at the lower terminal; (2) driving power at the upper terminal. If the line has no reverse grades, it will operate by gravity at a 10 per cent. incline for 10 tons per hour capacity and at 4 per cent. grade for 80 tons per hour. The above formula will determine whether it will operate by gravity.

The **power required** or developed by tramways is as follows: Let V = velocity of traction rope, ft. per min.; P = gross weight of loaded carriage, lb.; p = weight of empty carriage, lb.; N = number of carriages on one track cable; $P/50$ = friction of loaded carriage; $p/50$ = friction of empty carriage; W = weight of moving parts, lb.; E = length of tramway divided by difference in levels between terminals in feet. Then, power required =

$$\text{h.p.} = \frac{NV}{33{,}000}\left(\frac{P-p}{E} \pm \frac{P+p}{50}\right) \pm 0.0000001WV$$

Where power is *developed* by tramways, use 80 instead of 50 under $P + p$.

CAR-UNLOADING MACHINERY

Five types of devices are in common use for unloading material from all types of open top cars: Cross-over and horn dumps, used to unload mine cars with swinging end doors; rotary car dumps, for mine cars without doors; tipping car dumps, for unloading standard-gage cars where large unloading capacity is required; and the plow type, used for unloading flat cars.

Cross-over Dump. Fig. 39 shows car in the act of dumping; Fig. 40 shows loaded car pushing empty car off the dump. A section of track is

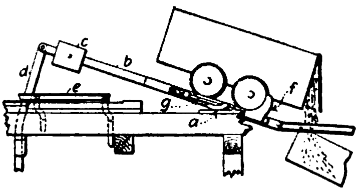

FIG. 39.

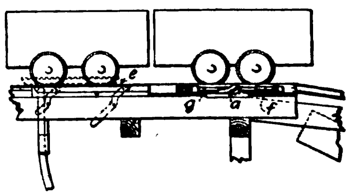

FIG. 40.

Cross-over Dump.

carried by a platform supported on rockers a. An extension bar b carries weight c and brake friction bar d. A hand lever controls brake, acting on friction bar and placing dumping under control of operator. A section of track e in front of the dump is pivoted on a parallel motion and counterbalanced so that it is normally raised. The loaded car depresses rails e, and through levers pivots horns *f* around shafts *g*, releasing the empty car. The loaded car strikes the empty car, starting it down the inclined track. After the loaded car has passed rails *e*, the springs return horns *f* so that they stop the loaded car in the position to dump. Buffer springs on shaft *g* absorb the shock of stopping the car. The center of gravity of the loaded car being forward of the rockers, the car will dump automatically under control of the brake. No power is required for this dump and one operator can dump from three to four cars per minute.

Horn Dump (Fig. 41). This consists of a curved track inclined so that the bottom of the car will be at the angle of slide of the material. A shaft *a* carries two horns *b* which engage the front wheels of the car as it starts down the incline. A band brake *d* controlled by lever *e* enables the operator to regulate the speed of car. The extension on one of the horns engaging the end of lever *c* holds the car in the dumping position. No power is required; one operator can dump from three to four cars per minute.

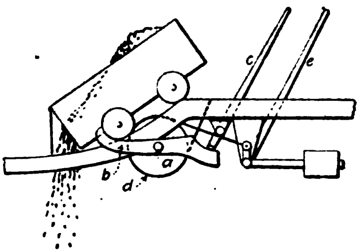

Fig. 41.—Jeffrey Horn Dump.

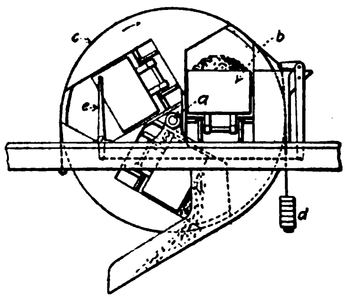

Fig. 42.—Rotary Gravity Dump.

Rotary Gravity Dump (Fig. 42). This consists of a steel cylinder supported by shaft *a*, its three compartments carrying three tracks. The loaded car *b* being to one side of the center, causes the cylinder to rotate, the material rolling to the chute beneath. The band brake *c*, with counterweight *d*, operated by lever *e*, places dumping under control of the operator. No power is required; one operator can dump from two to three cars per minute.

Rotary Power Dumps are made to handle from one to six cars at a time. They consist of a framework carrying track for cars and supported by steel rings, some of which consist of gears meshing with pinions on a shaft which is driven through gear reduction from motor. A band brake is provided so the operator may control dumping. Longitudinal beams in the framework engage the top of car to prevent it from leaving the track. A stop engaging the axle of the car wheels holds the car in proper longitudinal position. When built for one car, one operator can handle about three cars per minute; when long enough for six cars, about eighteen cars per minute. They require about 15 h.p. when handling three 5-ton cars.

Tipping Car Dump. Tipping dumps are made both electrically and steam-driven, and are built to handle cars up to 100 tons capacity. They are capable of handling 30 cars per hour, and under extremely favorable conditions, 40 to 45 cars. For 100-ton cars, 450 to 500 boiler h.p. is provided, where steam-driven, and about 400 motor h.p. where electrically driven.

Four to five men are required on the dump itself, this not including the men required to bring cars to the dump.

Plow-type Car Unloaders are used for unloading flat cars. They consist of a flat car carrying a single-drum reversible engine taking steam from the boiler of the locomotive. A flat car at the other end of the train carries a steel plow. Plows are made to discharge on one side or both sides at the same time. The spaces between the cars are covered with hinged steel plates, to bridge the openings. The trains consist of 17 to 20 cars each. Two posts, located at a convenient point along the track, support a chain spanning the track. The end of the hauling rope coiled on the drum is made fast to the chain and the train moved forward. The rope is drawn out along the top of the load until it reaches the plow, when it is released and hooked to the plow. The train is then moved to the dumping point and the plow drawn through the train, sweeping the load off to one side or the other. The cars may have side doors hinged at the top when used for fine material, but where large rock is handled the cars are provided with stakes about 2 ft. high to guide the plow. Two sizes of engines are used: 25-ton pull, with double steam cylinders 10 by 12 in., used with $1\frac{1}{4}$ in. rope; and 60-ton pull, with cylinders 12 by 12 in., used with $1\frac{1}{2}$ in. rope. A 17-car train can be unloaded in about 5 min., and any material which can be loaded on to the cars with steam shovels may be unloaded with plows. The hoisting engine is operated by the locomotive engineer or fireman, and, by moving the train at the same time the plow is in operation, it is possible to unload the entire train at one point or to distribute the train load over as great a length as desired.

CONTINUOUS CONVEYORS

Screw or Spiral Conveyors are used for conveying horizontally dry non-abrasive materials, such as grain, flour, seeds, cement and fine coal; also for sand, gravel, fine ashes, etc., although the wear from these abrasive materials is so rapid that the maintenance cost is excessive. The maximum length when

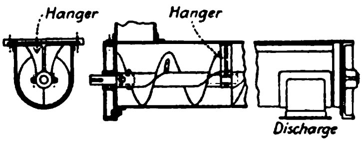

FIG. 43.—Spiral Conveyor.

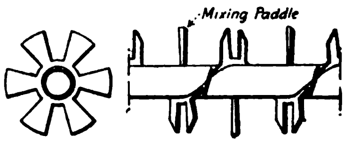

FIG. 44.—Cut-flight Conveyor.

handling grain or light pulverised materials is 400 to 500 ft.; for more abrasive materials, 100 to 150 ft. They may be used as feeders in single sections on inclines up to 15 deg. They should not be used for handling material containing lumps. The **spiral conveyor** (Fig. 43) consists of a stamped or rolled steel spiral secured by lugs to a shaft formed of pipe. The sections (6 to 12 ft. long) are joined by a piece of shafting which serves as coupling and bearing. The screw revolves in a box of steel, wood, cast iron or concrete which carries the hanger bearings. Wooden boxes are usually lined with light steel plate. The power is applied at one end by pulley, gear or sprocket. When used for mixing materials or breaking up lumps, a portion of the spiral is cut away, as shown in Fig. 44, forming a **cut-flight conveyor.** Mixing paddles are sometimes inserted both in cut-flight and standard conveyors to mix the material or retard the flow. When handling abrasive materials, cast-iron screws and boxes should be used.

The **ribbon conveyor,** Fig. 45, is used when handling damp or sticky material which would build up around the shaft of the standard type. It consists of a ribbon flight secured to the shaft by lugs, but with an open space between the ribbon and shaft.

Table 14 gives the maximum advisable speeds for various materials, and capacities based on conveyors with standard-width hangers, continuously fed. The capacity is limited by the quantity of material passing the hangers (1¼ to 3 in. wide). The end of one flight delivers material into the hanger space, and it must flow by gravity (seeking its natural angle of repose) assisted by the crowding action of the flight across this space to the next flight. The **power required** is given by h.p. $= TLC/1000$, in which T = short tons per hour, L = length of conveyor, ft., and C = 0.8 for grain, = 1.6 for coal and cement, = 2.4 for sand, gravel and ashes.

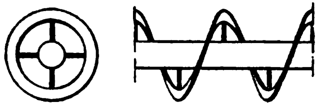

Fig. 45.—Ribbon Conveyor.

Table 14. Speeds and Capacities of Screw or Spiral Conveyors

(For ribbon conveyors take one-third of the capacities given)

Conveyor and Elevator Chains. Fig. 46 shows a **detachable-link chain** used for the lighter service in handling non-abrasive material, and consisting of a series of malleable cast-iron links hooked together. When straightened out, the links cannot come apart, but when folded up, as shown in Fig. 46, the links may be separated by slipping the bar sideways out of the hook through the recess *a*. When this chain is overstressed, the hooks straighten out, throwing the chain out of pitch. The articulating joint between the bar and hook being exposed, grit may enter, causing wear and elongated pitch preventing chain from properly fitting the sprockets. Fig. 47 shows in part cross-section a **closed-link riveted chain.** The riveted pins are kept from turning by the projection *a*, so that articulation takes place between link and pin, giving a large, well-protected bearing area. This chain will hold its pitch better than the detachable chain. Fig. 48 shows in part cross-section a **closed-link mal-**

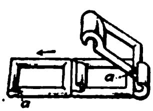

Fig. 46.—Detachable Link.

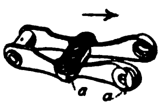

Fig. 47.—Closed Link.

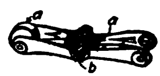

Fig. 48.—Closed Link with Roller.

leable chain with roller *a* to decrease wear on sprockets and support the chain in its horizontal travel. The pin is kept from turning by the projection *b*, and is usually made in the form of a bolt so that rollers may be replaced when worn. This type of chain is also made with bushings between the pins and links. These three types of chain are also made with projections of various forms on the links for the attachment of buckets, flights, etc.

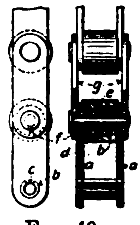

FIG. 49. Steel Bushed Roller Chain.

Fig. 49 shows a **steel bushed roller chain** used for heaviest service. It consists of steel side-bar links, the inner links *a* carrying the bushing *b*, which does not form a complete circle and is kept from turning by the projection *c* of the link. The cast-iron roller *d* turns on the steel bushing *b*. The pin *e* has a projection *f* under the head which fits into the recess of the outer bar *g* and keeps the pin from turning. The pin is riveted on the other end and, being attached to the outer bars and the bushing to the inner bars, the turning takes place between pin and bushing, both of which are replaceable. Attachments are riveted to the side bars for carrying buckets, flights, etc. In some cases, the side bars are made of malleable iron in place of steel. Chains of the type shown in Figs. 46 and 47, not being provided with rollers, will produce unnecessary wear on the sprockets if not properly installed. Fig. 50 shows a sprocket acting as a driver with the conveyor or elevator chain properly installed with the bar running first so that the articulation takes place between bar and hook, producing no wear on the sprocket tooth. If the hook ran first, the turning would take place between the hook and the sprocket tooth. The arrows on Figs. 46 and 47 show the proper direction in which these chains should run on conveyors and elevators.

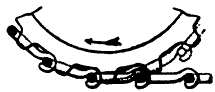

FIG. 50.

Scraper or Flight Conveyors are used for conveying non-abrasive materials such as coal horizontally and on inclines. Their length is limited by the strength of the chains. They may be built 200 to 300 ft. long, if horizontal, and operated on inclines up to 45 deg. Lumps are limited to sizes which may be fed readily between flights and between chains. Single-strand conveyors, Fig. 51, consist of a single chain *a*, to which are bolted flights *b*, of steel or malleable iron. Double-strand conveyors, Fig. 52, have two chains *a*, with the flights *b* suspended from them. Either type may be equipped with sliding blocks *c*, as Fig. 51, or with rollers *c*, Fig. 52, preventing the flights from touching the trough. For heavy duty, double-strand conveyors with rollers should be used. Troughs *d* are made of steel plate or cast iron. Chains are driven by sprockets at one end, take-ups being provided at the other end. The flights scrape the material along the trough, discharging at the end or through openings in the trough bottom controlled by gates. Scraper conveyors always pull the material toward the driving end. Single-strand conveyors should only be used in short lengths and for light duty. The working **speed** of the chain should not exceed 100 ft. per min. when large material is being handled, but it may be increased to 125 to 150 ft.

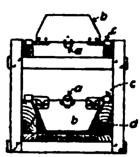

FIG. 51. Single Chain.

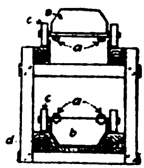

FIG. 52. Double Chain.

Scraper or Flight Conveyors.

when the material is small. The best results are obtained when the speed is kept low. Table 15 gives **capacities** and weights, based on an even and continuous feed. When the angle exceeds 30 deg. from the horizontal, the capacity figures given should be reduced 1 per cent. for each degree. For **power required**, see p. 1172.

Table 15. Capacities and Approximate Weights of Scraper Conveyors

Apron Conveyors may be used for practically any material which will not adhere to the carrying surface, except pulverized material which will leak through the joints between the apron plates. As the load is carried and not dragged, less power and smaller maintenance are required than by scraper conveyors. They are used with stationary skirt or side plates as feeders for taking material from hoppers or bins. The length is limited by the strength of the chains. They may be built 300 to 400 ft. long, if horizontal, and operated on inclines up to 30 deg. Sizes of lumps are limited by the width of the pans and the ability of conveyor to withstand the impact of loading. End discharge only is possible. The apron conveyor, Fig. 53, consists of two strands of roller chain separated by overlapping apron plates, forming the carrying surface, with sides 2 to 6 in. high. The chains are driven by sprockets at one end, take-ups being provided at the other end. The conveyors always pull the material toward the driving end. For light duty, flangeless rollers on flat rails are used; for heavy duty, single-flanged rollers and T-rails. Apron conveyors may be run without feeders, provided the opening of the feeding hopper is made sufficiently narrow to prevent material from spilling over the sides of the conveyor after passing from the opening. When used as a conveyor, the **speed** should not exceed 60 ft. per min.; when used as a feeder, 30 ft. per min. Table 16 gives weights and **capacities** based on an even and continuous feed. For **power required**, see p. 1172.

Open-top Carriers, Fig. 54, are similar to apron conveyors, except that dished or bucket-shaped receptacles take the place of the flat or corrugated apron plates used on the apron conveyor. They will operate on steeper inclines than apron conveyors (up to 70 deg.), as the buckets prevent material from sliding back. Neither sides extending above top of buckets nor skirt boards are necessary. **Speed** when loaded by a feeder, 60 ft. per min. (max.); when dragging the load from a hopper or bin, ≦ 30 ft. per min. The **capacity** should be figured on a basis of the buckets being three-fourths full, the angle of inclination of the conveyor determining the loading condition of the bucket. For **power required**, see p. 1172.

V-bucket Carriers are used for elevating and conveying non-abrasive materials, principally for handling coal when it is desired to elevate and convey with one piece of apparatus. The length and height lifted are limited by the strength of the chains, neither of which should exceed 75 ft. They may operate on any incline and may discharge at any point on the horizontal run. The size of lumps is limited by the size and spacing of the buckets. The carrier consists of two strands of roller chain separated by V-shaped steel buckets. Fig. 55 shows the most common form, where material is received on the lower horizontal run, elevated and discharged through openings in the bottom of the trough of the upper horizontal run.

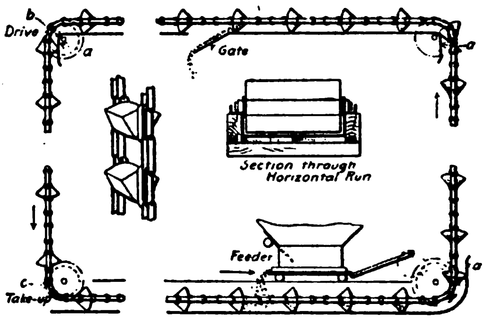

Fig. 55.—V-bucket Carrier.

The material is scraped along the horizontal portions of the conveyor, as in a scraper conveyor. The steel guard plate *a* at the lower bend, guides the material into the bucket. Fig. 56 shows a different form, where material is dug by the elevator from a boot, elevated vertically, scraped along the horizontal run and discharged through gates in the bottom of the trough. Fig. 57 shows a variation of Fig. 56, requiring one less bend in the conveyor. The troughs are of steel or wood steel-lined. When feeding material to the horizontal run, it is advisable to use an automatic feeder driven by power from one of the bend shafts to prevent overloading. Should the buckets of this type of conveyor be overloaded, they will spill on the vertical section. The drive is located at *b*, with take-up at *c*. The **speed** should not exceed 100 ft. per min. when large material is being handled, but when material is small, it may be increased to 125 ft. The best results are obtained when speeds are kept low. Table 17 gives the **capacities** and weights based on an even and continuous feed. For **power required,** see p. 1173.

Pivoted-bucket Carriers are used for elevating and conveying practically any material which will not adhere to the buckets, although at a disadvantage when handling finely ground abrasive material which can get into the bearings of the moving parts. They require less power than V-bucket carriers, as the material is carried and not dragged on the horizontal run. The length

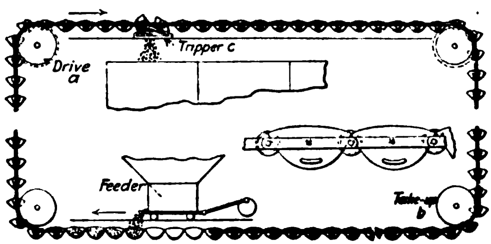

FIG. 58.—Pivoted-bucket Carrier.

and height lifted are limited by the strength of the chains. The length should not exceed 500 ft., and the height lifted 100 ft. They may be operated on any incline, and may discharge at any point on the horizontal run. The size of lumps is limited by the size of buckets. The pivoted-bucket carrier consists of two strands of roller chain with flanged rollers, between which are pivoted buckets of steel or malleable iron. Fig. 58 shows the usual form in which these conveyors are installed. The drive is located at *a*, the take-up at *b*. The material is fed to the buckets on the lower horizontal run (usually by an automatic feeder), elevated and discharged on the upper horizontal run. The tripper *c*, mounted on wheels so that it may be moved to the desired dumping position, engages the cams on the buckets, tipping the buckets until the material is discharged. The buckets, being pivoted above the center of gravity, remain in the carrying position on both horizontal and vertical runs, except when passing the tripper. The rollers of the chains run on T-rails on the horizontal section and between guides on the vertical runs. The conveyor operates best at from 40 to 50 ft. per min., the **speed** being limited by the impact of the buckets on the dumping tripper. Table 18 gives the **capacities** and **weights** based on an even and continuous feed. For **power required**, see p. 1173.

Power Required for Chain Conveyors. The following formulæ give the power required to be applied to the conveyor driveshaft. Allowance in engine or motor size must be made for the speed reduction through gears, driving chains and belts. The weights and capacities of each type will be found in the tables. For scraper conveyors, apron conveyors and open-top carriers,

$$\text{h.p.} = (AWLS/1000) + (BLT/1000) + X$$

where A and B are constants from Table 19; W = weight of conveyor per ft. of one run, lb.; L = length from center of head sprocket to center of tail sprocket, ft.; S = speed of conveyor, ft. per min.; T = capacity of conveyor per hour in tons (2000 lb.); X = 1 for conveyors up to 100-ft. centers and 2 for longer conveyors.

If the conveyor is composed of portions on different inclines, the various portions should be considered independently and the results added. Where such changes in the inclination occur, 10 per cent. should be added for each change in direction.

Example. Determine the power required to drive a scraper conveyor having 10 × 24-in. flights spaced 24 in. apart, and carrying 140 tons of bituminous coal per hour; sliding blocks to be used, and the conveyor to run as shown in Fig. 59. As the conveyor is inclined at 36 deg., 1 per cent. must be deducted from the rated capacity of 150 tons per hour for each degree over 30 deg. so that the conveyor will carry 141 tons per hour at a speed of 100 ft. per min. The values for the 30-ft. inclined section are A = 0.025, W = 26 lb., L = 30 ft., S = 100 ft., B = 1.08, T = 141 tons. The values for the 80-ft. horizontal section are A = 0.03, L = 80 ft., B = 0.60, X = 2, and 10 per cent. must be added for power consumed at the bend between the inclined and horizontal sections. Therefore

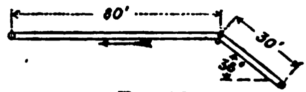

Fig. 59.

$$\text{h.p.} = \left[\left(\frac{0.025 \times 26 \times 30 \times 100}{1000} + \frac{1.08 \times 30 \times 141}{1000}\right) + \left(\frac{0.03 \times 26 \times 80 \times 100}{1000} + \frac{0.60 \times 80 \times 141}{1000}\right) + 2\right] \times 1.10 = 23.68 \text{ h.p.}$$

For V-bucket and pivoted-bucket carriers,

$$\text{h.p.} = (AWL_hS/1000) + (BL_cT/1000) + (TH/1000) + \tfrac{1}{2}X$$

where L_h = horizontal length of conveyor, ft.; L_c = total horizontal length traversed by loaded bucket, ft.; H = total vertical height traversed by loaded bucket, ft.; X = total number of 90-deg. turns in the conveyor; and A, B, W, S and T are the same as for the first formula.

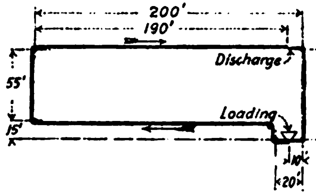

Fig. 60.

Example. Determine the power required to drive a pivoted-bucket carrier having 24 × 24-in. buckets carrying 67 tons of coal per hour; rollers 6 in. in diameter with 1⅜-in. pins; the path of the conveyor to be as shown in Fig. 60. The double lines show the distance traversed by the loaded buckets. $A = 0.0046$, $W = 80$ lb., $L_h = 200$ ft., $S = 50$ ft., $B = 0.076$, $L_c = 380$ ft., $T = 67$ tons, $H = 70$ ft., $X = 6$ bends. Therefore

$$\text{h.p.} = \frac{0.0046 \times 80 \times 200 \times 50}{1000} + \frac{0.076 \times 380 \times 67}{1000} + \frac{67 \times 70}{1000} + \tfrac{1}{2} \times 6 = 13.3 \text{ h.p.}$$

Bucket Elevators are of two types, chain-and-bucket, where the buckets are attached to one or two chains; and belt-and-bucket, where the buckets are attached to canvas or rubber belts. Either type may be vertical or inclined, and have continuous or non-continuous buckets. They are used to elevate any bulk material that will not adhere to the bucket. Belt-and-bucket elevators are particularly well adapted to handling abrasive materials which would produce excessive wear on chains. Chain-and-bucket elevators are frequently used with perforated buckets when handling wet material, to drain off surplus water. The length of elevators is limited by the strength of the chains or belts. They may be built up to 100 ft. long, but average from 25 to 75 ft. Inclined belt elevators operate best on an angle of about 15 deg. to the vertical. At greater angles the sag of the return belt is excessive, as it cannot be supported by rollers between the head and foot pulleys. This applies also to single-strand chain elevators. Double-strand chain elevators, however, if provided with roller chain, may run on any angle, as both the upper and return chains are supported by rails. The size of lumps is limited by the size and spacing of the buckets and the speed of the elevator.

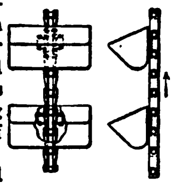

FIG. 61.—Single-strand.

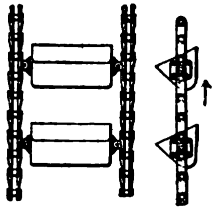

FIG. 62.—Double-strand.

Fig. 61 shows a **single-strand elevator** with back-hung buckets of the **Salem** type bolted to the ears of the **attachment links.** This type should be used only for short elevators handling free-flowing material without lumps, otherwise the buckets will be twisted off the chain. Fig. 62 shows a **double-strand elevator** with end-hung buckets and pivoted attachments, which is used for the heavier service. Fig. 63 shows the discharge end of a double-strand elevator with choke sprockets forming a perfect discharge. This type of discharge allows the non-continuous type of bucket to discharge the material into the chute, placed well under the buckets. Single-strand elevators cannot be built with perfect discharge, and must therefore be operated at sufficient speed to throw the material clear of the buckets into the chute. Fig. 64 shows **continuous overlapping end-hung buckets.** The back of one bucket forms the chute for the discharge of material from the bucket back of it, thus giving a clean discharge of material. When these buckets are made non-overlapping, they may be used with perfect discharge, as illustrated in Fig. 63. Overlapping buckets may run at slower speeds than the Salem type, owing to the nature of the discharge, and therefore handle larger and heavier material. The general operation of the **V-bucket elevator** is described under "V-bucket Carriers," p. 1170. Fig. 65 illustrates the **cast-iron boot** used in connection with Salem-bucket and V-bucket chain elevators and with Salem-bucket belt elevators. The shaft is provided with takeups and carries the tail sprockets or pulley. Fig. 66 illustrates the general form of a vertical belt-and-bucket or back-hung chain-and-bucket elevator with **structural-steel boot and casing.** The casing is made in sec-

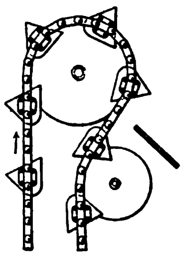

FIG. 63.—Perfect Discharge End.

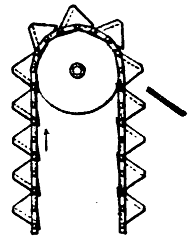

FIG. 64.—Continuous Overlapping Buckets.

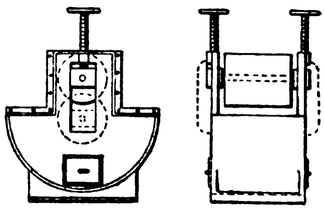

FIG. 65.—Cast-iron Boot..

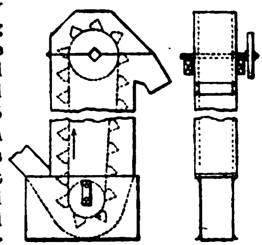

FIG. 66.—Structural Steel Boot and Casing.

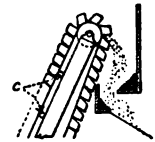
tions of light steel plate fastened together with angles. Elevators of this type must be run at sufficient speed to throw the material from one bucket clear of the bucket ahead of it into the chute. Fig. 67 shows a continuous belt-and-bucket elevator of the inclined type. These elevators give the best results when the material is fed directly into the buckets, because when they dig from boots the material becomes wedged between the bucket and belt above the bolts which attach the bucket to belt. The stone box *a* (Fig. 67), used for **feeding stone and ore** to elevators, allows the material to flow at its angle of repose to the buckets. The extension *b* of the box prevents the material from spilling when the bottom of one bucket passes the bottom of the stone box, directing the material into the bucket below. Stone boxes at the discharge end receive the impact of the material, thus reducing the wear on the chutes. The loaded side of the belt is supported by the rollers *c*, the empty side hanging unsupported between the head and foot pulleys.



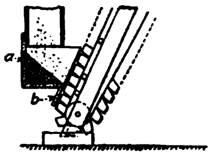


Fig. 67.—Bucket Elevator for Stone or Ore.

Single-strand non-continuous elevators should have a bucket **speed** of from 175 to 200 ft. per min. to insure good discharge. Perfect-discharge and gravity-discharge elevators should run at 150 ft. per min. maximum. Vertical belt-and-bucket elevators require 200 ft. per min. to insure good discharge. Inclined continuous-bucket elevators should not run over 150 ft. per min., and if handling heavy material in large lumps, these speeds should not exceed 100 ft. Table 20 gives the **capacity** of Salem-type bucket elevators and continuous bucket elevators at a speed of 100 ft. per min., handling coal weighing 50 lb. per cu. ft.; also the approximate weights of the elevators per foot of run. The capacities are based on an even and continuous feed, the buckets being figured three-quarters full. **Horse power** required = $TH/500$, where T = load in tons (2000 lb.) per hour, and H = vertical height of lift, ft. If the horizontal run of the V-bucket elevator is over 8 ft., use the power formula for V-bucket carriers.

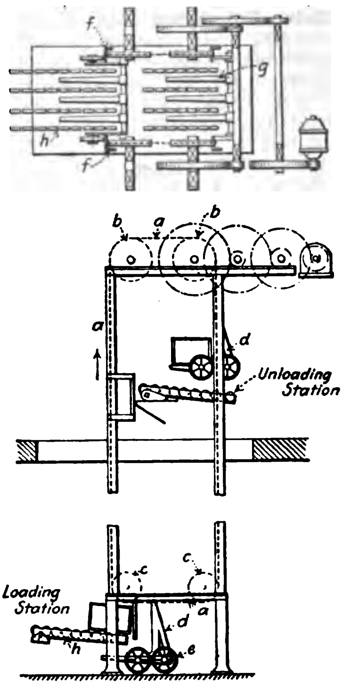

Fig. 68.—Tray Elevator.

Fig. 68 illustrates one type of **tray elevator** used for raising material in packages or boxes. The two chains *a* run over sprockets *b* at the head and *c* at the foot. Suspended from these chains are the trays *d*, carrying the guide wheels *e* which engage the columns *f* of the elevator, preventing the trays from tipping. The bottom of the tray consists of three fingers *g*, which pass between the pivoted rollers *h*. In Fig. 68, the tray is about to pick up the box in the basement and another tray is about to deliver a box on the floor above. As the tray descends, the box rests on the rollers and rolls off automatically. The pivoted rollers forming the loading and discharging stations are controlled by levers so that they may be moved out of the way when desired. Tray elevators operate at a maximum speed of 60 ft. per min.

Belt Conveyors will handle practically any material in bulk which may be properly fed to the conveyor and will not adhere to the belt. Light package material is also handled by belt conveyors.

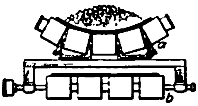

Fig. 69.—Robins Belt Conveyor.

Their length is limited by the strength of the belt. They may be built up to 1000 ft. long, if level, and be operated on inclines up to 20 deg. for material of uniform size and 18 deg. for unsized material. Under favorable conditions these angles may be increased 1 or 2 deg. The size of lumps is limited by the width of the feeding chute, and the temperature of material handled to 180 deg. fahr. Fig. 69 shows the cross-section of **conveyor** (Robins type, patented), which consists of an endless belt passing over pulleys at the conveyor ends. The loaded side is supported by troughed idlers *a*, and the empty belt by the straight idlers *b*. The troughing idlers are of the three- or five-pulley type. The five-pulley

Table 20. Capacities and Weights of Bucket Elevators

36	8	18	29	40	27	56	36	12	18	....	100	77	165

type is best for heavy service, as it supports the belt at five points instead of three, giving an easier curve to the belt. The pulleys are 5 in. in diameter on 12- to 18-in. idlers, and 6 in. on 20- to 48-in. idlers. They turn on hollow-steel shafts supported by cast-iron brackets and are lubricated from the interior by large grease cups on the shaft ends through holes in the shaft walls. The return idlers consist of a series of pulleys turning on hollow shafts with grease cups at one end, or pulleys attached to solid shafts turning in adjustable hangers. They are spaced about 10 ft. apart. For troughing idler spacing, see Table 21.

The **belts** generally used are of the rubber-covered type consisting of plies of cotton duck cemented together with rubber friction and protected from moisture and abrasion by a rubber cover. The duck gives the belt its tensile strength. The rubber cover on the carrying side is from 1/16 to 3/16 in. thick, according to the service. When the cover runs straight across the belt, as shown in Fig. 70, it seldom exceeds 1/8 in. in thickness. In the Robins patent belt, Fig. 71, several of the upper plies are stopped off at varying distances from the edges, forming a flexible middle and stiff edges. The rubber cover is 3/16 in. thick at the middle, where the wear is greatest, tapering to 1/16 in. at the edges, where the wear is least. A layer of loosely woven fabric is embedded in the cover over the duck, passing around the edges, increasing the adhesion of the cover. Stitched canvas and woven cotton belts are also used. The fabric of these belts is not protected from abrasion, hence they wear more rapidly. They also shrink and contract, due to atmospheric changes, requiring frequent adjustment of the take-ups to keep them at proper driving tension. The ends of the belts are joined by metallic **lacing** of the Bristol, Turtle, or Crescent type. The holes for the prongs should be punched with an awl to prevent cutting of the fabric.

Fig. 70.

Fig. 71.

Rubber-covered Conveyor Belts.

Belt conveyors are driven by power applied to one or more of the pulleys over which the belt bends. The **drive** may be located at either end or at any point between the ends on the return belt, as required by local operating conditions. On long, heavy conveyors elevating material from below ground to a bin or building, the drive is usually located at the ground level and is of the tandem type, in which the belt makes a part wrap around two pulleys geared together and turning at the same speed. This results in an effective arc of driving contact of 360 deg. or more, while the single-pulley drive has a maximum arc of contact of about 250 deg. The tandem drive will therefore operate with less initial tension on the belt. Driving pulleys for the heavy service are rubber-covered to increase the coefficient of friction. The pulleys over which the conveyor belt bends under driving tension should have a diameter of from 4 to 5 in. per ply of belt. Take-up bearings are provided, usually at the loading end, to take up slack in the belt. The adjustment varies from 12 to 36 in. When the power required to raise the load, given by the second part of the formula for inclined conveyors (p. 1179), exceeds that to drive a level conveyor of the same length, given by the first part of the formula, a hold-back device should be attached to the drive to prevent the conveyor from running backward, should it be stopped loaded.

Trippers of the fixed or movable type are used for discharging material between the two ends of conveyors. Fig. 72 shows a self-propelling tripper which consists of two pulleys *a* and *b*, over which the belt passes, the material being discharged into the chute *c* as the belt bends around the upper pulley *a*. The pulleys are mounted on a frame carried by four wheels driven by worm

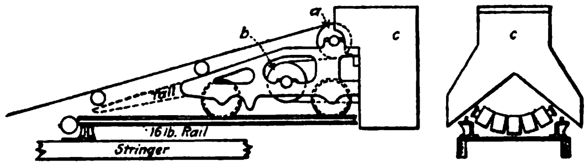

Fig. 72.—Self-propelling Tripper for Belt Conveyor.

gears. A lever on the frame and stops on the rails enable the tripper, taking power from the conveyor belt, to move automatically between the stops, thus distributing the material. Rail clamps are provided to hold the tripper in a fixed position when discharging. The smaller sizes may be moved by hand cranks. Fixed trippers have their pulleys mounted on the conveyor framework instead of on a movable carriage.

When the material handled is damp and sticks to the belt, **rotary brushes**, driven by chain and gears, are used to clean the belt. When handling material of uniform size that will flow readily through the chute, a simple feeding gate may be used. But when handling unsized material, a **feeder** of the shaking type or reciprocating plate type is advised, to insure an even and continuous feed to the conveyor.

Fig. 73 shows **typical arrangements of belt conveyors.** *A* is a level conveyor receiving material at one end and discharging at the other. *B* shows a level conveyor with traveling tripper. The receiving end of the conveyor is depressed so that the belt will not be lifted against the chute when the tripper is at its extreme loading end. *C* is a level conveyor with fixed trippers. *D* shows an inclined end combined with a level section. In passing from the inclined to the level section a crown-faced pulley is used, the belt flattening out at the bend; but as belt and material are moving at the same speed, there is no spill. *E* is a combination of level conveyor, vertical curve and horizontal section. The radius of the vertical curve depends upon the weight of the belt and the tension in the belt at the point of tangency. This must be figured in each case, the radius for average conditions being about 200 ft. *F* is a combination of level conveyor receiving material from a bin, a fixed dump, an inclined section and a series of fixed trippers.

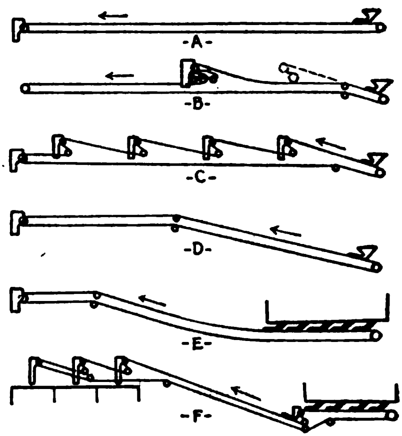

Fig. 73.—Typical Arrangements of Belt Conveyor.

When the quantity of material to be handled is small and the pieces are large, the size of the material fixes the **width of the belt;** when the quantity is large, the capacity fixes the width. In all cases the speed should be as slow as possible. When handling large material, the **belt speed** should not exceed 400 to 500 ft. per min. When feeding abrasive material to inclined conveyors, it should not exceed 400 ft. per min. owing to the wear produced in giving the material the same speed as the belt. Table 21 gives the maximum advisable speed for various widths of belt, but these values should not be ussd when handling the maximum-size pieces given in the table. Belt conveyore may be built to handle practically any quantity of material which can be fed to them. 1500 tons per hour of mine-run coal, 1500 tons per hour of limestone, ranging in size from 18 in. to sand, and 2000 tons per hour of iron ore, crushed to 4 in., are being successfully handled on single conveyors. Table 21 gives the **capacities** and maximum **size of lumps** for belts of different widths, based on an even and continuous feed to the conveyor.

The **power required** to drive belt conveyors depends upon the spacing of idlers, type of drive, etc. The belt should run no faster than required to safely carry the desired load, and if, for any reason, it is necessary to increase the speed, the power should be figured for the full capacity at the chosen speed. Let C = power constant from Table 21; T = load in tons of 2000 lb. per hour; H = vertical height that material is lifted, ft.; S = belt speed, ft. per min.; B = width of belt, in.; L = length of conveyor between centers, ft., then

$$\text{for level conveyors, h.p.} = CTL/1000$$

$$\text{for inclined conveyors, h.p.} = (CTL/1000) + (TH/1000)$$

For each movable or fixed tripper, add the horse power given in Table 21.

48	24	600	7,400	370	0.138	0.105	5	7	11	3 1/2	3

For friction of conveyor ends and drive, add 80 per cent. for conveyors 25 ft. in length, 50 per cent. for conveyors 50 ft. in length, 30 per cent. for conveyors 75 ft. in length, 20 per cent. for 100-ft. conveyors, 10 per cent. for 200-ft., 4 per cent. for 500-ft. To determine the number of plies P of belt, let G = constant determined by the type of drive (= 3600 for single bare pulley drive, 2700 for single rubber-lagged pulley drive, 2250 for tandem bare pulley drive and 2025 for tandem rubber-lagged pulley drive, based on 18.4 lb. per in. per ply working strength of duck) and h.p. = power required to drive the conveyor. Then $P = (\text{h.p.} \times G)/(S \times B)$.

Gravity Conveyors. Boxed, wrapped or bundled material may be lowered from one level to another by **spiral package chutes,** which are largely used in warehouses, stores, etc., to lower packages, boxes, bundles, baskets, etc., from upper floors to basement or intermediate floors. The size of packages is limited by the width of the spirals. Table 22 gives the maximum sizes of packages for spirals of different diameters. The height of package should not exceed its length, otherwise it would overturn. Packages or bundles containing abrasive materials which may leak, should not be handled, owing to destructive wear on the plates. Packages containing sticky material should not be handled, as it will affect the angle of slide. Packages from a few ounces to 500 or 600 lb. may be handled by the same spiral and they will descend at approximately the same speed. Where the spirals are built to handle only heavy material, the drop is less than where light packages only are to be handled.

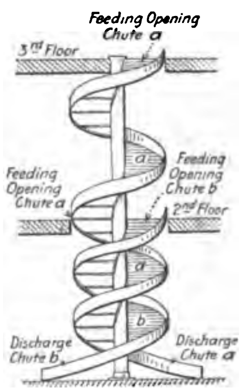

Fig. 74. Standpipe Chute.

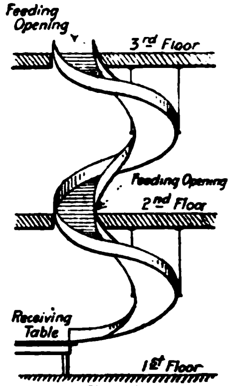

Fig. 75. Open-center Chute.

Spiral Package Chutes.

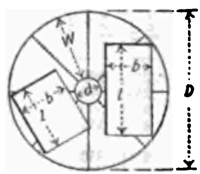

Fig. 76.

Two types of chutes are in use. The **standpipe chute,** Fig. 74, consists of a central column or pipe, supported by a foundation at the bottom or hung from the top. The wing plates forming the bottom of the chute are bolted to the column on the inside, and to a guard plate on the outside. The bottom plates are made of from No. 12 to No. 20 gage steel. When handling very heavy packages, the bottoms are made of cast iron. This type of spiral may be loaded only from the outside. The **open-center type,** Fig. 75, is suspended from the various floors by rods and may be loaded from either the inside or the outside. Where several classes of packages are to be handled and kept separate, the chutes may be made double- or triple-thread. Fig. 74 shows a double-thread. Chute *a* may be fed on either the third or second floor, while chute *b* is fed on the second floor. The open-center type may be constructed in the same manner. The type shown in Fig. 74 is frequently enclosed in a cylinder, in which case the opening in the floor is circular. Fire doors with fusible links may be installed in all of the chutes to close the openings in the floors. These spirals operate on a pitch of from 17 deg. to 29 deg. on the outside of the runway, depending on the material handled.

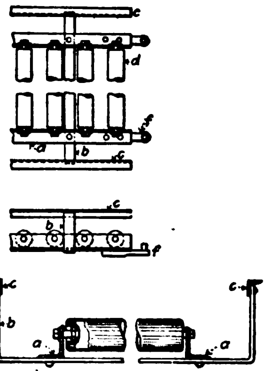

Fig. 77.—Gravity Roller Conveyor.

The **gravity roller conveyor** is used for conveying material on rollers down grade by gravity. It is adapted to handle all classes of merchandise packages and materials that will move by their own weight on the bed of rollers and have one flat, hard surface. Roller conveyors are used in warehouses, brickyards, sawmills, etc., for moving material in the process of manufacture and to cars for shipment. They cannot be used for material so rough that it will catch on the rollers. The length of a conveyor is limited only by the drop, although motor-driven inclines are used to raise the packages by endless chain to higher levels, delivering to another section of roller conveyor. Fig. 77 shows the most common form, consisting of angles *a* connected by bars *b* and carrying a series of rollers *d* provided with ball bearings. These rollers are made of steel tubing about 2½ in. in diam., spaced on 5-in. centers. This type is used for handling boxes, barrels, etc., and is usually provided with guard rail *c*. The conveyors are made in sections 10 ft. long, joined at the ends by the stud *f* entering a hole of the adjoining section. The sections are supported by light steel frames having adjustable legs so that the height may be varied to give the conveyor the proper slope. The legs may be provided with castors. Curved sections are similar in construction to straight sections, except that the rollers are tapered so as to keep the package in the center of the conveyor. The usual radius of curve is 4½ ft. at the outside.

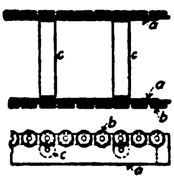

Fig. 78.

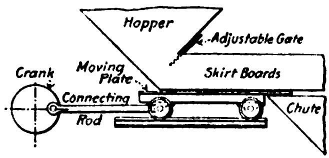
The conveyor for handling lumber, shingles in bundles, large, light cases, etc., is shown in Fig. 78. The shingles and cases travel on small wheels *b* carried by the side plates *a*. The lumber travels on the rollers *c*, **spaced 12 in.** apart. **Lumber conveyors** are made in straight sections only, but curved sections are provided for the shingle and case conveyors. The rollers may be made any desired length, depending upon the size of material to be handled. Filled boxes with smooth bottom surfaces, weighing from 25 to 100 lb. require an inclination of about 3/8 in. to the foot, empty boxes, 1/2 in. For the curved section, filled boxes require 3/4 in. and empty boxes 1 in. to the foot. Bricks require 3/8 in. to 1 in. per foot, depending on their smoothness. Lumber and shingles require about 1/2 in. to the foot. The **capacity** is usually determined by the quantity of material that can be placed on, and will move away from, the loading point.

Feeders. When drawing material from a hopper or bin to a conveyor, an **automatic feeder** should be used, unless the material is dry and free-running, such as grain. The satisfactory operation of any conveyor depends on the material being fed to it in an even and continuous stream. The automatic feeder not only insures a constant and regular feed, irrespective of the size of material, but saves the expense of a man who would otherwise be required at the feeding point. Fig. 79 shows a **reciprocating plate feeder**, consisting of a plate mounted on four wheels and forming the bottom



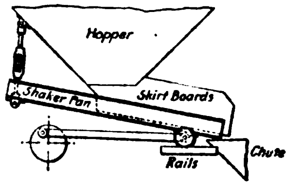


FIG. 79.—Reciprocating Plate Feeder. FIG. 80.—Shaking Feeder.
Automatic Feeders.

of the hopper. When the plate is moved forward, it carries the material with it; when moved back, the plate is withdrawn from under the material, allowing it to fall into the chute. The plate is moved by connecting rods from cranks or eccentrics. The capacity of this feeder is determined by the length and number of strokes, width of plate and the location of the adjustable gate. The number of strokes should not exceed 60 to 70 per min. When used under a track hopper, the material remaining on the plate will freeze in winter, as this type of feeder is not self-clearing.

Fig. 80 shows a **shaking feeder**, consisting of a shaker pan located under the opening in the bottom of hopper at such an angle that the material will not flow when the pan is stationary. When given a reciprocating motion by the cranks and connecting rods, the material is moved forward on the pan. The front end of the pan is carried by a pair of flanged wheels, the back end by two hanger rods provided with turnbuckles so that the angle of the pan may be varied. The crank having an adjustable length of stroke, there are three variables, *viz.*, number of strokes, length of stroke, and inclination of the pan. The number of strokes should not exceed 75 per min., the angle of the pan varying from 8 to 15 deg. This type of feeder, having a wide range of adjustment and being self-clearing so that material cannot freeze to the pan in winter, is adapted to the feeding of practically any material. Automatic feeders are usually driven by the conveyor which they feed, but a clutch should be provided so that the feeder may be stopped, should it become necessary to clear the conveyor for inspection or repairs.

Automatic Scales are often used for weighing and recording the weight of material being carried by belt conveyors, apron conveyors, open-top carriers or pivoted-bucket carriers. They may also be adapted to recording the gross weight of loaded cars such as are used on industrial cable railways or overhead transporters, without stopping the car on the weighing track. By returning the empty cars, the mechanism may be made automatically to deduct the tare weight from the gross weight, leaving the net weight of the material transported. Fig. 81 shows the Merrick Patent Weightometer attached to belt conveyor. Three of the supporting idlers *a* are carried by the steel framework hung by the four rods *b* from the scale beams. These scale beams are attached by levers to the weigh beam *c*. The weight of the load on the suspended portion of the conveyor at any instant is automatically balanced by the buoyancy of a cylindrical iron float suspended from the long end of the weighing beam and partially immersed in a bath of mercury. An increase or decrease of the load on the levers will raise or lower the float in the mercury until the loss or gain in buoyancy compensates for the variation in load. The function of the float is to insure that the movement of the beam from its zero position, when the conveyor is empty, be proportional to the weight of the material at any instant on the suspended portion of the conveyor. The extreme end of the weigh beam is connected by rod *d* to a totalising mechanical integrator. The Messiter Patent Electric Weigher is similar to the weightometer in the method of suspension of the loaded portion of the conveyor. The deflection of the weigh beam, due to load on the conveyor, is measured electrically. Either of these scales will weigh with an error of not over 1 per cent.

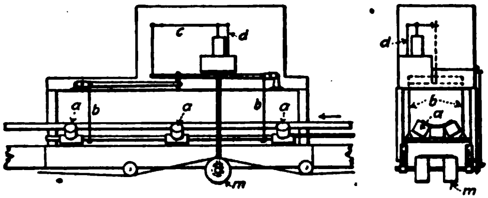

FIG. 81.—Automatic Scales for Conveyors.

Pneumatic Conveyors are used for handling material in bulk, such as ashes, coal, grain, wood waste and particles thrown off by grinding wheels and woodworking machinery. They are usually of the suction type, which makes the apparatus dustless in operation. Incandescent inflammable material should not be handled unless thoroughly quenched before it comes to rest in the separator. Compressed-air conveyors are used to some extent for feeding pulverised coal to kilns and boilers under pressure and handling mixed concrete or grout where it is desired to deliver the material under pressure. Their length is limited by the power required to move material by a current of air, which is not an economical method of conveying. The height material can be lifted is limited to about 125 ft., and the size of lumps by the length of pipe and frequency and location of bends. The latter is a most important consideration, because the velocity of the material is decreased at the bends and, if they are to close together, the air current will be unable to give the required velocity to carry it past the next bend.

The suction ash conveyor system, Fig. 82, consists of a conveyor pipe *a* with an inlet at one end and feeding openings *b* in front of the boilers. The conveyor pipe *a* discharges to the air-tight separator storage tank *d* near the top. Just before entering the tank, the ashes are sprayed by small streams of water *c* to thoroughly quench them and settle the dust. The suction pipe f leads from the top of the tank to the exhauster g, preferably of the positive type, and produces a suction of air from the feeding openings so that material is drawn through the conveyor pipe to the separator tank, where the material is stored ready to be drawn off by gravity through gate e. The air passes through the suction pipe, exhauster and discharge pipe.

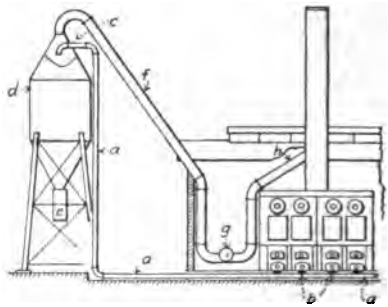

FIG. 82.—Suction Ash Conveyor System.

The method of handling coal, grain, wood waste and other materials is similar to that described above, except that where light material, such as wood waste, is handled, the separator is made circular with the inlet at the periphery, the material entering tangentially. The air outlet is in the center at the top and the material outlet at the bottom. The mixed air and material enter the separator with a whirling motion, but, as the velocity is reduced by the increase of area, the material settles and is thus separated from the air. When dusty material is handled, the water spray is used to prevent the dust and abrasive material from being drawn into the exhauster. The elbows are usually made with removable wearing pieces of manganese steel. The wear on the pipes is slight, as the air current draws the material away from the sides toward the center. Table 23 gives the approximate capacity and power required for different sizes of suction conveyors handling ashes, based on even and continuous feed.

Table 23. Capacities and Power Requirements of Suction Ash Conveyors

Diam. of conveyor pipe, in.	6	8	10
Capacity, tons of ashes per hour	3–4½	6–10½	9–18
Greatest advisable length, ft	200	500	800
Horse power required	20–30	25–50	50–150

STORAGE OF MATERIAL

Bulk material is stored in open piles and reclaimed in a variety of manners. For temporary storage piles, material is dumped from cars on trestles to the ground below and reclaimed by locomotive cranes, steam shovels or other types of excavating machinery. The type of permanent installation depends on the nature of the material, the quantity to be stored and the rate at which it must be reclaimed. Bituminous coal cannot be piled higher than 30 to 40 ft., owing to the danger of fire, some grades of coal being limited to 20 ft. Anthracite coal, stone, ore, sand, gravel and similar materials may be stored in high piles.

Fig. 83 shows a **storage pile spanned by a traveling bridge,** provided with a power-driven self-filling grab bucket. The material to be stored is received in hopper-bottom cars a, discharged into trench b, from which it is removed by the grab bucket c and placed in the storage pile. The material is removed from the storage pile by the grab bucket, discharged to hopper d carried by the bridge, from which it is fed to cars e. As the bridge is carried by wheels, it may travel the length of the pile. The capacity of a storage of this type is determined by the span of the bridge, the length of pile and the height to which material is stored. The capacity of bridges of this type is from 100 to 300 tons per hour from trench to storage and from storage to cars. The **Robins system** (patented) employs a bridge of the type shown in Fig. 83, on the truss of which is carried a belt conveyor with automatic tripper. The loading end of the conveyor is on an incline, receiving material

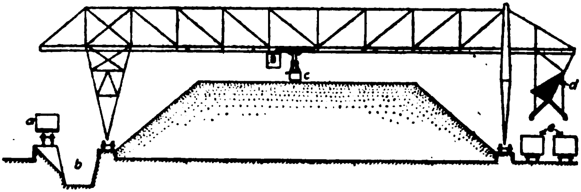

Fig. 83.—Storage System with Traveling Bridge.

from a belt conveyor running parallel to the bridge travel and supported by a trestle 15 to 20 ft. high. The tripper of this elevated conveyor discharges the material to the conveyor carried by the bridge, the tripper of which discharges to the storage pile. With this system, material may be put into storage without rehandling at a rate of from 500 to 1200 tons per hour, depending on the capacity of the conveyors. The **Mead-Morrison system** (patented) employs an endless-cable railroad on an elevated structure running parallel to the bridge travel, the cable being looped over the bridge so that the cars leave the trestle, pass over the bridge, dump and return to the trestle without being detached from the cable. Bridge-type storage is frequently made with one end of the bridge pivoted, forming a circular pile where the shape of the ground makes such a pile more economical than a rectangular one.

Fig. 84 shows **storage pile formed with a locomotive crane** (Link Belt Co. system, patented). The coal is received in hopper-bottom cars *a*, discharged into the track hopper *b*. The crane operates on a track of 80 ft. radius, digging the material from the hopper, discharging to the storage pile; or it may remove the material from the storage pile, discharging to cars. Plants of this type have a capacity of from 75 to 150 tons per hour, depending upon the size of the grab bucket. The height of storage is limited to from 25 to 30 ft.

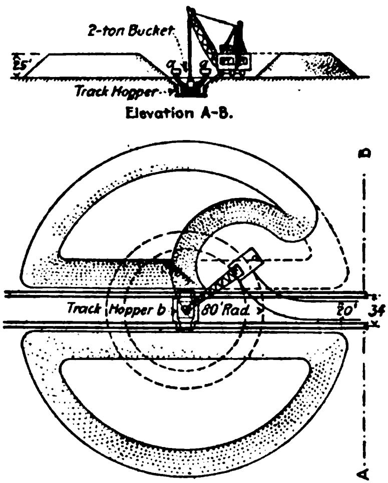

Fig. 84.—Locomotive Crane Storage System.

Fig. 85 shows a type of open **storage with overhead and tunnel conveyors**, used where the height of the pile is not limited and where it is desirable to have a large capacity both into and out of storage. It consists of a gallery supported by A-frames, carrying a conveyor which will discharge the material to the storage pile below. The material is withdrawn by conveyor in a concrete tunnel underneath the pile through gates in the top of the tunnel. The material forms its own angle, and the material which will not flow by gravity is used as reserve storage to be reclaimed in emergencies by locomotive crane or steam shovel. This type of storage is used for storing anthracite coal, crushed stone, sand, gravel, ore and other material which will flow by gravity. The capacity into and out of storage is determined by the size and type of conveyors. Where belt conveyors are used, capacities of 1000 to 1500 tons per hour are obtained both in and out.

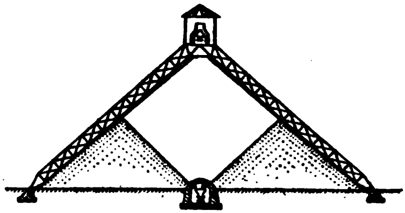

Fig. 85.—Storage System with Overhead and Tunnel Conveyors.

Fig 86 shows the **Dodge system** (patented) **of storing anthracite** coal. This consists of two conical piles, each spanned by the trusses *a* and *b*, which are pivoted at the lower ends to foundations and at the upper ends to each other. They are guyed by the wire-rope cable *c*. A scraper conveyor is carried by truss *b* and receives its material from track hopper *d*. The conveyor drags the material up the truss, discharging through openings in the trough, the crest of the pile increasing in height as the quantity increases. The material thus rolls on itself, eliminating breakage. Material is reclaimed by the pivoted scraper conveyor *e*, made reversible and operating in a horizontal plane. The frame of the conveyor is pivoted at *f* and is supported on a series of circular tracks *g*, of which *f* is the center. As conveyor *e* is swung into the pile, it drags the material to the pivot point *f*, from which

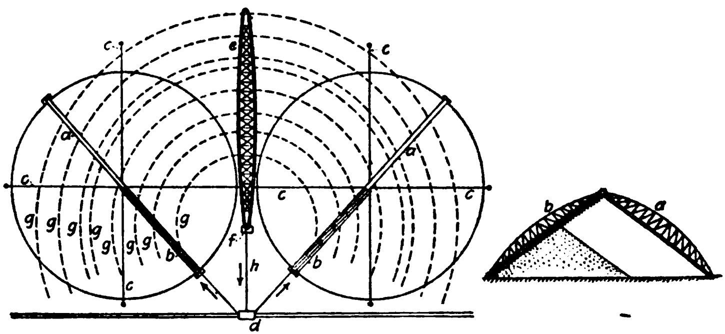

Fig. 86.—Dodge System of Storing Anthracite.

it is elevated on conveyor *h* to cars. A pile 300 ft. in diameter on the base will store approximately 50,000 tons of coal. The capacity in and out of storage is from 100 to 150 tons per hour, determined by the size of the conveyors.

Fig. 87 shows the **Robins-Messiter system** (patented) **of storing and averaging ore**, used to prepare charges of ore, flux, etc., for metallurgical furnaces. The material is crushed, automatically sampled, weighed and discharged to the storage pile by the tripper of conveyor, *a*, carried by gallery above the pile. The tripper discharges material only when moving in one direction, and distributes each carload of material over as many feet of the bed as possible. Analysis of the contents made from the samples enables the operator to keep accurate record of the chemical contents of material stored, so that when the bed is completed it forms a proper furnace charge. Material is removed from the bed by the reclaiming machine *b*, carried by four wheels and moved into the bed at a predetermined rate. A chain conveyor *c* consisting of a series of plows is carried

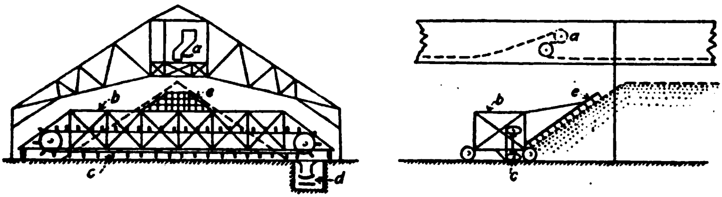

Fig. 87.—Robins-Messiter System of Storing and Averaging Ore.

by the reclaimer, dragging the material from the toe of the pile to the belt conveyor *d* in the trench, which carries the material to the furnace bins. On the front of the reclaimer there is mounted a mechanical harrow *e*, inclined at the angle of repose of the material. This harrow is given a reciprocating motion across the pile, loosening the material and causing it to flow at its natural angle of repose so that when the reclaimer has moved into the bed a predetermined distance it will remove a fixed quantity which is an exact average of the cross-section of the pile. The capacity of the system, both storing and reclaiming, is determined by the size of the reclaimers and conveyors, the average capacity being from 100 to 150 tons per hour reclaiming, and 200 to 300 tons per hour storing. The minimum number of beds is three, one being in the process of forming, one being reclaimed and one a surplus bed to store any excess of material received.

General. Motor road vehicles are usually propelled by multi-cylinder four-cycle gasoline motors. Practically all commercial-car engines have four cylinders; most pleasure-car engines have either four or six cylinders, a few eight and twelve. All parts of the mechanism are supported by the vehicle frame, which is generally made of channel-section members pressed from sheet steel. The **typical pleasure car** "chassis" (vehicle without body), as shown in plan view in Fig. 1, comprises the following main divisions or assemblies: The motor *A*, with its carburetor, ignition device, cooling and lubrication systems; a friction clutch, *B*; a change-speed gear or transmission *C*; a rear propelling axle *D* with wheel-hub brakes *EE*; a front steering axle *F*; a steering gear *G*; a control lever assembly *H*; frame *I*; springs

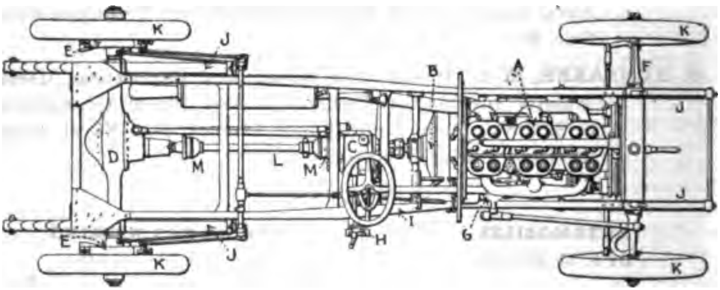

FIG. 1.—Plan of Chassis of Typical Pleasure Car.

J J J J; wheels *K K K K*. The change-speed gear, which is carried on the spring-supported frame, is connected to the driving rear axle through a jointed propeller shaft *L* having either one or two universal joints *MM* inserted in it. The rear axle is driven through a pair of bevel gears and embodies a differential gear through which the driving torque is under all conditions divided equally between the two rear wheels, even when the two wheels run at different speeds, as in turning corners.

In **heavy commercial vehicles** the power is transmitted from the change-speed gear either through a pair of bevels to a differential countershaft and thence by a pair of side chains to the rear wheels, or by a pair of bevels and a pair of internal gears to the rear wheels, or by a worm and worm gear to a live rear axle.

Resistances to Vehicular Motion. The total resistance to the motion of a road vehicle is made up of three items, (1) traction resistance, (2) air resistance and (3) resistance due to gradients. The **traction resistance** on most ordinary pavements can be figured at 25 lb. per 1000. The **air resistance** is about $0.0042\ V^2A$ lb., where V is the vehicle speed in miles per hour and A the forwardly projected area in sq. ft. The resistance due to an up grade of n per cent. in lb. $= nW/100$, where W is the weight of the vehicle. On a down grade there is an equal negative resistance, and on a down grade of 2½ per cent. or more, with smooth, hard road surface, a vehicle will coast.

According to M. Forestier (*Proc. Sec. Int. Aut. Congress*, Paris, 1902), the **traction resistance** f per 1000 lb. weight of vehicle and load is as follows on different kinds of road surfaces:

	f in lb.
Smooth dry macadam (or good dry dirt road)	15
Slightly defective macadam, reasonably dry	18
Good macadam softened by rain	20
Slightly defective macadam softened by rain	22
Irregular Belgian block pavement	22
Macadam in bad state of repair	25
In loose gravel	75–100
In sand	150–200

For pneumatic tires running on asphalt pavement at 15 miles per hour, f ranges from 21 to 31 lb. See also p. 236.

The Motor Horse Power Required for different types of vehicles is determined by empirical rules. Touring cars and roadsters are fitted with motors of 1 rated horse power per 60–100 lb. of vehicle weight. Motor trucks of t tons load capacity are fitted with motors of $15 + 5t$ rated horse power.

Tread and Wheelbase. The standard tread (center to center of tire-ground contact) for pleasure and light commercial vehicles is 56 in. For the Southern States' trade the tread is often made 60 in. For motor trucks there is no standard, the treads varying from 62 to 70 in. Wheelbases range as follows:

Four-cylinder cars:	H.p.	Wheelbase, in.
Runabouts and roadsters	30 and under	90 to 105
Runabouts and roadsters	>30<40	105 to 115
Taxicabs (4 to 5 passengers)		96 to 100
Touring cars	30 and under	100 to 115
Touring cars	>30<40	110 to 120
Touring cars	Over 40	120 to 130

Six-cylinder cars: About 10 in. longer than for four-cylinder cars of the same class.

AUTOMOBILE MOTORS

Motor Output. According to the A. L. A. M. **horse-power rating formula,** an automobile gasoline motor should develop $nb^2/2.5$ brake horse power at 1000 ft. piston speed per min., where n is the number of cylinders and b the cylinder bore in in. This formula is based on a "brake mean effective pressure" (product of the mean effective pressure by the mechanical efficiency) of 67.2 lb. per sq. in. This is a fair average figure, although many designers have improved upon it in recent years. The assumption involved in the formula that the horse-power output is independent of the length of stroke, is incorrect. Long strokes, large valves and light reciprocating parts have raised the piston speed corresponding to maximum engine output to 1400 ft. per min. and higher. The following formula, adopted in 1911 by the Society of Motor Manufacturers and Traders (Great Britain), takes account of the length of stroke:

$$\text{b.h.p.} = 0.45(b - 1.18)(l + b),$$

where l is the length of stroke and b the cylinder bore, both in in.

The Technical Committee of the Automobile Club of France has developed some motor-rating formulæ for the French Ministry of Public Works, to serve as a basis for taxation. These formulæ are based on a brake mean effective pressure of 75.2 lb. per sq. in. for touring-car motors whose piston speed does not exceed 1200 ft. per min.; 78.1 lb. per sq. in. for touring-car motors whose piston speed exceeds 1200 ft. per min.; 82.3 lb. per sq. in. for commercial-vehicle motors, and 92.3 lb. per sq. in. for aeronautic motors (*Bull. Off. d. l. Comm. Tech.*, June, 1912).

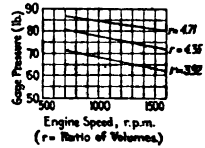

FIG. 2.—Compression Pressures in Motor Cylinders.

Compression. The compression space is made equal to from 0.25 to 0.35 the piston displacement. The **compression** obtained may be calculated by means of the equation $C = (V/v)^{1.3}p$, where C is the compression pressure in lb. per sq. in., absolute; V is the initial volume of the gas before compression begins; v the final volume and p the initial pressure. The value of p corresponding to operation at full load will not exceed 13 lb. per sq. in., owing to the resistance of the valve passages. Fig. 2 shows the results of some compression tests made by Prof. W. Watson on a four-cylinder Clement-Talbot engine of 3.35-in. bore and 4.72-in. stroke. The change in the compression ratio was obtained by inserting packing pieces of different thicknesses below the cylinder.

The **normal explosion pressure** may be taken as four times the gage compression pressure. This will be exceeded when one or more explosions are missed and the cylinder is completely cleared of dead gas.

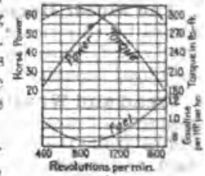

FIG. 3.—Variation of B. H. P., Motor Torque, and Fuel Consumption with Speed.

Characteristic Curves. The average four-cylinder automobile motor can be operated under full throttle over a wide range of speed, down to about one-third the speed of maximum output (depending upon flywheel capacity and carburetor characteristics), and a six-cylinder motor is even more flexible. The variation of the torque, brake horse power and specific fuel consumption with variations in the speed is shown by the diagram, Fig. 3. The torque is a maximum at a speed slightly above the lowest speed of stable running, and decreases at first slowly and then more rapidly. The fuel economy is highest slightly below the speed of maximum output, the **specific fuel consumption** then being about 0.76 lb. per h.p.-hr. These curves were obtained from an Alco six-cylinder motor of 4¾-in. bore by 5½-in. stroke. A good figure for the average fuel consumption of automobile motors under full load is 0.8 lb. per h.p.-hr. For maximum fuel economy the amount of air should exceed that theoretically required by from 15 to 50 per cent., according to speed and throttle position. Fig. 4 shows the variation of the **thermal efficiency** for maximum output at different throttle positions, and the variation of the speed of maximum output with the throttle position. These curves are based on the tests (Taylor, *Horseless Age*, March 4, 1908) of a four-cylinder Mercédès Motor of 4.72-in. bore and 5.9-in. stroke.

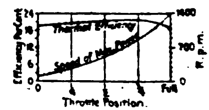

FIG. 4.—Variation of Thermal Efficiency and Speed of Maximum Power with Throttle Position.

Engine Parts

For the theory of the gasoline motor, see p. 320. See also Internal-combustion Motors, pp. 1020–1050. A part sectional elevation of a four-cylinder automobile motor is shown in Fig. 5 and a cross-section through another motor in Fig. 6.

Cylinders and pistons are cast of gray iron. Cylinders of four-cylinder motors are cast either in pairs or all in one block, rarely singly; cylinders of six-cylinder motors either in pairs, in threes, or all in one block. Cylinder-wall thickness can be made $(b/30) + 1/8$ in. Water spaces are made comparatively deep, from 1/2 in. for a bore of 3 to 4 in. to 3/4 in. for a bore of 6 in. The jacket wall is made of a thickness varying from 3/16 in. for 3- to 4-in. bore to 1/4 in. for 6-in. bore. There are three common arrangements of valves, viz., all valves on one side of cylinders, with inlet between exhaust valves; inlet valves on one side and exhaust on the other; and all valves in the cylinder heads. The first arrangement is gaining, for one reason because it lends itself most readily to enclosure of the valve mechanism.

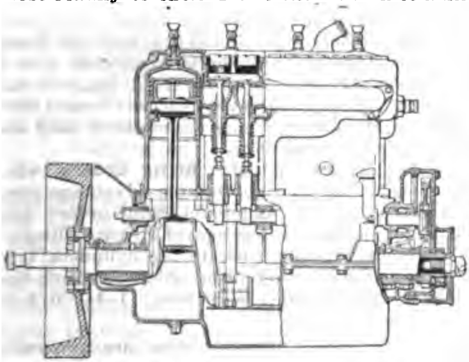

FIG. 5.

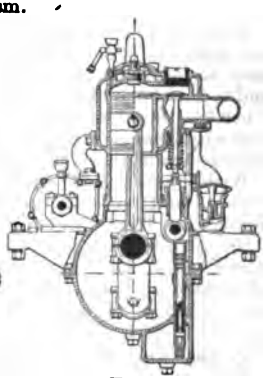

FIG. 6.

FIGS. 5 AND 6.—Sectional Elevations of Automobile Motors.

Pistons are of the trunk type with internal bosses for piston-pin bearings. They are generally provided with three or four packing rings above the piston pin. Rings are turned from cast iron to an outside diam. $= 1.035b$ and an inside diam. $= 0.973b$, have a slot cut in them to form either a 45-deg. diagonal or a lap joint and so as to remove $0.085b$ in the direction of the circumference; the rings are then compressed and clamped on an arbor and ground to an outside diameter b.

The piston head and side wall above the piston pin (underneath rings) can be made of the same thickness as the cylinder wall. Below the piston pin the wall is made thinner. The length of the piston is usually made about $1.25b$; the piston pin is placed substantially at the middle. The length of the piston-pin bearing in connecting rod $= 0.5b$. The pin diameter is figured on the basis of 2000 lb. explosion pressure per sq. in. of projected bearing area. Pins are usually made hollow and case-hardened.

Connecting Rods. Length $= 2l$ to $2.25l$, where $l =$ length of stroke. They are generally drop-forged, of I-section so proportioned that the cross-sectional area is about one-half of the full section of same overall dimensions and height = 1.5 × width of section. If forged of carbon steel, the cross-sections can have 1 sq. in. of area per 7500 lb. explosion pressure on the piston for a length of rod of 14 in., and 10,000 lb. for a length of rod of 8 in. For other lengths and other materials, in proportion.

Crank Shafts are made of 0.45 per cent. carbon steel or nickel steel, and are generally drop-forged. For four-cylinder motors they are supported mostly in three bearings, occasionally in two (small motors) and in five. The crank-pin bearing area is figured on the basis of 900 lb. per sq. in. of projected area with three-bearing support and 700 lb. per sq. in. for two-bearing support, the ratio of length to diameter being made 1.35 in the first case and 1 in the latter. Main journals are made of the same diameter as crank pins; provided the flywheel is at the rear, the rear bearing can be made 1.75 times the length of the crank pins and the other two bearings 1.25 times the crank-pin length. All crank arms are made the same width, about 1.3 times the crank-pin diameter. The thickness or small dimension of the long arms is made equal to $\sqrt{d^3/2w}$, and the thickness of the short arms to $\sqrt{d^3/3.5w}$, where d = shaft diameter and w = width of arm.

Four-cylinder crank shafts for four-cycle motors are made with their two inner crank pins in line and the two outer ones at 180 deg. from the inner ones, to insure proper balance. Six-cylinder crank shafts have crank pins 1 and 6, 2 and 5, 3 and 4 in line, respectively, and each pair at 120 deg. with the other two pairs, for the same reason. Crank shafts are generally forged with a flywheel flange and a clutch pilot at their rear end. Sometimes they are drilled through the arms and pins for oil circulation.

With four-cylinder motors there are two possible **firing orders**, viz., 1–2–4–3 and 1–3–4–2, neither of which has any appreciable advantage over the other. With six-cylinder motors there are six possible firing orders, and if the cylinders are cast in pairs and the exhaust passages of the two cylinders in each pair are "siamesed" or come together close to the cylinders, it is advantageous to choose one of the following three firing orders in which the two cylinders of any pair never fire in direct succession: 1–4–2–6–3–5, 1–5–3–6–2–4, 1–3–2–6–4–5.

Valves and Valve Gear. Conical-head poppet valves are generally employed. With all valves on the same side the clear diameter of the valve port is limited to about $0.4b$; with other valve arrangements it is made $0.5b$ and even greater. The lift is made small, for noiseless operation at high speed, usually about $\frac{1}{8}d + \frac{1}{8}$ in., where d = clear diam. of valve in in. The valve is held to its seat by a coiled compression spring of such strength as to equal the inertia force on the valve and intermediate reciprocating members at the highest engine speed. Following is a good average **timing** of the valves: Inlet opens 15 deg. past top dead center; inlet closes 30 deg. past bottom dead center; exhaust opens 45 deg. ahead of bottom dead center; exhaust closes 10 deg. past top dead center. Early exhaust opening and late inlet closing go together with high speed and great maximum output, but interfere with operation at low speeds. Inlet and exhaust pipes can be calculated for a mean gas speed of 7200–8000 ft. per min.

Weights of Flywheels and Engines. Flywheels are generally made with a solid web which is bolted to an integral flange on the crank shaft. The outside diameter varies between 15 and 20 in., the ground clearance required setting the latter limit for pleasure cars. The weight in the rim for either four- or six-cylinder motors can be made $8.5(bl/r)^2$ lb., r being the mean radius of the wheel rim in in. The weight of a complete motor with aluminum crank case is about $5b^2l$ lb. for four cylinders, and $7b^2l$ lb. for six cylinders. This is equivalent to about 15 lb. per h.p. for a stroke of average length.

Lubrication. Engines are generally lubricated by combined circulating and splash systems.

Carburetors. Nearly all automobile carburetors work on the spray jet principle (Fig. 7). The gasoline is kept at a constant level just below the top of the spray nozzle A by means of a float B and float valve C in a communicating float chamber, and is drawn from the nozzle by the suction created in the air passage D around it by the downward stroke of the engine piston. The fuel delivery increases faster than the air delivery with an increase in suction (due to increased engine speed or greater throttle opening), and to compensate for this effect a supplementary air valve E is placed in the wall of the passage beyond the spray nozzle A, which opens automatically with

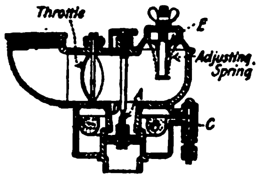

Fig. 7.—Spray Jet Carburetor.

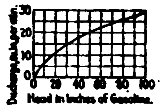

Fig. 8.—Gasoline Flow Through Carburetor Nozzles.

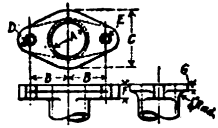

Fig. 9.—S. A. E. Standard Carburetor Flange.

increasing suction and dilutes the charge to keep its proportions constant. The rate of gasoline flow Q/t is connected with the suction head h by an equation of the form $C_1(Q/t)^2 + C_2(Q/t) = h$ where C_1 and C_2 are constants and Q is the volume or weight flowing in a time t. The curve Fig. 8 gives the rates of gasoline flow from an 0.83 mm. (0.0327 in.) carburetor nozzle under different suctions, as determined by Lauret. The standard carburetor flange recommended by the Society of Automobile Engineers is shown in Fig. 9. Following are the dimensions in in. for different sizes, the letters referring to Fig. 9:

Carburetor, size, in.	*A*	*B*	*C*	*D*	*E* *	*F*	*G*
3/4	15/16	1 1/16	1 5/8	11/32	5/16 × 18	3/8	1/8
7/8	1 1/16	1 1/8	1 3/4	11/32	5/16 × 18	3/8	1/8
1	1 3/16	1 3/16	1 7/8	11/32	5/16 × 18	13/32	5/32
1 1/4	1 7/16	1 11/32	2 3/16	13/32	3/8 × 16	15/32	3/16
1 1/2	1 11/16	1 15/32	2 1/2	13/32	3/8 × 16	15/32	3/16
1 3/4	1 15/16	1 21/32	2 13/16	15/32	7/16 × 14	9/16	7/32
2	2 3/16	1 25/32	3 1/8	15/32	7/16 × 14	9/16	7/32

* U. S. Standard threads.

Ignition. For ignition systems, see p. 1608. High-tension **magnetos** usually furnish the ignition current in regular operation and a storage or dry-cell battery in starting the motor. Magnetos must be positively driven at crank-shaft speed for four-cylinder motors and at 1½ times the crank-shaft speed for six cylinder. The conventional **battery equipment** consists of three storage cells of about 60 amp-hr. capacity or six 6-in. dry cells. Magnetos are usually clamped down to their bases (which are cast integral with the crank case) by means of screw-clamp straps, and are located in position by four dowel pins at the corners of a 50-mm. square. The shaft center is 45 mm. above the bottom plane of the base. With the **high-tension magneto** ignition system the only parts besides the magneto that have to be accommodated on the engine are the **spark plugs**, which are usually screwed into holes in the caps over the inlet valves. The part screwing into the cylinder or valve cap, known as the spark-plug shell, has been standardized. The S. A. E. standard spark-plug shell is illustrated in Fig. 10. It has 18 threads to the inch, of the U. S. S. type, cut perfect into the recess. Besides the S. A. E. standard shell, a shell with a ½-in. pipe thread is used, and a metric standard shell with a thread 18 mm. in diam. and of 1.5 mm. pitch.

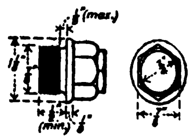

FIG. 10.—S. A. E. Standard Spark-plug Shell.

Engine Cooling. Cooling water is generally circulated through a **radiator** at the front of the engine by means of a pump (generally of the centrifugal type) positively driven from the engine crank shaft, and a **fan** driven from the engine is placed back of the radiator to increase the air circulation through it. The radiator should be provided with from 2 to 2¼ sq. ft. of **radiating surface** per motor horse power, counting only one side of gills or flanges which are not in direct contact with the water. With natural or thermo-siphon circulation, and on slow-running motor trucks, more radiating surface is required.

Two-cycle Motors (for principle of operation, see p. 1021) are comparatively little used on automobiles, but much for marine work. The conventional type employs a crank-case precompression of about 8 lb. per sq. in. To get this compression the connecting rod must be made as short as possible (length = $1.8\,l$) and the crank-chamber walls brought close to the crank sweep. The inlet port to the cylinder should be of such height as to open and close 44 deg. of crank motion on either side of the dead center; exhaust port, 58 deg. Both ports should be flush with the bottom end of piston stroke. In case the charge is admitted to the crank case through a piston-controlled port, the latter can be made of the same dimensions as the cylinder inlet port. The piston must be made longer than the stroke. Ports in cylinder walls must have at least one "bridge" to prevent piston rings getting caught. According to Roberts ("Gas Engine Handbook"), the output of a two-cycle motor is given by the equation h.p. $= nb^2lr/9000$, where n = number of cylinders; b = bore in in.; l = stroke in in., and r = r.p.m. Engines with crank-case precompression cannot be run economically above 750 ft. per min. piston speed. Very large ports make higher speeds possible but entail an appreciable loss of fuel through the exhaust port. For automobile work so-called concentric-piston engines are generally used, in which the charge is precompressed in an annular space at the bottom of the working cylinder.

Metals and Alloys Used in Automobile Construction

Standard Specifications have been adopted by the Society of Automobile Engineers. For **Iron and Steel Specifications**, see p. 464.

Specifications Nos. 24 to 29 for brass, bronze and bearing metals are given in the following table:

Brass, Bronze and Bearing Metals

(S. A. E. Standard Specifications)

Spec. No.	Alloy	Cu	Sn	Pb	Zn	Sb	P
24*	Babbitt metal	7	84			9	
25†	White brass	3–6	≥65		28–30		
26‡	Phosphor bronze bearing metal	80	10	10			0.05–0.25
27§	Brass casting metal	84–86	5	5	5		
28‖	Yellow brass	62–65	2–4		36–31		
29**	Cast manganese bronze	60			40		

Values in percentages. * Permissible variations: In tin, 2 per cent. either way; in antimony and copper, 0.5 per cent. either way. No impurities permitted other than lead, and that not in excess of 0.10 per cent. † Shipments containing more than 0.10 per cent. of other metals may be rejected. ‡ Tolerances of 1 per cent. plus or minus permitted, except in the phosphorus. Iron, zinc and antimony in excess of 0.1 per cent. not permitted. § Tolerance of 1 per cent. plus or minus permitted in tin, lead and zinc. ‖ Iron in excess of 0.5 per cent. not permitted. ** Main dependence placed upon physical properties, which should be as follows: Tensile strength, 60,000 lb. per sq. in.; elastic limit, 30,000 lb.; elongation in 2 in., 20 per cent.

Specifications Nos. 30 to 32 for aluminum alloys are given below.

Aluminum Alloys

(S. A. E. Standard Specifications)

Spec. No.	Al	Zn	Cu	Mn
30	≥90	....	8.50–7.00	....
31	≥80	≤15	2.00–3.00	....
32	65	35	....	≤0.40

The alloy according to Specification No. 30 is not to contain more than 1.5 per cent. impurities and no other elements than carbon, silicon, iron and manganese. No. 31 is not to contain more than 1.65 per cent. impurities, of which not more than 0.50 per cent. should be silicon, not more than 1.00 per cent. iron and not more than 0.15 per cent. lead. No. 32 is not to contain more than 1.65 per cent. impurities. Nos. 30 and 31 can be used for machinery casings and other parts requiring considerable strength; No. 32 should only be used where no great strength is required, as in foot boards, running boards, etc.

Specifications Nos. 33 to 40 for brasses are given on p. 538. Specifications 1 and 2 for Babbitts are given on p. 549.

Standard Steel Tube Sizes

(Society of Automobile Engineers)

Outside diameters, in.	1/2, 5/8, 3/4, 7/8, 1, 1 1/8, 1 1/4, 1 3/8, 1 1/2, 1 3/4, 2, 2 1/4, 2 1/2, 2 3/4, 3, 3 1/4, 3 1/2
Wall thicknesses, in.	.035, .049, .065, .095, .120, .134, .156, .188, .250, .313, .375, .500, .625

Steel tubes of 2 in. outside diam. (o.d.) or less vary between 0.005 in. plus and minus on both the inside and outside diameters; tubes above 2 in. o.d., between 0.010 in. plus and minus on both inside and outside diameters.

Transmission Mechanism

Friction Clutches. (See also Machine Elements, p. 698.) Either leather-faced cone clutches or multiple-disk clutches are generally used. The latter have either metal-to-metal contact surfaces and operate in oil, or metal-to-asbestos-fabric contact surfaces and operate dry. The driven part of the clutch should have a low moment of inertia to facilitate gear changing and minimize injury to the change-gear teeth by "clashing." In cone clutches (see

Fig. 72, p. 698), the female cone is usually formed by the flywheel rim and the male cone is an aluminum casting. The angle of the cone varies between 10 and 13 deg., 12½ deg. being most frequently used. The male cone is guided on an extension of the engine crank shaft (clutch pilot) and connects with the change-speed gear through a sliding and flexible coupling. The clutch diameter is determined by the flywheel diameter. The width of the leather facing is based on a unit friction force of 12 lb. per sq. in. A friction coefficient of 0.2 can be figured on for either leather or asbestos fabric facing. The clutch is normally held in engagement by a coiled spring whose pressure may be determined from the inequality $P > Tf \sin a$, where T = tangential force at the mean circumference of the cone; f = coefficient of friction, and a = angle of cone. The clutch is disengaged by means of a foot lever whose leverage should be such that a pressure of less than 40 lb. on it will overcome the clutch spring.

For metal-to-metal disk clutches a friction coefficient of 0.04 can be figured on, and for dry disk clutches (asbestos fabric), 0.2. The unit friction in the case of the former should be restricted to 1 lb. per sq. in. and in the case of the latter to 3 lb. The "disks" are generally made in the form of comparatively narrow rings, to minimize the difference in wear at their inner and outer circumferences. Let h.p. = horse power to be transmitted at N r.p.m. and let the clutch have n disks of r in. mean radius. Then, with a friction coefficient of 0.04 the spring pressure required, $P > (\text{h.p.} \times 33{,}000 \times 12)/(Nnr \times 2\pi \times 0.04)$. For dry plate clutches substitute 0.2 for 0.04 in this inequality. The disks are made of saw steel and ground. From 20 to 50 are used in metal-to-metal clutches and from 8 to 14-in. dry plate clutches.

Change-speed Gears. Most change gears are of the sliding type with either three or four forward speeds and one reverse. The highest forward speed is a direct drive through the change-gear box. The lowest is made ⅓ to ¼ the high, depending upon the proportion of motor power to vehicle weight and the number of gear changes. Intermediate gear ratios are so proportioned as to approximately form a geometric series with the extreme ratios. The reduction ratio of the reverse gear is made equal to or lower than the lowest forward gear. The sliding pinions slide on a fluted shaft. There are generally either two or three sliding members, which are operated selectively by means of a hand lever. In order to insure noiseless operation, short, heavy shafts are used. The shaft center distances are usually about as follows: 20 h.p., 3.5 in.; 30 h.p., 4¼ in.; 40 h.p., 4¾ in. Gears are generally cut with stub teeth with a 20-deg. pressure angle, 6-8 pitch being very common, and are chamfered at their engaging sides. All gears in one set are usually made of the same width of face. This width can be determined for the driving pinion by means of the Lewis method (see p. 730) or a modification of same for stub teeth, on the basis of a stress of 15,000 lb. per sq. in. for case-hardened gears and 30,000 lb. per sq. in. for alloy-steel gears hardened all through.

An efficiency test of a three-speed-and-reverse sliding-pinion change gear made at the works of the Franklin Mfg. Co., showed maximum efficiencies of 98 per cent. on the direct drive; 95.5 per cent. on the intermediate gear; 94 per cent. on the low gear and 87 per cent. on the reverse. At full load and maximum engine speeds the efficiencies were as follows: Direct drive, 97 per cent.; intermediate speed, 95 per cent.; low speed, 93 per cent.; reverse, 86 per cent.

Final Drive. The drive from the change-speed gear to the rear axle is effected in pleasure cars by means of a propeller shaft with one or two universal joints and a pair of bevel gears, or spiral bevel gears giving a reduction ratio of between 3 : 1 and 5 : 1. In motor trucks the transmission is effected either by means of a pair of bevel gears to a countershaft and thence by side chains to the rear wheels, or by a propeller shaft and worm and worm wheel to the rear axle. In case only a single universal joint is used, the propeller shaft should be made relatively long—by placing the change-gear box close to the engine—and the engine and change gear should be placed at such a level or at such an angle that the shafts connected by the universal joint are substantially in a straight line when the car carries its normal load—in order to prevent periodic fluctuations in the drive.

In a chain-driven car the rear axle must be connected to the frame by a pair of radius rods which, in heavy vehicles at least, should have a universal connection at each end. These rods take up the chain pull and transmit the driving thrust from the rear axle to the frame. They should be of adjustable length with a range of adjustment equal to at least one pitch of the chain. In shaft-driven cars the rear axle must be provided with a torque arm or a torque tube concentric with the propeller shaft which takes up the reaction due to the pressure of the bevel pinion or worm. Means must also be provided for transmitting the driving thrust to the frame, and the rear-axle housing must either be made inherently strong enough, or else must be braced to the propeller-shaft housing, to enable it to withstand any shocks due to one road wheel striking an obstruction. Tests made by the Franklin Mfg. Co. show that the efficiency of a rear-axle bevel-gear drive may attain a value of 97 per cent.

Running Gear and Control

Rear Axle. A live rear axle consists of the axle housing, axle shafts, and differential and driving gear. The axle housing is often made of pressed steel, in halves which are welded together by the autogenous process; occasionally it is made of a single drop-forging, but most frequently it is assembled from a malleable iron or aluminum driving-gear housing and two axle tubes. Brake-supporting brackets and spring seats are riveted to the tubes near their outer ends. Nearly all live axles are stiffened in a vertical plane by an underrunning truss anchored to the brake supports, the driving-gear housing forming the strut.

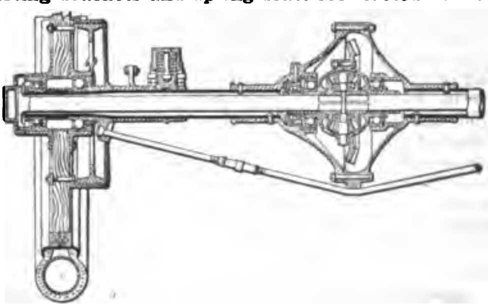

Fig. 11.—Full-floating Live Axle.

Live Axles are divided into full-floating, semi-floating and three-quarter-floating axles. In the first (Fig. 11) the shafts are subjected to torsional loads only, the wheel bearings being mounted on the outside of the axle tubes and the inner bearings of the axle on the hubs of the differential casing, the axle shafts being connected to the driving-wheel hubs by floating driving dogs. Three-quarter-floating differ from full-floating axles in that the floating driving dog is replaced by a driving flange rigidly fastened to shaft and wheel hub. In a semi-floating axle the axle tube extends only to the inner edge of the wheel hub and the load due to the vehicle weight there is transferred to the shaft. Shafts for full-floating axles can be calculated for torsion only, allowing a maximum stress of 20,000 lb. per sq. in. for heat-treated carbon steel (taking account of any reduction in the section at the joints) and 30,000 lb. per sq. in. for nickel-chrome steel. In the case of semi-floating axles the combined bending and torsional stress must be figured with, the same maximum stresses being allowed. Axle tubes are generally made of an outside diameter equal to about twice the shaft diam., and in full- and three-quarter-floating axles are reduced at the wheel hub.

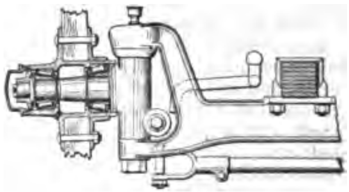

Fig. 12.—End Construction of Pleasure-car Front Axle.

Differential Gear. This serves to divide the torque equally between the two driving wheels, and permits one wheel to run faster than the other in turning curves. It consists of a frame or housing receiving the power and carrying three or four bevel pinions with their axes radial to the axis of the frame. Each pinion meshes with two master gears secured to the two rear axle shafts (or countershafts) respectively. A spur type of differential is also used, in which the master spur gears each mesh with three or four spur pinions. The faces of the pinions are of about twice the width of those of the gears, and each pinion meshing with one spur gear also meshes with a pinion meshing with the other gear.

Rear Dead Axles of motor trucks are made of solid rectangular section, about 1.5 times as high as wide, and are calculated on the basis of 15,000 lb. per sq. in. stress under full-load.

Front Axles for pleasure cars are drop-forged with a relatively light I-section so proportioned as to give from 2½ to 3 times as much bending strength in the vertical as in the horizontal plane, and can be calculated on the basis of 10,000 lb. per sq. in. stress under full load. Truck front axles are made with either a solid or a heavy I-section. Fig. 12 shows one end of a pleasure-car front axle.

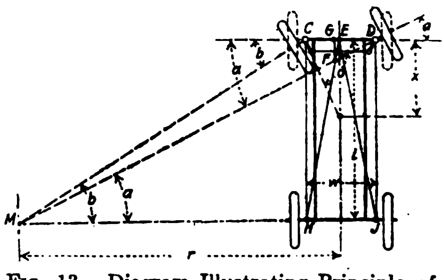

Fig. 13.—Diagram Illustrating Principle of Ackermann Steering Gear.

Steering Gear. Fig. 13 illustrates the principle of the Ackermann steering gear generally employed on automobiles. In order that there may be no slippage of any of the wheels when describing a curve of radius r, the point of intersection of the two front wheel axes produced must always fall in a vertical plane through the rear axle center. When this condition is fulfilled, $\cot a - \cot b = w/l$.

The value of b corresponding to any given angle, a, may be found without laying off the point M, which falls generally beyond the limits of the drawing board, since the angle $FCE = b$. The above-mentioned condition of perfect steering is not fully attainable by means of the customary steering linkage consisting of two steering arms of equal length secured to the steering knuckles which by means of a steering tie rod are connected up into a trapezium.

According to an investigation of Lutz (*Der Motorwagen*, 1908, p. 699), for values of l/w between 1.5 and 2.5 and with maximum steering deflections

$a_{max} = b_{max} =$	35°	40°	45°
o (for tie rods located in front of the axle) may be chosen between	58° and 69.5°	59° and 71°	60° and 72°
or x/w between	0.8 and 1.3	0.84 and 1.4	0.9 and 1.5

Also,

o (for tie rods located back of the axle) may be chosen between	66° and 74.5°	67° and 75°	68° and 76.5°
or x/w between	1.12 and 1.79	1.17 and 1.86	1.26 and 2.0

without in any case exceeding an error of 1 per cent. in the steering.

These values are calculated for the ratio: (Length of steering arms)/(Distance between knuckle pivots) = 0.14, but are sufficiently accurate for values of the ratio between 0.11 and 0.17. The tie rod is preferably placed back of the axle, where it is protected against injury.

Pleasure cars are steered by means of a hand wheel 15 to 18 in. in diam., usually with a cast aluminum center and a hardwood or hard rubber rim. The motion is reduced through a worm and sector (or worm wheel) or a screw and nut mechanism, the pitch being so chosen that the gear is completely or very nearly self-locking or irreversible. The worm or screw is usually cut with 4 or 5 threads, and the leverages are so arranged that from 1 to 1½ turns of the hand wheel will move the steering wheels from hard over one way to hard over the other way.

Brakes. American designers of pleasure cars usually place both the service and emergency brakes on the rear wheel hubs, either making both sets expanding or one expanding and the other contracting. In Europe, it is customary to place one brake on the transmission shaft directly back of the change-gear box. In motor trucks with side-chain drive, one set of brakes is placed on the rear hubs and the other on the outer ends of the countershaft. **Service brakes** are operated by a pedal, and **emergency brakes,** as a rule, by a hand lever. Brake shoes or bands are generally faced with asbestos fabric secured by copper rivets (in Europe with cast-iron blocks), and brake drums are pressed from sheet steel. Wheel brake drums are made of a diameter equal to about 0.4 the wheel diam., except in the very lightest cars, and each set of wheel brakes is provided with 1 sq. in. of **braking surface** per 15 lb. of car weight (unloaded). Half this amount of surface is sufficient in the transmission brake. The operating **effort applied to** the two **brakes** of each set, respectively, must be equalized in order to prevent **skidding.** A maximum pressure of about 100 lb. can be exerted on the brake pedal, from which the operating linkage can be calculated for strength.

Frames of pleasure cars are almost universally made of sheet steel, all members being of channel section, the height of the section of the side members decreasing from the center to both ends. Cross members are riveted to side members with substantial gusset plates, generally formed integral with the former. Golden (*Horseless Age*, Aug. 26, 1908) gives the following formula for the strength of pressed-steel side members: $Z = 39W/L_e$, where Z is the section modulus; W the weight of car with load, in lb., and L_e the elastic limit of the frame material. Truck frames are made of pressed steel or of rolled I-section or channel steel.

Automobile frames weave and distort more or less under road shocks.

Hence bearings in different parts supported on the frame cannot be kept in alignment, and shafts supported by them must be flexibly joined together. To prevent injury to housings from distortion of the frame, they should preferably be supported at three points. Engine and change-gear bearings can be kept in alignment by rigidly bolting their housings together into a unit power plant.

Springs. Chassis frames are usually supported by half-elliptic springs in front and three-quarter or full-elliptic or cantilever springs in the rear. Cross springs are employed in a few instances both in front and rear. The front springs are pivoted to the frame at their forward ends and shackled to it at their rear ends. The connection of the rear springs to the frame depends upon the axle linkage employed; three-quarter elliptic and cantilever springs are generally shackled at their forward ends. Spring bolts must be provided with grease cups. Spring seats usually turn on the rear axle housing and sometimes have a spherical seat thereon.

Tires. The load ratings of pneumatic tires adopted as standard by the Society of Automobile Engineers, are given in the following table. The oversize tires, which fit on the rims of the regular tires on the same line of the table, are not intended to be fitted by car manufacturers.

Load Ratings of Pneumatic Tires

Regular sizes			Over sizes		
Size, inches	Rear, pounds	Front, pounds	Size, inches	Rear, pounds	Front, pounds
30 × 3	375	450	31 × 3½	475	575
30 × 3½	450	550	31 × 4	635	775
32 × 3½	500	625	33 × 4	675	850
32 × 4	650	800	33 × 4½	825	1050
34 × 4	700	875	35 × 4½	935	1175
34 × 4½	900	1125	35 × 5	1000	1250
36 × 4½	1000	1250	37 × 5	1100	1350
36 × 5	1000	1375	37 × 5½	1150	1400
38 × 5½	1350	1600	39 × 6	1800	2100

The load ratings of solid rubber tires are given in the following table. The Society of Automobile Engineers recommends the use of three wheel diameters only for commercial vehicles, 32, 36, and 40 in.

Load Ratings of Solid Rubber Tires, Lb.

	Diameters						Miles per hour
Cross-section	32 in.	34 in.	36 in.	38 in.	40 in.	42 in.	
2-in. singles	450	475	500	525	550	575	20

ELECTRIC VEHICLES

Electric vehicles carrying storage batteries as the source of current, are used almost exclusively as city vehicles, on account of their limited mileage capacity on a single charge. Aside from the running gear, the essential parts of an electric vehicle are the battery, the motor or motors, the controller and the driving gear.

Batteries. Either a special light type of lead storage battery or an Edison nickel-iron type of battery is used. Lead battery cells for vehicles are made with specially thin plates and give about 10 watt-hr. per lb. of cell weight. These cells are relatively frail and require constant care. They must not be overcharged nor be discharged below 1.8 volts per cell. The average discharge voltage is 2 volts per cell. Most lead batteries increase in capacity during the first period of service and then gradually lose capacity until it becomes necessary to renew the plates. Thin-plate lead batteries used the year around will cost for washing and renewal of plates from two-thirds to four-fifths of their initial cost. In the so-called "iron clad" type of lead battery the annual maintenance cost is about one-third the initial cost. Formerly, batteries of 40 or 44 cells were generally used, because of the convenience in charging from 110-volt circuits, but since most electric distribution lines now carry alternating current and a transformer has to be used in any case, a smaller number of cells is now frequently used.

The Edison nickel-iron battery occupies about one-third more space than the thin-plate lead battery and costs about three times as much for the same capacity, but is guaranteed to retain its full capacity for 4 years. This battery has an average discharge voltage of 1.2 volts and a specific capacity of 13.5 watt-hr. per lb. of cell weight. For charging from 110-volt circuits, 60-cell batteries are used.

The weight of the battery usually constitutes from 30 to 40 per cent. of the weight of the car complete without load. Since too rapid a rate of discharge is injurious to the battery, electric cars must be geared to run at moderate speeds. For pleasure vehicles 20 miles per hour is usually the maximum speed and for commercial vehicles on solid or cushion tires, from 6 to 12 miles per hour according to load capacity. As the rate of discharge increases, lead batteries lose in ampere-hour capacity, Edison batteries mainly in discharge voltage.

Motors. Vehicle motors are generally of the multipolar (4 to 6 poles) iron-clad type with forged or laminated poles. Formerly, two motors were frequently used on the heavier vehicles in order to dispense with the differential, but single-motor equipment is now well-nigh universal. Motors are generally hung from the spring-suspended frame. Series-wound motors are used, on account of their high starting torque. Motors of from 2 to 2.5 kw. rating are generally used for pleasure cars and the following sizes for trucks: One ton load capacity, 2 kw.; 2 tons, 2½ kw.; 3½ tons, 3½ kw.; 5 tons 4¼ kw. These motors generally have a momentary overload capacity of 250–300 per cent. A double reduction is frequently employed between the motors and rear axle or rear wheels, such combinations as a silent chain and bevel gear set, a silent chain and herringbone gear set, and a spur gear set and side chains being used. For electric pleasure vehicles the worm drive is being extensively adopted. Correctly cut worm gears may operate at efficiencies as high as 98 per cent. (Lanchester, *Proc. Inst. Auto Eng.*, London, 1913.)

Control by paralleling the battery is no longer used. From five to six forward speed combinations are generally provided. The field coils are generally arranged so that they can all be connected in series or in two parallel groups. One control system is as follows: 1st speed, fields in series, resistance in series; 2nd speed, fields in series, resistance out; 3rd speed, fields in series, resistance shunted across fields; 4th speed, fields in parallel, resistance out; 5th speed, fields in parallel, resistance shunted across fields.

A two-passenger electric runabout weighs about 2000 lb.; a four-passenger open car, 2500 lb. Pleasure cars have a radius on one charge of from 60 to 100 miles on hard, level road; motor trucks, from 30 to 40 miles.

Electric Vehicle Data

Rated load capacity, lb.	Two passenger.	1,000	2,000	4,000	7,000	10,000

C. "Locomotive Tests and Exhibits," Pennsylvania Railroad Company. *Bulletins* of the Pennsylvania Railroad Test Department. "Locomotive Performance," W. F. M. Goss. "Locomotive Operation" (2d Ed.), G. R. Henderson. "Railway Track and Track Work" (3d Ed.), E. E. R. Tratman.

LOCOMOTIVE DESIGN

Types. The types shown in Fig. 1 comprise all but about 1/10 of 1 per cent. of the locomotives in service in the United States. The numerals of the type symbol indicate successively the number of leading wheels, drivers and trailing wheels, beginning at the front end. For example, the Atlantic locomotive is designated as the 4-4-2 type.

Eight of these types—the American, Atlantic, Mogul, Prairie, Ten-wheel, Pacific, Consolidation, and 6-wheel Switcher—comprise 95 per cent. of the locomotives in service. Those of the Consolidation type alone constitute 31 per cent. of the total number. The trailing-wheel types, which permit the use of larger grate areas, are being built in ever-increasing numbers, and will probably eventually displace the other types in road service.

Service. The usual service of the ordinary types of road locomotive is shown in Table 1. Service requirements and character of road occasionally necessitate variations from the uses there indicated.

Table 1. Service of Locomotives of Ordinary Types

Type	Service	Type	Service
American (4-4-0)	Ordinary passenger	Consolidation (2-8-0)	Freight
Atlantic (4-4-2)	Fast passenger	Mikado (2-8-2)	Freight
Mogul (2-6-0)	Light freight	Twelve-wheel (4-8-0)	Freight
Prairie (2-6-2)	Heavy passenger and fast freight	Decapod (2-10-0)	Freight, on heavy grades
Ten-wheel (4-6-0)	Heavy passenger and fast freight	Articulated	Freight, on heavy grades
Pacific (4-6-2)	Fast and heavy passenger		

Costs. The cost of recently built locomotives varies from about 8.3 to about 10.8 cents per pound. These costs include the cost of the tender, but

Table 2. Weights and Costs of Various Types of Locomotives

Type	Weight, lb.	Cost	Type	Weight, lb.	Cost
6-Wheel switcher	138,500	$12,500	Consolidation	203,500	$17,000
Atlantic	187,000	17,500	Consolidation	223,000	18,000
Atlantic	191,000	20,500	Consolidation	229,000	22,500
Pacific	224,000	21,000	Mikado	284,000	24,000
Pacific	245,000	22,000	Mikado	285,000	24,500
Pacific	258,000	23,500	Mallet	465,000	40,000
Ten-wheel	209,000	21,000			

they are based on the weight of the locomotive only, in working condition (with water in the boiler). In general, the cost per lb. is likely to decrease

FIG. 1.—Types of Locomotives.

as the weight increases. Table 2 presents total costs of locomotives and tenders of various types of locomotives, all built within the last 5 years. The weights are for the locomotive only, in working order,

Locomotive Dimensions. Table 3 presents the principal dimensions of the ordinary types of road locomotives. Where two locomotives of a type are included, the first is one whose main dimensions are approximately the average of the dimensions of all those of its type in service, whereas the second is the largest or almost the largest of its type. Where only one of a type is given, it is the largest or nearly the largest of its type recently built.

Clearance Limits. The maximum width of existing locomotives is about 11 ft. 6 in., and the maximum height about 16 ft. The maximum width occurs usually at the cylinders. On curves there is some **overhang** sidewise, which, in articulated locomotives, is a considerable amount. In particular localities and on individual roads, the clearance dimensions are considerably less than those above stated.

Wheel Loads. The allowable **maximum wheel load** varies on different roads and depends upon the strength of track and bridges. The weight on each driver varies from 25,000 to 31,000 lb. in those types which demand the heaviest wheel loads. It rarely exceeds the latter amount. The maximum is at present 36,500 lb., which is, however, quite exceptional. The load on each trailing wheel is occasionally almost equal to the load per driver; but generally less. The load on each front truck wheel is generally about one-half the load per driver. Wheel loads on locomotives over 10 years old are generally less than those here cited.

Boiler Pressure, in locomotives using saturated steam built within the last 12 or 15 years, is in the majority of cases 200 lb. per sq. in. Higher pressures—up to 225 lb.—are occasionally used. Pressures have been carried to this point in the desire to obtain maximum capacity within the available space limits. General overall economy is better promoted by pressures in the neighborhood of 180 lb. ("High Pressure Steam in Locomotive Service," W. F. M. Goss, Publication 66 of the Carnegie Institution, Washington); but the demand for capacity has overshadowed that for maximum economy. The economy resulting from the use of superheated steam has greatly enhanced the capacity of the locomotive as a whole and has therefore rendered it feasible to return to a lower boiler pressure, which in superheated-steam locomotives is generally from 170 to 200 lb.

Valve Gears. The great majority of American locomotives are equipped with the Stephenson link motion (p. 974). In recent years the larger locomotives have been quite generally equipped with the Walschaerts gear (p. 977), which is rapidly becoming their characteristic valve motion. This gear has been adopted chiefly because of its greater accessibility to inspection and repair, and because of the difficulty of finding adequate space for the Stephenson gear on large locomotives.

Master Mechanics' Association Standards. The annual volumes of the *Proceedings* of the American Railway Master Mechanics' Association (Am. Ry. M. M. Assn.) contain the association's standards concerning such features of design as sizes of wheels, journals, axles, tires, etc.; specifications for boiler and fire-box steel, iron and steel boiler tubes, iron and steel axles; and rules for boiler inspection, locomotive efficiency tests, etc.

Counterbalance. The weights of the revolving parts, such as the crank pins and side (parallel) rods, if unbalanced, would produce equal radial forces for all positions of the crank. These forces can be and are perfectly balanced for all crank positions. The inertia of the reciprocating parts produces at the main crank pin radial forces which vary in magnitude throughout each revolution, and which attain their maximum values when the crank is at either the front or back dead center. Since the cranks on opposite sides are set 90 deg. apart, these maximum forces occur four times during each revolution and they amount, at high speed, in a modern passenger locomotive, to as much as 90,000 lb., which is exerted first forward on one side, then forward on the other; next backward on the first side, then backward on the other. These forces, if unbalanced, would throw the front end of the loco-

§ Includes surface of a feed water heater. ‖ For superheaters this is total equivalent heating surface, = total water heating surface + 1.5 × superheating surface. † Includes arch tube heating surface. * Includes 65 sq. ft. of combustion chamber heating surface.

motive from side to side, causing it to "nose," and they would also cause great fluctuations in the pull exerted on the tender drawbar. **The purpose of counterbalancing** is to reduce these disturbing forces. They could be almost entirely eliminated by adding, opposite the cranks, counterbalance equal in weight to the main rod and reciprocating parts, but so great a weight of counterbalance would produce, when it was on the bottom center, undue rail pressure, and when on the top center, would lift the driving wheels from the rails at high speed. In the face of these difficulties counterbalancing becomes a compromise, and these horizontal forces are only partially balanced.

The following **system** of counterbalancing is **in general use.** (See "Locomotive Operation," by G. R. Henderson, 2d Ed., p. 41, and *Proc. Am. Ry. M. M. Assn.*, 1896, vol. 29, p. 148, and 1897, vol. 30, p. 117.) It consists essentially of three steps:

1. A weight (R_1, R_2, etc.—see below) is put in each driver to counterbalance the weight of the purely revolving parts which pertain to that wheel.

2. A weight, M, is put in the main driver (to which connecting rod is attached) to counterbalance the vertical forces due to the weight of main rod and reciprocating parts when the crank is on either the top or bottom center.

3. Additional weight, P, is distributed among the drivers to counterbalance, on the horizontal centers, that portion of the weight of the main rod and reciprocating parts which is to be balanced and which remains after M in item 2 is provided for.

These weights and their distribution may be determined by means of the following formulæ, in which all weights are expressed in lb. and all dimensions in ft.:

B = Weight of total combined counterbalance in all drivers on one side, placed opposite the cranks and assumed to be placed with its center of gravity at radius r from the wheel center. When, as is usual, it is placed nearer the wheel rim it must be so reduced that its centrifugal force equals that of the weight B at radius r. This weight is all carried in the driving wheels.

R = Total weight of balance for revolving parts.

M = Weight of balance for *vertical thrust* on main pin due to main rod and reciprocating parts, when crank is on top or bottom centers.

P = Total weight to partially balance, on the front and back centers, the horizontal forces due to main rod and reciprocating parts.

W = Total weight of the locomotive, excluding the weight of the tender.

W_1 = Total weight of the main rod.

W_2 = Total combined weight of all those parts which have a purely reciprocating motion, namely, cross head, piston rod, piston, and all parts pertaining thereto. For locomotives with Walschaerts valve gear, W_2 includes also the weight of the valve-gear arm, link, and the lower half of the combining lever.

$R_1, R_2 \ldots\ldots R_n$ = The respective total weights of the purely revolving parts attached to each driver. (Subscripts refer to the position of the drivers, No. 1 being the front driver.) R_1, for example, is the combined weight of the revolving parts on the first driver, namely, the weight of the forward end of the front side rod, the weight of the crank pin with its washer and nut, and the equivalent weight of the crank-pin hub. (The hub weight must be reduced to a weight which, with its center of gravity placed at crank radius, would have a centrifugal force equal to that of the actual hub weight.) In dealing with locomotives of more than two drivers on a side, it must be borne in mind that one or more crank pins carry portions of the weight of two side rods. In locomotives equipped with Walschaerts valve gear, the weight of the eccentric arm and approximately one-half the weight of the eccentric rod are revolving weights pertaining to the *main* driver.

n = Number of drivers on each side.

r = Crank radius.

l = Length of the main rod, center to center of pins.

d = Distance of the center of gravity of the main rod from crank-pin center.
k = The radius of gyration of the main rod about cross-head-pin center.

Under this notation:

$$R = R_1 + R_2 \ . \ . \ . \ . + R_n \tag{1}$$

$$M = W_1\left[\frac{k^2}{l^2} + \frac{d}{l} \times \frac{r^2}{l^2 - r^2}\right] + W_2\frac{r^2}{l^2 - r^2} \tag{2}$$

or, for rods of usual design

$$M = W_1\left[\frac{1}{2} + \frac{3}{8} \times \frac{r^2}{l^2 - r^2}\right] + W_2\frac{r^2}{l^2 - r^2} \tag{3}$$

$$M = W_1/2 \text{ approximately,} \tag{4}$$

$$P = W_1 + W_2 - M - (W/400) \tag{5}$$

$$B = R + M + P \tag{6}$$

The value of M is given exactly by equation (2); almost exactly, for rods of usual design, by equation (3); and less exactly by equation (4). Equation (4) is frequently used, and its use results in a deficiency of the main wheel balance which is generally not more than 20 lb. The last term of equation (5) is the amount of main-rod and reciprocating weight which is allowed to remain unbalanced. Variations in practice from the system here set forth consist chiefly in differences in the denominator of this term. Other variations lie in the determination of M, which is occasionally—though less logically—assumed equal to the weight of the crank-pin end of the main rod. P is sometimes determined by means of the formula $P = (W_1 + W_2) \times A$, in which the value of A varies from 0.50 to 0.67.

The **total weight of counterbalance on one side** of the locomotive is given by equation (6). Its **distribution** is effected as follows: R is divided into its components R_1, R_2, etc., each of which is placed on the wheel to which it pertains. M is placed in the main wheel. P is usually divided equally among the drivers, each of which receives an amount equal to P/n. When, however, the static weights on drivers are unequal, the weight P may be unequally divided among them, in such a way as to result in ecual maximum rail pressures under all drivers. The components of the counterbalance weight thus determined for each driver are added and the total placed in the wheel opposite the crank. If placed at crank radius this weight would give correct balance. The actual balance cast in the wheel weighs less, in the ratio $r \div$ radius to center of gravity of the actual balance.

The balance for a 4–6–2-type locomotive, whose main rod is attached to the middle driver, would be distributed thus:

Driver No.	1	2(Main)	3
Balance for revolving parts	R_1	R_2	R_3
Balance for main rod	......	M	......
Balance for main rod and reciprocating parts	$P/3$	$P/3$	$P/3$
Balance per wheel =	$R_1 + (P/3)$	$R_2 + (P/3) + M$	$R_3 + (P/3)$
Total balance =	$R_1 + R_2 + R_3 + M + P = B.$		

All of the foregoing applies to one side only of the locomotive. Balance for the opposite side is determined in like manner. The system applies only to locomotives having two main cranks, set 90 deg. apart.

When the cranks are on either the top or bottom center, the counterbalance weight P/n ("excess balance") produces in each wheel a centrifugal force which is not neutralized by the action of the engine parts. At maximum speed, the sum of this force and the static weight on the driver must not exceed the allowable rail pressure, nor should this force exceed 75 per cent. of the static weight on each driver.

Electric Locomotives. A few of the principal dimensions of characteristic electric locomotives are given in Table 4.

Railway Motor Cars. During the last ten years self-propelled "motor cars" have made their way into service on steam roads. Their use is thus far infrequent, is limited to passenger and express service, and has been warranted only on branch lines with very light traffic. With respect to their **general design** they group themselves as follows:

1. Cars with an internal-combustion engine, using gasoline or similar fuel, usually located within the car and connected by chain or friction drive to the driving axle. In some designs the engine is carried in the truck and is geared to the driving axle. Examples of this type are the McKeen and the Daimler cars.

2. Cars with an internal-combustion engine located within the car and driving an electric generator which furnishes current for motors carried in the trucks, as in the ordinary electric car. Cars of this type are those built by the General Electric Co., those of the North-Eastern Railway (England) and the Dra-Car. Others, now rarely used, like the Strang and the Hicks cars, have a storage battery added to this equipment.

3. Cars equipped with simple or compound steam engines, supplied from boilers which use oil —and occasionally coal—for fuel and which generally supply superheated steam. In most cases the engine is carried in the truck and is either directly connected to the driving axles or is geared to them. In one design the engine is carried on the car frame and is chain-connected to the driving axle. Examples of this type are the Ganz and the Purrey cars, and those of the Canadian Pacific Railway.

4. Cars carrying storage batteries as the sole source of power, from which current is supplied to electric motors carried in the trucks as in the ordinary electric car. Cars of this type are thus far rarely used on steam roads.

The **cost of operation** of these cars in American service, including the cost of labor, fuel and supplies, is from 11 to 20 cents per mile, under ordinary branch-line conditions. The cars weigh from 30 to 60 tons. More detailed information may be found in *Proc. Am. Ry. M. M. Assn.*, 1906, vol. 39, p. 416; 1907, vol. 40, p. 194; 1909, vol. 42, p. 86; *Proc. International Ry. Fuel Assn.*, vol. 5, 1913.

LOCOMOTIVE PERFORMANCE

The locomotive is a power plant which is required to work under loads that vary widely and suddenly, and which is designed to come within space limits nowhere approached in other practice. Under ordinary conditions of service, the load on boiler and engines frequently decreases from the maximum to one-fifth or one-sixth of that amount within a period of a few minutes. Under such conditions, the efficiency of the boiler performance depends in a peculiar degree upon the judgment of the fireman, and of the engine performance upon the skill of the engineer. These facts account for great variations in general or average performance. Throughout this article, unless otherwise specifically stated, coal and steam, when mentioned, refer respectively to bituminous coal and dry saturated steam.

Firebox Performance. The rate of combustion in locomotive boilers is much greater than in boilers of other types. The usual range of **relations between draft and the coal burned** per sq. ft. of grate per hour is shown by the shaded area in Fig. 2. Variations in draft for the same rate of combustion are due to differences in the thickness and in the condition of the fire, and also to differences in the construction of the ash pan and front end. In the diagram the draft is the difference between the pressure of the atmosphere and the pressure existing in front of the diaphragm in the front end. A rate of 150 lb. per sq. ft. of grate per hour is rarely exceeded—indeed, rarely attained—in modern locomotives, and this rate is reached only under unusual demands and for short periods. Before the advent of the wide firebox, the combustion rate on small grate areas was occasionally carried up to 200 lb.

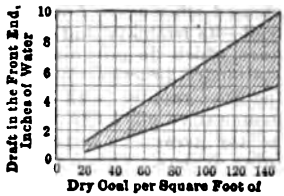

FIG. 2.

In freight service, with large locomotives of the usual types, and in runs of from 8 to 10 hr. duration, the average **hourly coal consumption** is frequently about 4000 lb., occasionally about 5000 lb. In locomotives hauling heavy and fast passenger trains, this hourly consumption occasionally—though rarely—averages 6500–7500 lb. in runs of about 3 or 4 hr. duration. For periods of an hour or less, an unusually skillful fireman may fire at the rate of 9000 lb. per hour; but such a performance is rare. In general, the average hourly coal consumption is much less than these maximum rates. The rates stated may be exceeded by the use of mechanical stokers.

Draft. In locomotives of ordinary design, the draft necessary to draw the air from the ash pan through the fire is only from 0.2 to 0.3 of the total draft shown in Fig. 2. The remainder is required to draw the gases through the tubes and under the diaphragm. Total draft varies directly with the weight of steam discharged through the front end per min. and maximum draft is therefore attained when the boiler is working at maximum power. Ten inches of water is about the **maximum draft** ordinarily obtained. Under the action of maximum draft, from 12 to 15 per cent. of the coal fired may be ejected as sparks into the front end and through the stack.

Mechanical Stokers. The ultimate capacity of the grates and heating surface of the largest locomotives cannot be realised by hand firing, and, under the demand for increased capacity, mechanical stokers have been applied in considerable number to such locomotives during the last 5 or 6 years. Their design is, however, just emerging from the experimental state and their use is not yet general. About 950 are now in service. Descriptions of the various designs and data concerning their performance are contained in *Proc. Am. Ry. M. M. Assn.*, 1909–1915.

Boiler Performance. Under ordinary conditions, the **maximum equivalent evaporation** from and at 212 deg. per sq. ft. of heating surface per hour is about 12 lb. Under the variable rates of power consumption which prevail in service, the evaporation averages much less, from 6 to 8 lb. per hour. Under unusually severe demand, this rate is occasionally raised, for short periods, to 15 or even 16 lb. per hour, but the modern locomotive with ample heating surface is rarely driven beyond a rate of 12 lb. per hour. Each sq. ft. of heating surface therefore delivers, on the average, about 0.2 boiler h.p., and, when driven, will supply from 0.35 to 0.45 h.p.

When driven at very low rate, the equivalent evaporation per lb. of coal in locomotive boilers is about equal to that obtained in good stationary practice. This evaporative efficiency falls off rapidly as the rate of evaporation is increased. The heavy draft employed causes large quantities of the coal fired to be ejected into the front end and through the stack, resulting in decreased efficiency. For this reason differences in the physical character of coal—its friability and size—produce variations in locomotive boiler performance which do not make themselves felt in stationary practice. Since these stack losses increase rapidly with increased power, the evaporative efficiency falls off more rapidly as the power is increased than it does in other boilers. Other losses also are greater in locomotive boilers when driven at high rates.

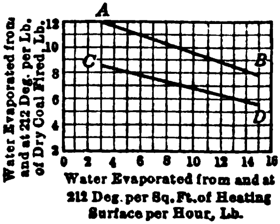

FIG. 3.

The range in values of **equivalent evaporation per lb. of dry coal** and of **evaporation per sq. ft. of heating surface per hour** is indicated in Fig. 3, which shows also the ordinary relation existing between these two quantities. The line *AB* represents about the best performance obtainable with the highest grade of coal, ample grate area, and excellent firing. Line *CD* represents poor performance, such as may be expected with either poor coal or poor firing. Performance in individual cases may be expected to be represented by a line lying between these two. **Results with** good **anthracite** coal will, with skillful firing, equal those indicated by the line *AB*.

In locomotives of modern design, from 35 to 50 per cent. of the total evaporation takes place on the heating surface of the firebox, although the latter constitutes generally only from 4 to 8 per cent. of the total heating surface.

Cylinder Performance. In a locomotive, cylinder performance is affected by variations in both speed and cut-off. Run at constant speed, the steam consumed per i.h.p. per hour in simple locomotives is a minimum at from 30 to 40 per cent. cut-off, and increases at either earlier or later cut-offs. When run at constant cut-off, the steam consumption decreases rapidly with speed until it reaches its minimum at a speed which lies generally between 120 and 180 r.p.m., and then increases rapidly as the speed is increased beyond this point. Within approximately these limits, the speed of best performance varies, depending on the cut-off and the steam pressure. (It is generally lower in compounds.) There is therefore in any locomotive a combination of a particular cut-off and a particular speed which produces **maximum economy.** These facts are exemplified in Figs. 4 and 5, which are fairly typical high-grade performance curves for a simple freight locomotive with 22 × 28-in. cylinders, 56-in. drivers, and 200 lb. boiler pressure. It is difficult, under the circumstances, to formulate any general statement for cylinder performance, but it may be approximately represented as in Fig. 6, in which the range in values of steam consumption is shown, for various speeds, by the shaded belts there drawn. Any of the larger modern simple locomotives, using steam at from 190 to 210 lb. may, when well handled, be expected to give a performance within the range shown in the upper part of Fig. 6. In using this diagram to predict the probable steam rate for a particular locomotive, the influence of cut-off should be remembered.

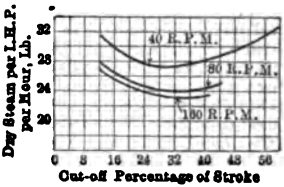

FIG. 4.

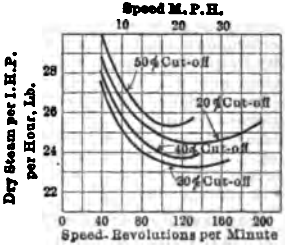

FIG. 5.

Compound Locomotives, under the most favorable conditions, give a cylinder performance similar to that shown by the lower part of Fig. 6. Under the fluctuations in load which prevail in ordinary operating conditions, their economy is reduced and is variously claimed at from 10 to 20 per cent. less than that of simple engines. Their performance is sensitive to changes in operating conditions, and their first cost and cost of maintenance are somewhat higher than for simple locomotives. Save on a few roads, they have never established themselves very firmly in American practice. Of the locomotives in service in the United States, only 3 per cent. are compounds. Of this number, about one-fourth are articulated freight locomotives in which, since 4 cylinders are required, compounding follows as a matter of course, and without being chargeable with complicating the design.

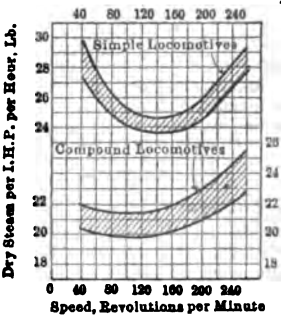

FIG. 6.

Use of Superheated Steam. What has preceded relates to saturated steam. The most important recent development in locomotive practice consists in the use of superheated steam. It was first introduced in Germany in 1898, and 10 years later was firmly established in German practice. It was in the meantime experimented with on American railways, being here first extensively used on the Canadian Pacific Railway, which in 1906 had about 200 superheater locomotives in service. Within the last 6 years superheaters have been rapidly applied to locomotives in the United States and Canada, where at present more than 14,000 are in service; most of them being of the fire-tube type. For descriptions of the various types and data concerning their performance in service, see *Proc. Am. Ry. M. M. Assn.*, 1910–1915.

The degree of superheat used in locomotive service varies up to a maximum of about 270 deg. fahr. Most superheaters now in use are designed to produce a superheat varying from 150 to 250 deg. The use of low superheat (up to 100 deg. fahr.) results in a relatively slight decrease in steam and coal consumption. The use of medium and high superheats (150 to 250 deg.) results, on the other hand, in very significant **reductions in the amount of steam and coal consumed** per i.h.p. per hour, as compared with the performance of locomotives using saturated steam. The consumption of steam and coal not only decreases as the superheat is increased, but the rate of this decrease is greatest in the highest ranges of superheat, *e.g.*, a greater gain in economy results from increasing the superheat from 200 to 250 deg. fahr. than in increasing it from 150 to 200 deg. Comparative tests of simple locomotives using saturated and superheated steam (150 to 250 deg.), made on testing plants, show the steam and coal consumptions of the latter to be from 15 to 35 per cent. less than those of the former, for continuous running under constant loads. Not all of this saving is realized on the road, for under the conditions of service much coal and some steam are used in ways upon which the superheater can have no beneficial effect. Numerous road tests and long-term comparisons of road performance make it clear, however, that, even under the conditions of service, simple locomotives using moderately or highly superheated steam may be relied upon to consume from 10 to 20 per cent. less coal and from 15 to 25 per cent. less steam than simple saturated-steam locomotives performing like service. The greater gains are apt to be obtained in passenger service. The cylinder performance of superheater locomotives is also less sensitive to changes in speed and cut-off, and their water rate at speeds beyond the point of minimum consumption increases but slightly. The best test-plant performance yet recorded is that of a simple Pacific type locomotive using steam at 204 lb. pressure and 223 deg. superheat, in which 1.93 lb. of dry coal and 14.6 lb. of steam were required per i.h.p. per hour.

On account of this economy in steam consumption, superheater locomotives may be designed—within given limits of space and weight—to have a considerably greater capacity than saturated-steam locomotives; and this increase in capacity is perhaps an even more important factor in bringing about their general adoption than is their economy of operation. Nearly all the locomotives most recently built have been equipped with superheaters.

General Performance. Among locomotives of other types than the articulated, the **maximum tractive effort** thus far attained is 84,500 lb., reached with a 2–10–2 type weighing 406,000 lb. The most powerful articulated locomotive thus far built, a 2–8–8–8–2 type weighing 853,000 lb., has a tractive effort of 160,000 lb. working as a compound. Among passenger locomotives the current maximum tractive effort is about 47,000 lb. These tractive forces are attained only at very late cut-offs and can be maintained only at very low speeds. The average maximum tractive effort of all locomotives in service is about 30,400 lb.

Maximum horse power is usually attained at speeds of from 25–35 miles per hour in freight locomotives, and at speeds of from 50–60 miles per hour in passenger locomotives. At higher speeds the power decreases in saturated-steam locomotives; but is maintained nearly constant in those using superheated steam. The i.h.p. developed under service conditions, even with the largest locomotives, rarely exceeds 1800; and the maximum thus far attained and measured in road or laboratory tests is about 3200 i.h.p.

Efficiency. The losses between the cylinder and the tender drawbar include (1) friction of all parts of the engine mechanism; (2) net resistance on level track at uniform speed (journal resistance, resistances at the wheel rim, and air resistance); (3) grade resistance, and (4) acceleration resistance. Items 3 and 4 may be absent. Items 1 and 2 are always present and are at their minimum at low speeds. Consequently, the losses between the cylinders and the tender drawbar are least at low speeds, on level track, and at uniform speed.

Defining locomotive efficiency as the ratio of the horse power developed at the tender drawbar to the i.h.p. developed in the cylinders, it is obvious that the efficiency is 0 whenever the locomotive moves only itself and its tender. It reaches its maximum when the locomotive hauls the heaviest train it is capable of handling, on level track at very low and uniform speed. This maximum is about 92 per cent. Between these limits efficiency may have any value, depending on the speed and on the relative weights of the locomotive and the train. Table 5 presents values of efficiency obtained in tests of four freight locomotives hauling their maximum tonnage on a 0.58 per cent. grade 4.5 miles long, at practically uniform speed. These values are all averages for two trips of each locomotive over the whole 4.5 miles.

Table 5. Efficiencies of Freight Locomotives

Type of loco-motive	Speed, miles per hour	Ratio of train weight to weight of train, locomotive and tender, per cent.	Efficiency, per cent.	Equivalent values on level track	
				Ratio of train weight to weight of train, locomotive and tender, per cent.	Efficiency, per cent.
2-6-0	11.8	89.3	84.2	95.8	90.1
4-6-0	14.2	88.9	83.6	96.0	90.7
2-8-0	11.7	92.3	87.8	97.0	92.5
4-8-0	10.1	92.0	86.0	97.1	90.9

The values in columns 2 to 4 are the actual results of tests and they represent performance which may be attained in ordinary service where the ruling grades do not exceed about 0.5 per cent. The efficiency values of column 4 are not likely to be exceeded except on lines of unusually low grade or in starting trains on level track. Column 6 shows what the efficiency of these locomotives would have been, had they been operated on level track at the same power output. These values indicate what the locomotive may do; but they are not likely to be realized in service, because they imply ratios of train weight to total weight which are generally impracticable.

Tractive Effort. While the tractive effort of a locomotive is determined primarily by the action within the cylinders, it is limited on the one hand by the adhesion and on the other by the amount of steam which the boiler can supply. Cylinders are so designed that, at the latest cut-off used in their normal operation, the tractive effort does not exceed the weight on drivers $\times$ A, in which A is the coefficient of adhesion between the drivers and the rails.

The coefficient of adhesion, A, varies with the weight on the drivers and with the condition of the driver and rail surfaces. It probably does not vary much with speed. When the rail and drivers are very clean, A reaches its maximum of 0.35, which, though frequently attained, may never be relied upon. When the surfaces are greasy, or muddy, or moist, or frost-covered, the value of A decreases to from 0.15 to 0.20; but even under such conditions it can be restored to almost its maximum value by the use of sand. In design, it is not safe to assume that A will be greater than 0.25. The moment the drivers slip, this coefficient of *static* friction ceases to act, and its place is taken by a very much smaller coefficient of *sliding* friction. A committee of the American Railway Master Mechanics' Association recommends that for purposes of cylinder design the coefficient of adhesion be assumed as follows: For passenger locomotives, 0.250; for freight locomotives, 0.235; for switching locomotives, 0.220. A later committee, in view of the general use of effective sanders, recommends that the value 0.25 be assumed for all locomotives. In late designs of all classes of locomotives the ratio of tractive effort to weight on drivers varies from 0.18 to 0.25.

Maximum Tractive Force. The maximum tractive force of locomotives is realized only under full boiler pressure, wide-open throttle, and latest cut-off. Latest cut-off can be maintained without exhausting the steam supply, only below a speed which, with ordinary ratios of heating surface to cylinder volume, varies from about 6 to 10 miles per hour. This maximum tractive force may be determined by means of the following formulæ, in which T = maximum tractive force as herein qualified, lb.; P = steam pressure in the boiler, lb. per sq. in., gage; S = stroke of the piston, in.; D = diam. of the driving wheels, in.; d = diam. of the cylinders, in.; d_H = diam. of the high-pressure cylinder, in., and d_L = diam. of the low-pressure cylinder, in.:

Type	Working Simple	Working Compound
Simple, 2-cylinder.....	$T = 0.85\,d^2(PS/D)$....(1)	
Compound, 2-cylinder.	$T = 0.80\,d_H^2(PS/D)$..(2)	$T = (2\,d_H^2/3)(PS/D)$.............(3)
Compound, 4-cylinder.	$T = 1.6\,d_H^2(PS/D)$...(4)	$T = [(2\,d_H^2/3) + (d_L^2/4)](PS/D)$....(5)
Mallet compound, 4-cylinder................		$T = 0.52\,d_L^2(PS/D)$..............(6)

Tractive force determined by the formulæ is the maximum force available at the tender drawbar when the locomotive is moving on level track at uniform speeds up to 6 or 8 miles per hour. A more conservative view assumes the values thus obtained to be the maximum force available at the rim of the drivers; but if the maximum possible mean effective pressure and the maximum possible efficiency between cylinders and tender drawbar are both actually attained, the forces defined by the formulæ may be safely assumed to be available at the tender drawbar. If the locomotive is moving up grade and if its speed is accelerating, the value of T must be reduced by the sum of the forces required to lift and accelerate its mass, in order to find the force available for work upon the train. If the value of T exceeds the adhesion as above defined, it cannot, of course, be made available.

Formula (1) is almost universally used in American practice, although a few authorities use a constant 0.80 instead of 0.85. Formulæ (2) to (6) are in general use for compound locomotives of current design, although occasionally divergence from common practice as regards ratio of cylinder diameters and steam distribution, makes desirable slight variations in the constants of these formulæ. Compound locomotives at very low speeds (in starting trains) are occasionally worked "simple," *i.e.*, high-pressure steam is used in all cylinders. Under such conditions, formulæ (2) and (4) are applicable. In formula (6) the value of the constant generally lies between 0.51 and 0.53, although it occasionally is as great as 0.56. When the ratio $d_L^2/d_H^2 = 2.47$, formulæ (5) and (6) give identical values of T.

As the speed increases above 6 to 10 miles per hour, the steam supply becomes inadequate to maintain maximum cut-off and the cut-off must be continually decreased, resulting in a continuous decrease in tractive force as the speed increases.

COSTS OF OPERATION

The information here presented relates to the steam railways of the United States. It is compiled from the latest available statistics published by the Interstate Commerce Commission.

Summary of Operating Expenses. The annual operating expenses for railways which have operating revenues above $100,000 per year, are summarised in Table 6.

In Table 6, item 1 includes expenses for superintendence, advertising, traffic associations, industrial and immigration bureaus, etc. Item 2 includes expenses for general officers and clerks, office supplies and expense, legal service, insurance, relief department, pensions, etc. Item 3 covers the expenses for all features of the permanent way, such as track material, roadway tools and supplies, bridges, tunnels, station and other buildings, telegraph and telephone, signals, docks, wharves, etc. The content of item 4 is indicated in Table 8, and that of item 5 in Table 7.

Transportation Expenses. The expenses for conducting transportation amount to more than half of the total operating expense. They are composed of the expenditures shown in Table 7, which presents an analysis of item 5 in the first column of Table 6.

Table 6. Annual Operating Expenses for Railways Which Have Operating Revenues Above $100,000 per Year

Items	Year Ending June 30, 1913		Year Ending June 30, 1914	
	Amount	Per cent. of total	Amount	Per cent. of total
1. Traffic Expenses....	$62,826,186	2.89	$63,769,677	2.90
2. General Expenses...	78,028,425	3.60	83,529,665	3.80
3. Maintenance of Way and Structures..	421,030,360	19.41	419,277,779	19.06
4. Maintenance of Equipment..........	511,467,852	23.58	532,138,606	24.20
5. Transportation Expenses............	1,095,909,503	50.52	1,101,597,432	50.04
Total*..............	2,169,282,326	100.00	2,200,313,159	100.00

* Total for *all* railways, year ending June 30, 1913, $2,182,769,000.

Table 7. Transportation Expenses for the Year Ended June 30, 1913, for Railways Which Have Operating Revenues Above $100,000 per Year

Item	Amount	Per cent. of total operating expense
1. Fuel for locomotives..................	$249,507,624	11.503
2. Water for locomotives................	15,416,010	0.710
3. Lubricants and other supplies...........	11,311,205	0.521
4. Enginehouse expense..................	46,195,703	2.129
5. Enginemen..........................	170,216,533	7.846
6. Train supplies and expenses............	39,305,182	1.812
7. Conductors and brakemen..............	202,573,960	9.339
8. Yard employees and expense...........	36,053,328	1.661
9. Station employees and expense..........	159,621,463	7.359
10. Superintendence and dispatching trains.	44,848,036	2.067
11. Flagmen, gatemen, signalmen..........	25,302,813	1.166
12. Loss and damage to property, injury to persons............................	71,139,555	3.278
13. Miscellaneous expense................	24,418,091	1.125
	1,095,909,503	50.516

Maintenance of Equipment. The expenses for maintaining equipment, which constitute a little more than one-fifth of the total operating costs, are composed as indicated in Table 8 which presents the maintenance of equipment costs for four representative roads which differ in the character of their territory and traffic.

Operating costs vary greatly with the character and volume of traffic, with the character of the roadway and equipment, and with the conditions of service. No specific conclusions should therefore be drawn from them, nor comparisons made between them, without definite knowledge of the underlying conditions. Operating costs and statistics are fully presented in "Statistics of Railways in the United States," Interstate Commerce Commission, Washington; and well analyzed in "Railroad Operating Costs," Suffern and Son, New York.

Table 8. Expense for Maintenance of Equipment of Four Representative Roads—Year Ending June 30, 1911

Dimensions of Wheels and Axles. Practically all freight-car wheels are made of cast iron and are 33 in. in diam. They vary in weight as follows:

For cars of 95,000 lb. max. gross weight, from 615 to 625 lb. per wheel.

For cars of 132,000 lb. max. gross weight, from 665 to 675 lb. per wheel.

For cars of 161,000 lb. max. gross weight, from 715 to 725 lb. per wheel.

Passenger-car wheels are generally of cast iron with steel tires, or of solid steel. They vary in diam. from 33 to 36 in.

100,000	5½ × 10	7	5⅞	38,000
....	6 × 11	7⅝	6 7/16	50,000

Costs. The cost of cars varies greatly, depending upon their size and capacity and type of construction. The allowed values of freight-car parts and of entire freight cars are given in detail in the Interchange Rules of the Master Car Builders' Association (*Proc. M. C. B. Assn.*, vol. 48, 1914, pp. 490 to 547). Costs of a few typical freight cars and passenger cars are presented in Table 12.

TRAIN RESISTANCE

Elements of Train Resistance. The term **gross train resistance**, as here used, means the total force exerted by the locomotive on the train, that is, the force exerted at the rear tender drawbar. The various elements which make up gross resistance are: 1. Resistance due to grade. 2. Resistance due to track curvature. 3. Resistance due to acceleration. 4. Resistance due to wind (as distinguished from still-air resistance). 5. Net resistance on straight and level track, at uniform speed, in still air. Item 5 is always in operation to retard a moving train. One or more (or none) of the others may also be acting with item 5 to form gross resistance.

The resistances due to grade, curvature, and acceleration (items 1, 2, 3) need no comment in addition to what is given below. Wind resistance (item 4) is herein considered as the resistance due to wind only, and is distinguished from still-air resistance which is treated as one of the elements of net resistance.

Net resistance (item 5), as here defined, is what is ordinarily meant by the unqualified term "train resistance." It comprises all those resistances which are always encountered when a train moves in still air, at uniform speed, over straight and level track, namely: (*a*) Air resistance, due to friction and impact of the air. (*b*) Rolling resistances, including all resistances which develop at the wheel rim, *viz.*, those due to the rolling of the wheel on the rail and those due to the yielding of the track under the wheel load. (*c*) Journal friction. (*d*) Flange friction, due to the rubbing of the wheel flanges on the rail head. (*e*) Resistances due to the energy-absorbing oscillations and impacts of the car bodies and trucks.

Of these elements of net resistance, air resistance is probably the greatest at very high speeds. At very low speed the journal friction probably exceeds the sum of all the others. Various attempts have been made to differentiate these components of net resistance; but there is great diversity in the results. Net resistance, therefore, is here treated as a unit, and no attempt is made to distinguish its various elements.

Determination of Train Resistance

The data needed for the determination of train resistance are ordinarily best obtained by the use of a **dynamometer car**, in which there is produced a curve of drawbar pull, a curve of speed, a record of the location of the train on the road, and a record of time. These records, supplemented by an accurate track profile and train data, will provide the information required for the application of the following formulæ.

Momentary values of resistance may be determined at the instant the train passes a point on the road (method 1). Average values of resistance may be determined for the period during which the head of the train passes over a definite section of track (method 2). The significance of the notation as applied in method 1 is illustrated in Fig. 7; and its significance in method 2 is illustrated in Fig. 8. The notation used in the formulæ is as follows:

P = Total gross resistance = drawbar pull, lb.
R = Net resistance on tangent, level track, at uniform speed, in still air, lb. per ton.
R_g = Resistance due to grade, lb. per ton.
R_c = Resistance due to curvature, lb. per ton.
R_a = Resistance due to acceleration, lb. per ton.
R_w = Resistance due to wind, lb. per ton.
W = Total train weight, tons.
w = Average gross weight of cars, tons.
V, V_1, etc. = Train speed, miles per hour.
G = Grade, ft. per mile.
A = Acceleration of the train speed, miles per hour per second.

E_1 and E_2 = Elevations of the center of mass of the train, ft.
S = Length of track section used in method 2, ft.
N = Number of cars in the train.

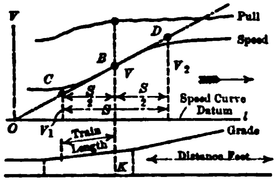

FIG. 7.

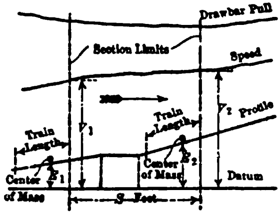

FIG. 8.

Wind Resistance. Resistance due to wind (R_w, item 4) varies greatly with the wind velocity and with the angle at which the wind strikes the train. Its value is generally indeterminate. It is frequently great enough to necessitate reductions in train tonnage and, in rare instances, great enough to stall trains. It may be eliminated from resistance calculations by running tests in quiet weather. When not so eliminated it will appear as part of net resistance, from which it cannot be separated.

Curve Resistance. The resistance due to track curvature (R_c, item 2) varies with the curvature, and by some authorities is considered to vary also with speed. Ordinarily, the influence of speed is ignored and the value of curve resistance is assumed at from 0.5 to 0.8 lb. per ton per degree of curve. In experimental determinations of resistance, curve resistance is ordinarily eliminated by making experiments on straight track only.

Grade Resistance. The resistance due to grade (R_g, item 1) varies only with the grade and may be exactly determined by the following formulæ. Momentary resistance at a point =

$$R_g = 0.379\,G \tag{1}$$

Average resistance over a section =

$$R_g = 2000(E_2 - E_1)/S \tag{2}$$

Acceleration Resistance. The resistance due to acceleration (R_a, item 3) is made up of two parts. The first is the force needed to produce the acceleration in the motion of translation of the train as a whole; the second is the force needed to produce the acceleration in the rotation of the wheels and axles. The sum of these two forces is the total acceleration resistance R_a. Its value, both for momentary resistance at a point and for average resistance over a section, is given by the formula

$$R_a = \left[91.05 + 145.5\left(\frac{N}{W}\right)\right] \times A \tag{3}$$

In this equation the second constant (145.5) applies to cars with 4 axles and is approximately correct for all standard weights of wheels and axles. The maximum error in R_a, resulting from changes in this constant due to differences in the weight of wheels and axles, is about 1 per cent. For cars with 6 axles this constant is 218.3. When the acceleration resistance due to translation only is desired, the second term within the brackets, or 145.5 (N/W), should be dropped.

The value of A in (3) may be determined by means of the formula

$$A = 0.733(V_2^2 - V_1^2)/S \tag{4}$$

in which, for the determination of resistance at a point, V_1 and V_2 are found by drawing at B (the point at which resistance is to be determined—see Fig. 7) a tangent to the speed curve, prolonging it to C and D equidistant from B, and dropping from C and D ordinates which are proportional to V_1 and V_2, respectively. For the determination of average resistance over a section, V_1 and V_2 are the speeds at entrance to and exit from the section respectively (see Fig. 8).

Net Resistance. If, as above assumed, the resistances due to wind and curvature are eliminated, the value of net resistance (R, item 5) may be found by the use of the following formulæ.

Momentary resistance at a point =

$$R = \frac{P}{W} - 0.379\,G - \left[91.05 + 145.5\left(\frac{N}{W}\right)\right] \times A \qquad (5)$$

Average resistance over a section =

$$R = \frac{P}{W} - \frac{2000\,(E_2 - E_1)}{S} - \left[91.05 + 145.5\left(\frac{N}{W}\right)\right] \times A \qquad (6)$$

If the train is on a down grade, the sign of the second term in equation (5) must be changed to plus.

In applying formulæ 1 to 6, the following **precautions** must be taken in selecting the point or section at which resistance is to be determined:

METHOD 1:

The entire train must be on tangent track and on a uniform grade.

The speed curve must be nearly straight for a short distance both sides of the point chosen, in order to permit the tangent to be accurately drawn.

The point should preferably be chosen where the acceleration is low, so that acceleration resistance is not a large share of the gross resistance.

METHOD 2:

The track must be straight over the section, and also before the entrance to the section for a distance equal to the train length.

To facilitate the determination of E, the entire train should be on a uniform grade at the moment its head end enters the section, and again when it leaves the section. These grades need not, however, be alike.

There should not be much variation in speed over the section.

Values of Net Resistance

The resistance in still air, at uniform speed, on straight and level track (R) increases with the speed and decreases as the weight of the cars increases. This decrease with increase of car weight is due chiefly to the increase in journal load. Net resistance increases also as the air temperature decreases. For ordinary weather conditions net resistance cannot, therefore, be predicted, unless both the speed and the average car weight be known.

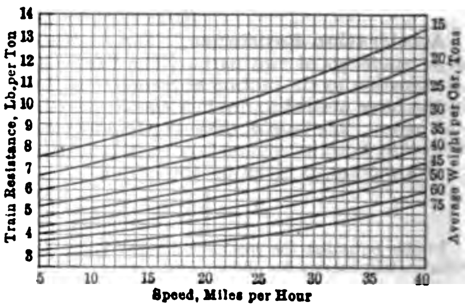

FIG. 9.—Freight-train Resistance.

Freight-train Resistance. Fig. 9 gives the values of net resistance for freight trains running on well-constructed track in weather when the air temperature is above 30 deg. fahr. The use of the figure requires a knowledge of speed and of the average gross-weight of the cars of which the train is composed. Values of R are more conveniently and accurately given in Fig. 9, but they may be approximately derived from the empirical formula

$$R = (V + 39.6 - 0.031w)/(4.08 + 0.152w) \qquad (7)$$

Passenger-train Resistance. The net resistance of passenger trains increases with speed. It presumably varies also with the load per axle, as in freight trains; but experimental evidence on this point is deficient. Since, however, the load per axle of passenger cars does not vary through a wide range, there is justification for ignoring the influence of axle load, as is usually done in considering passenger-train resistance.

The formula proposed by Mr. F. J. Cole, of the American Locomotive Company, gives values for net passenger-train resistance which are reliable for the heaviest cars, the best track, and good weather conditions. This formula is

$$R = 5.4 + 0.002(V - 15)^2 + 100/(V + 2)^3 \qquad (8)$$

Formula (8) gives the following values of resistance R for various values of V:

For V (mi. per hr.) =	5	10	15	20	25	30	35	40	45	50	60	70	80	90
R (lb. per ton) =	5.9	5.5	5.4	5.5	5.6	5.9	6.2	6.7	7.2	7.9	9.5	11.5	13.9	16.7

For ordinary cars and track and to make allowance for adverse weather, it is preferable to use formula (9), which is based on the Berlin-Zossen tests, and which gives results considerably greater than those derived by means of formula (8).

$$R = 4 + 0.1V + 0.278(V^2/W) \qquad (9)$$

References. Reviews of train-resistance experiments and formulæ are presented in Bulletin 84 of the American Railway Engineering and Maintenance of Way Association, Feb., 1907, and in a series of articles by F. J. Cole, in the *Railroad Age-Gazette*, vol. 47, Nos. 9 to 14, Aug. 27 to Oct. 1, 1909. Data on freight-train resistance are given in Bulletins 43 and 59 of the Engineering Experiment Station of the University of Illinois.

TRACK

Mileage. For the year ended June 30, 1914, the total number of miles of single track in operation in the United States was 252,000. Including second, third, and fourth track, and the track in yards and sidings, the total mileage in operation was 387,000.

Gage. The gage of railway track is the distance between the inner sides of the rail heads. The gage to which practically all American railways are laid is 4 ft. 8½ in., which is known as **standard gage.** Rail wear causes an increase in this distance. Owing to the wear of rails and to the practice of widening the gage of curved track at the rate of about ¼ in. for each 5 deg. of curvature, it is not uncommon to find the gage on sharp curves as great as 4 ft. 9½ in.

The distance from center to center of rails is variable, depending upon the width of the rail head. This width varies from 2⅜ in. in rail weighing 60 lb. per yd. to 2¾ in. in rail weighing 100 lb., so that the distance from center to center of rails varies usually from 4 ft. 10⅞ in. to 4 ft. 11¼ in.

In America, the gage of **narrow-gage** track varies usually from 2 ft. 6 in. to 3 ft. 6 in., although 3 ft. 0 in. is most common. One meter is the prevailing narrow gage on European railways.

Track Spacing. The distance between centers of main-line tracks is usually 13 ft., although it is occasionally only 12 ft. In yards it has been customary to space tracks 12 ft., or even as little as 11 ft. 6 in. apart; but 13 ft. is coming to be the standard distance. This is none too great, since the largest cars are occasionally as wide as 10 ft. 4 in.

Clearances. Obstructions adjacent to track should be kept far enough away to clear a man riding on the side of a car. This, with large cars, requires that the minimum distance from the center of track to the nearest point of the obstruction should be 8 ft.

Any overhead obstruction should be high enough to clear a man standing on the highest car. This implies a minimum height of at least 21 ft. On main lines 22 ft. is commonly specified wherever practicable. In some states 21 ft. or 22 ft. is a minimum clearance height fixed by law. Where it is certain that trainmen will be kept off the cars and where conditions require the minimum clearance, as in tunnels, these clearances are much reduced. For tracks entering buildings, a door opening 12 ft. wide and 16 ft. high will ordinarily suffice to pass the largest locomotive or car.

Curvature. The curvature of track is designated in terms of "degree of curve." **Degree of curve** is the number of degrees of central angle subtended by a chord of 100 ft. length (measured on the track center line). Table 13 gives the radii for ordinary steam railway curves.

Table 13. Radii of Steam Railway Curves

Degree of curve	Radius to track center line, ft.	Degree of curve	Radius to track center line, ft.	Degree of curve	Radius to track center line, ft.
1	5730	9	637.3	17	338.3
2	2865	10	573.7	18	319.6
3	1910	11	521.7	19	302.9
4	1433	12	478.3	20	287.9
5	1146	13	441.7	21	274.4
6	955.4	14	410.3	22	262.0
7	819.0	15	383.1		
8	716.8	16	359.3		

On important main lines where trains are operated at high speed the curves are ordinarily not sharper than 6 or 8 deg. In mountainous territory in very rare instances main-line curves as sharp as 22 deg. occur. Even in restricted yard spaces the curvature is very seldom as great as 22 deg. A 22-deg. curve, if operated over with great care and at very low speed, will pass even the largest locomotive. A car alone will pass considerably sharper curves.

Rails. Until within a few years ago the **standard length** of rails was 30 ft.; but it is now 33 ft. The weight of rail varies between different railways and between the different parts of the same railway. Table 14 shows the proportions of the various weights of rail used in main tracks of the railways of the United States in January, 1912.

Table 14. Rail Used in Main Tracks of U. S. Railways

Weight of rail per yard, lb.	Percentage of total in use
100 lb. and upward	5.845
90 lb. and less than 100 lb.	8.324
80 lb. and less than 90 lb.	32.941
75 lb. and less than 80 lb.	12.809
70 lb. and less than 75 lb.	8.564
60 lb. and less than 70 lb.	18.158
Less than 60 lb., mixed, and unknown	13.359

Material Required per Mile of Single Track. Details of rails, splice-bars, bolts and spikes are given in Tables 15 and 16.

Table 15. Rails and Accessories, Weights and Dimensions

Rail section (Numbers indicate lb. per yd.)	Length of splice bar, in.	Size of bolt, in.	Size of spike, in.	For one joint: Weight of one pair of splice bars, lb. 8A	16½	⅜ × 1½	2½ × 5/16	2.00		0.45	364	1456	10,640	0.33	0.07	0.43	0.83	12.57

Above table is based on 90 per cent. of rails to be 33 ft. long, and 10 per cent. not less than 24 ft. long, varying by even feet. Ties 2 ft. to centers, or 2640 ties per mile, Rails below 50 lb. per yd. are furnished 30 ft. long, and 10 per cent. not less than 20 ft. long. No excess has been allowed.

The amount of **ballast** required depends upon the depth to be used under the ties, the spacing and dimensions of the ties, the width of ballast on top, and the angle of side slope. It must be separately computed for each set of conditions. Ordinarily, it will vary from ½ to ¾ cu. yd. per lineal foot of track.

Costs. Ordinarily, a single-track railway built through favorable country will cost—including equipment and all other charges—not less than $25,000 to $30,000 per mile. Where land is very valuable, as on the outskirts of large cities, and where frequent overhead highway or stream crossings are necessary the cost may be as high as $150,000 per mile, and in rare cases even higher.

PRINCIPAL DIMENSIONS OF SHIPS

Definitions. The **dimensions of a ship** may refer to the molded body or form defined by the outside of the frames; to general outside or overall dimensions; and to dimensions on which the determination of tonnage or of classification is based. There are thus (1) molded dimensions, (2) overall dimensions, (3) tonnage dimensions and (4) classification dimensions.

The **molded length** is the distance between two vertical lines. The forward vertical is located at the forward edge of the stem. With sailing and twin-screw ships the after vertical is located at the after face of the stern or body post. With single- or triple-screw ships there is some difference in practice by different authorities and in different countries. In some cases the after vertical is located at the after face of the body post, and in others at the after face of the rudder post. This difference depends primarily on whether the after boundary of the geometrical form of the ship is the rudder or stern post. The **length between perpendiculars** is again the distance between two verticals. Often, though not necessarily, it coincides with the molded length. The forward perpendicular is usually located at the forward edge of the stem. In the United States the after perpendicular is usually taken at the after edge of the body post on the load water line. In Great Britain it has the same location except for single- and triple-screw ships, where it is usually taken at the after edge of the rudder post at the load water line. The **length on the load water line** is the length between two verticals touching the bow and the stern at the load water line. The **length overall** is the extreme length between two verticals touching the ship at the forward tip of the stem and the overhang at the stern. In the case of a war ship with ram bow and war-ship stern, it may be defined as the extreme length between two verticals touching the ship at bow and stern. The **tonnage length** is especially defined in various countries according to the rules for computing tonnage. The **classification length** is likewise specially defined by the various societies (Lloyd's, Bureau Veritas, Am. Bureau of Shipping, etc.) for purposes of classification and rating.

The **molded beam** is the extreme breadth of the molded form. With steel ships this is the only value ordinarily considered. The extreme or overall breadth is occasionally used, referring to the extreme transverse dimension on the outside of the plating.

The **depth** is the vertical distance from the inner surface of the plating at the keel to the inner surface of the upper continuous deck. There is, however, some difference of meaning of the term depth in ships of different types of construction.

The **draft** is the vertical distance from the bottom of the keel to the water line.

The **displacement** is the weight (in tons of 2240 lb.) of the water displaced by the immersed part of the ship, and is equal to the weight of the ship and everything on board. The density of sea water averages about 64 lb. per cu. ft. (1 ton = 35 cu. ft.), hence the displacement in sea water is measured by the immersed volume divided by 35. In fresh water the corresponding divisor is usually taken as 36.

The **tonnage** is an arbitrary measure of capacity used in estimating navigation charges of various kinds, and is intended to be proportional to the earning capacity of the vessel. In general, tonnage is based on the **cubic capacity** of the ship below the main or upper continuous deck, with an allowance for such part of this volume as is occupied by machinery, fuel, crew quarters, light and air shafts and certain like uses. According to U. S. law, the tonnage is equal to the residual volume in cu. ft. divided by 100. (For directions in detail, see U. S. Revised Statutes, Sec. 4153, with subsequent amendments.)

Coefficients of Form. Assume the following notation: L = length on water line, ft., B = beam, ft., H = draft, ft., D = displacement in tons of sea water, V = displaced volume in sea water, cu. ft. (= $35D$), A = area of water plane at surface of water, sq. ft., M = area of midship section below water plane, sq. ft.

Then b = block coefficient of fineness = $35D/LBH$
w = water plane coefficient = A/BL
m = midship section coefficient = M/BH
p = mean length or prismatic coefficient = $35D/ML$
q = mean depth coefficient = $35D/AH$

and the following relations may be noted:

$$p = b/m;\ q = b/w;\ p/q = w/m;\ b = \sqrt{pqmw}$$

The typical and usual **values of** these **coefficients** range as follows:

	b	w	m	p	q
Freight Steamers	.65–.80	.75–.85	.85–.95	.75–.85	.80–.95
Passenger Liners	.55–.65	.65–.75	.80–.90	.60–.70	.80–.90
Battle Ships	.60–.65	.70–.75	.85–.92	.65–.70	.80–.90
Fast Cruisers	.50–.55	.60–.65	.80–.90	.55–.60	.75–.85
Torpedo Craft, Fast Yachts, etc.	.35–.45	.55–.60	.75–.85	.50–.60	.65–.80

STABILITY

The Problem of Stability. (See p. 253 for Buoyancy and Flotation.) A ship or other floating body is in vertical equilibrium under the action of two systems of forces: (*a*) gravity, acting down, and (*b*) buoyancy, acting up. The center or point of application of the gravity system considered as a whole is at the center of gravity of the ship and its contents. The corresponding center for the buoyancy system is at the center of volume of the immersed body of the ship, called the center of buoyancy. These two centers lie in the same vertical line, when the body is in vertical equilibrium.

If a couple with a longitudinal axis be brought to bear on a ship in such equilibrium, a rotation about such axis will result. Notwithstanding this rotation, the center of the gravity system will remain fixed at the center of gravity of the ship. On the other hand, the buoyancy system will change its center due to the changing form of the immersed body. Furthermore, these two points will no longer lie in the same vertical, and the two systems will constitute a couple with equal and opposite vertical forces and with a moment arm measured by the distance between their present lines of action. This **gravity-buoyancy moment** developed as a result of such an inclination of the ship is a measure of the so-called "**stability**" of the ship.

For small inclinations, as, for example, up to 5 or 10 deg., the lines of action of the buoyancy system will all pass very near a single point M in the ship known as the **metacenter.** If this be taken as a fixed point for small inclinations, the expression for stability becomes very simple. For positive stability the metacenter must lie above the center of gravity, G. Let $\overline{GM}$ denote the distance between these points. Then it is readily seen that $\overline{GM}$ sin c will be the moment arm for a small inclination of c degrees, and $\overline{GM} \sin c \times D$ will be the **stability moment,** D being the displacement or weight of the ship. For inclinations of greater amount and for which the line of action of the buoyancy system no longer passes through the metacenter, the problem becomes that of finding the center of figure of the immersed body in the inclined position and the resulting value of the arm drawn from the center of gravity to a vertical passing through this buoyancy center. To carry out this program requires the location of the water plane for the inclined position and the center of volume of the under-water body thus determined. The entire process involves only the elementary principles of geometry and mechanics applied to the immersed body of the ship.

Dynamical Stability. Starting with a ship in equilibrium in the upright position, suppose it to be heeled over continuously to any ultimate angle c. The moment opposed by the statical stability must be overcome, and work will therefore be performed. The amount of such work is a measure of the so-called **dynamic stability** of the ship for any angle of inclination c. Let M_s denote the moment of static stability, and R the dynamic stability. Then $R = \int_0^c M_s dc$. The determination of dynamic stability therefore requires the previous determination of a series of values of the static stability, which may then be integrated either by numerical means or plotted in the form of a curve and integrated by a planimeter or integraph.

The dynamical stability may also be directly computed for any given inclination as the work represented by the expression $D(\overline{G_0B_0} - \overline{G_1B_1})$, where D = displacement and $(\overline{G_0B_0} - \overline{G_1B_1})$ is the difference in the vertical distances between the centers of gravity and buoyancy in the upright and in the inclined positions.

Trim. The problem of trim or change of trim is simply that of rotation about a transverse axis, and hence of longitudinal stability. For all ordinary changes of trim the vertical through the center of buoyancy passes through a point practically fixed relative to the ship—the longitudinal metacenter. Let $\overline{GM_1}$ denote the distance of this point above the center of gravity. Then moment of longitudinal stability $= \overline{GM_1} \sin c \times D$. Also, if L = length of ship in ft. and h = change of trim in in., then for small angles, approximately, $\sin c = \tan c = h/12L$. Hence, moment $= \overline{GM_1}hD/12L$ (ft.-tons). In general, the moving of a weight of W tons a distance l ft. in a fore-and-aft direction will produce a disturbing moment which must be balanced by the development of an equal trim moment. Hence, $Wl = \overline{GM_1}hD/12L$. This equation serves to connect together the moving of weights and the resulting change of trim.

SHIP RESISTANCE AND POWERING

Ship Resistance. The resistance to the movement of a ship through the water may be classified under the four following heads: (1) **Stream-line resistance,** due to the energy required for the maintenance of a system of stream lines in a liquid not perfectly free from viscosity; (2) **eddy or head resistance,** due to the energy required for the maintenance of systems of large eddies of water in vortex motion (such eddies are of special importance in ships of full form, in all bodies of an irregular form and in particular in approximately plane surfaces moving at an angle with their own plane); (3) **skin resistance,** due to the energy required for the maintenance of a belt or blanket of eddying water close about the surface of the ship resulting from the action of minute irregularities of form and of adhesive forces between the water and the ship's surface; and (4) **wave resistance,** due to the energy required for the maintenance of systems of waves which surround and accompany the ship. These waves are a surface manifestation of differences of liquid pressure in the water immediately surrounding the ship. In all cases (1) is relatively small. In ships of normal form (2) is relatively small and most of the resistance arises from (3) and (4). The sum of (1), (2) and (4) is often called **residual resistance.**

The proportion between skin and residual resistance decreases with increase in speed relative to the length. This is due to the rapidly increasing importance of the wave-making resistance (4) at relatively high speeds. Let v = speed in knots and L = length in ft. Then the ratio v^2/L is called the **speed-length ratio.** With ships of fine form and moving at speeds such that the speed-length ratio is less than 1, the residual resistance is likely to comprise only some 10 to 20 or 25 per cent. of the total resistance, and the skin resistance will comprise the remainder. With increase in the speed-length ratio the relative proportion of residual resistance (composed mostly of the wave-making component) will rapidly increase to 40 or 50 per cent., and at high values of the ratio to 60 or 70 per cent. of the total.

Skin resistance is expressed by the formula $R_s = fAv^{1.83}$, where R_s = skin resistance, in lb., f = coefficient of skin resistance, A = wetted surface, in sq. ft. and v = speed in knots. With these units the values of f for clean, painted steel plates vary approximately and gradually from 0.0085 to 0.0100 for lengths from 600 ft. to 20 ft., respectively. With rough bottoms due to barnacles and marine growths the coefficient may increase, varying with the degree of roughness, to values 50 to 100 per cent. greater, and in extreme cases even to three or four times the values for smooth plates.

To find **wetted surface** A: For approximate purposes Taylor proposes the formula $A = 15.6\sqrt{DL}$, where D = displacement in tons and L = length in ft. A method requiring more labor but giving more accurate results consists of the rectification of the wetted girth lines and their integration throughout the length of the ship. This gives an area known as the **reduced wetted surface,** A_r. This value is then used in the formula $A = A_r[1 + (p - 0.2)(B/L)^2]$. Residual resistance [composed largely of (4)] varies with the form and dimensions of the ship as well as with the speed. Resistance as a whole will vary with the size and form of the ship, with the character of wetted surface and, for moderate speeds, closely as the square of the speed, while as the speed increases the index of resistance variation with speed fluctuates between 2 or less to 3.5 or more. These fluctuating terms arise from varying relations between the ship and combinations of the various trains of waves resulting from the movement of the ship through the water. For relatively moderate speeds, which may be defined as speeds for which the speed-length ratio (see above) is not greater than 1, Taylor suggests the formula $R = fAv^{1.83} + 12.5\,bDv^4/L^2$, where R = total resistance, lb. The first term gives the skin resistance as above, and the second the residual resistance.

In shallow water or in restricted channels, as in the case of canals, the **resistance is greatly increased.** With a depth equal to or greater than half the length of the wave corresponding to the speed of the ship the influence of the bottom should, on the simple theory of wave formation, be negligible. This is equivalent to a depth in ft. of $v^2/3.6$, where v = speed in knots. Experience indicates that for small high-speed ships such as torpedo boats, destroyers, fast launches, etc., this depth is somewhat excessive. For large ships it is presumably none too much. At the **critical depth,** $v^2/11.3$, the resistance undergoes a very marked increase. The desirable depth should apparently be not less than about $v^2/5$ and preferably nearer $v^2/4$, or $v^2/3$, especially for large, full-formed ships. From a consideration of stream-line phenomena, Taylor has suggested a depth of 6 to 10 times the draft, or, for boats with a high speed-length ratio, a depth not much less than the length.

For restricted channels, as in canal navigation, at moderate speeds, if the transverse dimensions of the canal section are as much as 6 to 10 times those of the ship, the added resistance will be negligibly small, while with a ratio of 2.5 or 3 the increase in resistance is excessive and with further restriction compels a speed so low as to be prohibitive from the standpoint of operation.

Power Required for Propulsion. The relation between the size of ship, speed and power required is conveniently represented by the Admiralty formula $H = D^{2/3}v^3/K$, where H = the indicated horse power required; D = displacement of ship in tons of 2240 lb.; v = speed of ship in knots of 6080 ft. per hour; and K = factor or coefficient intended to include the influence of all factors in the problem other than those above noted.

The more important of the factors included in K are those representing the influence due to the characteristics of form and that due to the overall dimensions (and in particular the length) relative to the speed. The factor K must also include recognition of any special variation from the normal in the efficiency of the propeller or in the mechanical efficiency of the engines. Assuming normal values for the latter, the speed-length ratio (see Resistance) serves in some degree, in combination with the characteristics of form, as a guide in the selection of a suitable value of K. The following brief indications may be given.

Values of K in Admiralty Formula. For ships of large size and with fine to medium characteristics of form (in particular prismatic coefficient) at speeds such that $v^2/L \leq$ 0.8 to 0.9, values of K = 250 to 350 are found.

For similar ships at higher speeds when $v^2/L \geq 1$, the values of K range from 220 to 250 or 275.

With medium to full forms at speeds where $v^2/L < 1$, values of 220 to 250 are common.

With medium to small ships, other things being equal, the values range somewhat smaller than for large ships.

With medium to small ships of average form characteristics and at speeds where v^2/L may considerably exceed 1, values of 150 to 200 for K are common.

With small boats of moderately full forms and urged to speeds where v^2/L may rise to values of 5 to 10 or more, the value of K may fall to 100 to 150, or in extreme cases to less than 100.

For small craft of fine lines driven at excessively high speed and of such under-water form as to rise partly out of the water, the resistance is decreased with corresponding reduction in power and increase in the value of K. In such cases values of 200 to 250 and more are met with.

No exact rules can be given for selecting the value of K in any particular case. Judgment must enter largely in the use of such a formula. In case the speed v is measured in miles per hour instead of knots, the values of K will be increased in the ratio of 1.526 to 1, or approximately by 50 per cent.

By the application of **Froude's law of comparison** extended to cover approximately all components of ship resistance, much more reliable results may be determined. This law may be stated in many ways. For the present purpose it may be put as follows: For ships of similar geometrical form and proportion, *corresponding speeds* are in the ratio of the square roots of the lengths. For such ships *at corresponding speeds*, the values of K in the Admiralty formula are the same.

Still otherwise the law may be put in the form: For similar ships *at corresponding speeds* the powers will be in the ratio of the products of the displacements by the speeds, or the power ratio will equal the product of the displacement ratio by the speed ratio.

Thus, given a type ship having a length of 400 ft., a displacement of 7500 tons, a speed of 16 knots, and requiring 6300 i.h.p., by substitution in the formula the value of K

is readily found to be 250. Then, assuming a similar ship 480 ft. in length, length ratio = 480/400 = 1.2; corresponding speed ratio $= \sqrt{1.2} = 1.095$; corresponding speed = 16 × 1.095 = 17.53; displacement ratio = $(1.2)^3 = 1.728$; displacement = 7500 × 1.728 = 12,960. Then, using the same value of $K(= 250)$ and substituting in the Admiralty formula, H for the larger ship at the higher speed = 11,900 i.h.p. Or, again, by the second form in which the law is stated, $H = 6300 \times 1.728 \times 1.095 =$ 11,900 as before.

Where a sufficient number of test results are available, the method by comparison gives a means of determining closely the power which any given ship will require at any proposed speed. For satisfactory application, however, the ships employed in such a comparison must not differ widely in form or proportion. The precise application of the rule assumes exact geometrical similarity. Closely approximate results, however, may be found in case the departure from exact geometrical similarity is not extreme.

SCREW PROPELLERS

The **performance** of a screw propeller may be conveniently related to the following characteristics and conditions of operation:

Diam. (in ft.) = d.
Pitch (in ft.) = p.
Projected blade area (in sq. ft.) = A.
Revolutions per minute = N.
Speed in knots = v.
Speed of advance of propeller relative to water at stern in which it is working, knots = u.
Shaft horse power = S.

Pitch is often replaced by its **ratio** to the diameter, thus: $p = dl$, or $l = p/d$.

The relation between projected **blade area** and actual or helicoidal area is given by the following approximate empirical equation due to Taylor:

$$\text{Actual Area} = \text{Projected Area}/[1.067 - 0.229(p/d)].$$

This formula is intended for blades of elliptical form, but will hold less accurately for any blade with a generally oval contour.

Speed is often represented by its relation to N and p through the **slip ratios**. Thus,

$$\text{True slip ratio } s = (pN - 101.3u)/pN \quad (1)$$
$$\text{Apparent slip ratio } s' = (pN - 101.3v)/pN \quad (2)$$
$$\text{whence } u = pN(1 - s)/101.3 \text{ (knots)} \quad (3)$$
$$v = pN(1 - s')/101.3 \text{ (knots)}. \quad (4)$$

The **true slip** s is measured relative to the body of water at the stern in which the propeller is working, and which has had impressed upon it by the movement of the ship a certain forward motion relative to the surrounding and outlying body of still water. The **apparent slip** s' is measured relative to the surrounding or outlying body of still water through which the ship is moving. Since the propeller should be judged and determined relative to the water in which it is actually working, the true slip should be used in all formulæ directly relating to its design.

The relation between true and apparent slip is indicated by means of a so-called "**wake factor**" w, through the equation

$$1 - w = (1 - s)/(1 - s') \quad (5)$$

Values of w vary from small or almost vanishing amounts for high-speed yachts, torpedo boats and similar craft, up to 0.10 for vessels of average size and moderate speed, and to values of 0.15 and more for vessels of very full form or large dimensions. In the lack of special information, the value 0.10 is often taken as an approximate mean value.

The speeds u and v have the following relation:

$$u = v(1 - w) \quad (6)$$

The mechanical efficiency of marine engines is usually taken, in the absence of more direct information, at 88 or 90 per cent. Hence, approximately, $S = 0.9 \times$ i.h.p.

For purposes of **propeller design** or the analysis of propeller performance, Taylor's coefficients, which are defined by equations (7) and (8), may be employed:

$$R = N^{1/2}S^{1/4}/u^{5/4} \tag{7}$$

$$D = dN^{3/4}/(Su)^{1/4} \tag{8}$$

Numerical values of R and D for **three-bladed propellers** based on Taylor's researches at the Government Experimental Tank at Washington and adapted for use by Peabody will be found in Tables 1–3. These tables likewise include values of the efficiency e which may be anticipated in any given case. These three quantities, R, D and e, are given for various values of the pitch ratio, true slip, area ratio and thickness ratio. The **area ratio** is defined as the area of the blades projected on a plane perpendicular to the shaft, divided by the disk area of the propeller or by the area of the circle described by the tips of the blades. The **thickness ratio** is defined as the ratio of OE in Fig. 1 to the diameter.

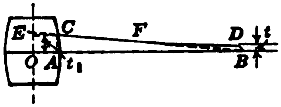

Fig. 1.

It should be noted that the values of R, D and e presuppose *projected* blade contours elliptical in form with smooth, true pitch surfaces and clean, sharp edges. No serious error will be involved in their application to a generally oval form of projected area so long as the departure from the ellipse is moderate. Any marked departure from these general characteristics or in the thickness ratio as noted, will seriously affect the value of these quantities.

Four-bladed Propellers. The characteristics and proportions of propellers with four blades may be derived from those with three blades by means of the following relations:

Assuming the blades to be of the same shape and proportions, and the pitch ratio, speed and true slip to be alike in both cases, then for the diameter and

pitch of the four-bladed propeller, divide those dimensions of the three-bladed propeller by 1.145; and for the **revolutions** per minute of the four-bladed propeller, multiply the value of N for the three-bladed propeller by 1.145. The **efficiencies** may be expected to range from 90 to 95 per cent. of the values for three-bladed propellers, or, under usual conditions, from 0.04 to 0.07 less on the actual values. These reductions in efficiency range from the smallest values (0.04) for low area ratio and low pitch ratio to the higher values (0.07) for the highest area ratios and highest pitch ratios.

Example showing method of using Tables 1–3. Let i.h.p. = 3600 and speed v = 18 knots. Assume the power absorbed in friction to be 12 per cent. = 432 h. p. Then S = 3168 h.p. Assume wake factor = 0.10. Then $u = 0.90 \times 18 = 16.2$. Assume also that N is fixed at 120. Then, by substitution in (7), the value of R = 2.53. Referring next to Table 1 for three-bladed propellers with area ratio 0.27, it is possible to find by interpolation the following combinations of pitch ratio and slip with the corresponding values of the efficiency, all for a value of R = 2.53:

Pitch ratio	True slip	Efficiency	Pitch ratio	True slip	Efficiency
1.08	0.12	0.689	1.68	0.32	0.678
1.16	0.16	0.705	1.20	0.18	0.708
1.25	0.20	0.710	1.40	0.25	0.707
1.37	0.24	0.710	1.60	0.305	0.689
1.51	0.28	0.698			

An indefinite number of combinations may be selected. The above are simply those for the tabular values of the slip, 0.12, 0.16, etc., and for the pitch ratios 1.2, 1.4, etc.

So far as practicable, the values finally chosen should be such as to indicate the highest values of the efficiency. In the present case the true slip may be taken equal to 0.20 and the pitch ratio to 1.25. This gives for D the value 54.5. Then, substituting in (8) and solving for diam., d = 13.65, and $p = 13.65 \times 1.25 = 17.06$. The apparent slip results from equation (5), substitution in which gives s' = 0.11.

For a **four-bladed propeller** working at the same slip and having the same pitch ratio and with blades of the same proportions and hence with area ratio 0.36, from the values just calculated:

Diameter = 13.65/1.145 = 11.92 ft.; pitch = 17.06/1.145 = 14.9 ft.; rev. per min. = 120×1.145 = 137.4. The speed and slip are the same for both propellers.

In the **selection of propeller characteristics** the following points may be noted. The action of the propeller in producing an augmentation of the resistance of the ship as a result of the defect of pressure produced at and about the stern increases with the diameter and with the amount of rotation impressed on the water and hence is more pronounced with high than with low pitch ratios. This argues for the use of relatively low pitch ratios and high revolutions for ships of full form for which such augmentation represents a more serious item, while for ships of fine form, high pitch ratios with the resulting larger diameters may be employed. The use of low pitch ratios, high revolutions and resulting small diameters must not, however, be carried too far with full forms, as in such case the propeller will work almost wholly in the dead or eddy water close to the stern of such forms, with resulting irregularity and loss of efficiency.

The number of blades is usually three or four, depending partly on the desired total area, partly on questions of vibration. In the absence of special considerations, three blades is standard practice.

The immersion of the tips of the blades when nearest the surface of the water should be not less than 0.2 to 0.3 the diameter. If this distance is less there may be indraft of air, with resulting irregularity of working and probable loss of efficiency.

At excessive speeds of the propeller blade through the water, as may result with high-powered turbine-driven craft, **cavitation** may occur. This is due to the movement of the blade, especially at the tip, at a speed faster than the water under its hydraulic head can close in around it. Cavities are formed in the wake of or about the moving blade, resulting in unsteadiness of motion and in great loss of thrust in proportion to revolutions. It has been found empirically that this condition can be controlled by a suitable value of the thrust per unit of projected blade area. With an immersion of the blade tip of about 12 in., a safe value of the average thrust per sq. in. of projected blade area was found by Barnaby and Parsons to be about 11 lb., while, according to the former, every additional foot of immersion will permit an increase in this value of about ¾ lb. For approximate purposes the actual thrust T in lb. may be estimated by the formula $T = 220H/v$, where H = i.h.p. and v = speed in knots. Above a limiting value of the peripheral speed of about 12,000 ft. per min., cavitation is very likely to develop. Peripheral speeds should therefore be kept below this value and the intensity of thrust should not exceed 11 or 12 lb. per sq. in. of projected blade area.

Thickness of Propeller Blades. The thickness of blades at the tip is determined by the possibility of making smooth, reliable castings. Such thickness, t, Fig. 1, is usually from ½ to ¾ in. The thickness AC at the root is to be determined by the formula given below and a straight line BC drawn. This line is then joined by a smooth curve FD to the thickness value at the tip, thus giving a continuous line CFD representing relative to AB the maximum or mid-blade thickness from root to tip. For the thickness AC, employ the formula

$$t_1 = A\sqrt{Hf/bNn} \tag{9}$$

where t_1 = thickness, in., H = i.h.p.; b = length of section at root, in.; N = rev. per min.; n = number of blades; A = 9 to 12 for bronze or steel and 14 to 17 for cast iron; and f = a factor having the following values for various ratios of p to d:

p/d	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0	2.1	2.2	2.3
f	1.10	1.02	0.95	0.89	0.85	0.81	0.77	0.74	0.72	0.70	0.68	0.66	0.64	0.63

PADDLE WHEELS

Paddle Wheels are of two types: (1) **Radial,** with fixed radial floats, and (2) **feathering,** with movable or oscillating floats so connected as to enter and leave the water as nearly as may be possible in the direction of their own plane.

The **effective diameter** of a paddle wheel is usually taken as the distance between the centers of opposite floats. This is not exact, but sufficiently so for practical purposes. The **pitch circle** is then defined as the circle on this diameter. Let D = diam. of pitch circle, ft.; N = r.p.m.; U = speed in miles per hour, and s = apparent slip ratio. Then $s = (\pi DN - 88U)/\pi DN$. For **feathering floats,** Seaton gives the following formulæ: Number = $n = 60/\sqrt{N}$; area of one float = (i.h.p. $\times K)/n(DN)^3$, where $K = 40 \times 10^6$ for vessels plying in smooth water $= 45 \times 10^6$ for sea-going steamers $= 50 \times 10^6$ for tugs and craft requiring special control.

When working in smooth water the immersion of the top edge need not exceed ⅛ × breadth. For general service at sea the immersion should be about ½ × breadth. The length of the float should be from 2.5 to 3 times its breadth.

Radial Wheels. The area of each float is usually made from 70 to 80 per cent. that for feathering floats. The number may be taken as one for each foot of diameter. The length should be from 3 to 3.5 times the breadth. Under these conditions the slip for radial wheels will be some 5 to 10 per cent. greater than for feathering wheels.

BOILERS

Performance of Scotch Boilers. With coal fuel and natural draft, from 15 to 20 or 25 lb. of coal may be burned per sq. ft. of grate surface per hour. With mechanical draft the combustion may be raised to 30 or 40 lb. or more. The usual ratio of heating to grate surface is 30–40 to 1, and with such ratio and under usual operative conditions, an evaporation of 4 to 8 lb. of steam per sq. ft. of heating surface may be realised.

With an overall boiler efficiency of 70 to 75 per cent. and the usual type of triple-expansion marine engine, an indicated horse power will be developed in the main engines for 2½ to 3 sq. ft. of heating surface, or 10 to 15 h.p. per sq. ft. of grate surface. The weight of Scotch boilers with water and fire-room auxiliaries, all in steaming condition, will usually range from 80 or 90 to 150 lb. per h.p. at the main engines.

Structural Design. The various marine registration societies, as well as the British Board of Trade and the U. S. Treasury Department have laid down extended sets of rules for the structural proportions of Scotch boilers. Below are given excerpts from the rules of the American Bureau of Shipping, which cover the more important items. In any individual case care must be taken to insure the fulfillment of all rules which may be significant for the case in hand for purposes of registry, classification or governmental inspection, and as laid down in the particular codes to which due reference must be made.

Rules for the Construction of Scotch Boilers

Riveted Joints. For circumferential seams, single- or double-riveted lap joints with efficiencies from 0.55 to 0.70 are employed. For longitudinal seams, butt-strap joints are employed with double cover plates and double or multiple riveting in various patterns, and with efficiencies rising to 0.85. For discussion of riveted joints see p. 674.

Pressure, Diameter and Thickness may be connected by the formula: $p = tTe/Df$, where p = pressure to be allowed, lb. per sq. in.; t = thickness of shell, in.; T = lowest tensile strength of any plate in the shell, lb. per sq. in.; e = efficiency of riveted joint; D = mean diam. of shell, in.; and f = 2.05 (2.10), when longitudinal seams are made with double butt straps of equal (unequal) width and the circumferential seams are at least double-riveted.

Bumped Heads. For shells or drums with bumped heads the design may be determined as follows: For heads convex on the outside, $p = 0.4tT/R$; and for heads concave on the outside, $p = 0.2tT/R$, where R = radius in in. to which head is bumped—other notation as above.

Stays. For steel screw stays whose smallest diam. is 1½ in. or less, a maximum tensile stress of 8000 lb. per sq. in. may be allowed. For steel screw stays whose smallest diam. is above 1½ in. and for all other stays, a maximum tensile stress of 9000 lb. per sq. in. may be allowed.
