Girders Supporting Combustion Chambers. Let d = depth of girder, W = width of combustion chamber, P = pitch of supporting bolts, D = pitch of girders, L = length of girders, and t = thickness of girders (both plates), all in in., p = working pressure, lb. per sq. in., and C = a factor depending on the number of bolts per girder = 6600 for 1 bolt, 10,000 for 2 or 3 bolts, 11,000 for 4 or 5, 11,500 for 6 or 7, and 12,000 for 8 or more. Then $d^2 = p(W - P)DL/Ct$, or $p = d^2Ct/(W - P)DL$.

Flat Plates. The allowable pressure on flat surfaces $= p = C(t - 1)^2/A$, where p = working pressure, lb. per sq. in., t = thickness in sixteenths of an inch, A = area supported, sq. in., and C = constant having the following values:

1. Plate reinforced with a doubling plate over whole area to be supported, and of thickness not less than one-half that of main plate, and stays fitted with double nuts: for t take 0.8 combined thickness of both plates and C = 160.

2. Stays fitted with double nuts and riveted doubling strips or double nuts and riveted washers, the width of strip or diam. of washer not less than 0.6 pitch of stays and thickness *equal* to that of plate to be supported: C = 277 for doubling strips and 259 for washers.

3. Stays fitted with double nuts and riveted doubling strips or double nuts and riveted washers, the width of strip or diam. of washer not less than 0.6 pitch of stays and thickness *not less than* 0.8 thickness of plate to be supported: C = 238 for doubling strips and 226 for washers.

4. Stays fitted with double nuts and riveted doubling strips or double nuts and riveted washers, the width of strip or diam. of washer not less than 0.6 pitch of stays and

thickness not less than 0.6 thickness of plate to be supported: $C = 199$ for doubling strips and 193 for washers.

5. Stays fitted with double nuts without doubling strips or washers: $C = 160$.
6. Stays screwed through plates and fitted with nuts: $C = 160$.
7. Stays screwed through plates and riveted over: $C = 140$.

For other proportions of riveted doubling strips or riveted washers, the values of the constant may, if desired, be found from the following formulæ. It is required, however, that the diameter of washer or width of doubling strip shall be at least 0.4 the pitch of the stays, and thickness at least 0.5 that of the plate to be supported:

For doubling strips, $$C = 160 + 156\left(\frac{d - 0.3p}{0.4p}\right)\left(\frac{t_1 - 0.4t}{0.6t}\right)$$

For washers, $$C = 160 + 132\left(\frac{d - 0.3p}{0.4p}\right)\left(\frac{t_1 - 0.4t}{0.6t}\right)$$

where d = diam. of washer or width of strip, p = pitch of stays, t = thickness of plate to be supported, and t_1 = thickness of washer or strip, all in in. For boiler fronts in the steam space unprotected from flame in the uptakes, the above values of C must be reduced by 20 per cent.

Thickness of Tube Sheets. The thickness of tube sheets should not be less than that given by the formula $t = 1 + \sqrt{pA/200}$, where t = thickness in sixteenths of an inch, p = pressure, lb. per sq. in., and A = area supported by each stay tube, sq. in.

Angle-iron Stiffeners for Flat Surfaces. Flat surfaces of boilers stiffened with double angle irons riveted on, with thickness of leaf at least two-thirds that of plate and depth at least one-fourth the pitch, may be allowed pressure as given by the formula $p = 200(t - 1)^2/h^2$, where h = pitch of angle irons in in., p and t as before. The spacing of such stiffeners must in no case exceed 16 in.

Angle-iron Stiffeners for Rounded Convex Surfaces. Where single angle-iron stiffeners are used to stiffen the rounded bottoms of combustion chambers, such angles must be efficiently riveted to the plate to be supported, and must have a thickness of leaf $= 0.8t$ and a depth at least equal to $\frac{1}{2}h$. Where such angles are used to stiffen the rounded tops of combustion chambers, they must be of thickness and depth of leaf not less than as specified above for rounded bottoms, and such angles must be carried on thimbles and riveted through with rivets not less than 1 in. in diam. and spaced not more than 6 in. between centers. Rounded surfaces supported in this manner may be allowed a pressure: $p = 700t^2/hD$, where h = pitch of angle stiffeners, in., and D = diam. of circle to which plates are curved; p and t as before.

Compressive Stress on Tube Plates. Where the pressure on top of combustion chambers is borne by the vertical plates of such chambers, the compressive stress on tube plates as found by the following formula or rule must not exceed 12,500 lb. per sq. in.: $S = pWP/2(P - d)t$, where S = stress on tube sheet and p = pressure to be carried, both in lb. per sq. in.; W = width of combustion chamber, P = pitch of tubes, d = inside diam. of tubes, and t = thickness of tube sheet, all in in.

Reinforce for Holes Cut in Boiler Shell. All holes exceeding 6 in. in diam. cut in either the flat heads or circumferential shell of steel boilers, should be reinforced with wrought- or cast-steel rings to compensate for the material removed. In lieu of such a reinforce ring, holes in flat heads may, if preferred, be reinforced by flanging the metal about the hole inward to a depth of not less than ¾ in., measured from the inner surface. Reinforce rings on flat heads must be efficiently riveted to the head, and must have a sectional area not less than 0.8 the section of metal removed, the latter being measured across the shorter axis of the opening.

Reinforce rings on the circumferential shell must be efficiently riveted to the shell, and must have a sectional area not less than 0.7 the section of metal removed, the latter being measured across the hole in a direction parallel to the length of the boiler. Reinforce rings should be of thickness not less than that of plate to which attached.

Corrugated Furnaces circular in section and with corrugations 8 in. from center to center, the radius of outer corrugation being not more than one-half that of the reverse or suspension curve, and with plain parts at the ends not exceeding 9 in. in length, may be allowed steam pressure in accordance with the formula $p = 15{,}000t/D$, where p = pressure, lb. per sq. in., t = thickness of metal, in., and D = mean diam., in. = inside diam. + thickness + 1½ in. For the thickness, the formula becomes $t = pD/15{,}000$.

Water-tube Boilers. Of the many types of water-tube boilers, a certain number have been developed with special reference to the requirements of marine service. Among these may be mentioned the Thornycroft, Yarrow, Mosher, Marine Babcock and Wilcox, and Normand boilers.

In general, such boilers fall into two classes: (1) Those with relatively large and heavy straight tubes expanded into headers or junction boxes and intended for use where the saving of weight is relatively less imperative, and furnishing thus a larger margin for safety and for durability under the normal conditions of use; and (2) those with relatively small and light tubes, either straight or curved, expanded usually into upper and lower drums and intended for use where the saving of weight is imperative in character, as on torpedo boats, destroyers, fancy racing craft, etc. The latter are often termed the **"express" type** of water-tube boiler.

Performance of Water-tube Boilers. With coal fuel and forced mechanical draft, a combustion from 20 lb. per sq. ft. of grate surface to 50 lb. and above may be realized. The ratio of heating surface to grate surface is usually between 40 to 1 and 60 to 1, increasing with the proposed rate of combustion per sq. ft. of grate. This ratio, with an actual evaporation of from 7 to 11 lb. of steam per lb. of coal (decreasing with increase of draft), will give an evaporation of 6 to 10 lb. of steam per sq. ft. of heating surface. This, with good triple-expansion engines or turbines, will give an indicated horse power for 1.5 to 2.5 sq. ft. of heating surface. Such values by no means indicate the limit, and tests have shown an evaporation of 13 to 16 lb. per sq. ft. of heating surface, or practically 1 h.p. per sq. ft.

The weight of water-tube boilers of the heavy straight-tube type is but slightly less than of Scotch boilers of like capacity. Boilers with water and fire-room auxiliaries all in steaming condition will weigh usually from 50 to 90 lb. per i.h.p. with good triple-expansion engines or turbines. With the lighter express types, the weights range from 16 to 30 lb.

MARINE ENGINES

The typical marine steam engine is of the vertical inverted triple- or quadruple-expansion form, and acts on three, four or five cranks spaced at equal or nearly equal angular intervals about the circumference. Compound engines acting on three cranks, or more rarely on two, are also met with.

The **steam pressure** employed for such engines ranges about 200 lb. per sq. in. and lower for those of the compound type, or higher for torpedo boats, destroyers and fast yacht designs. The **number of expansions** ranges from 10 to 15 or higher in accordance with special conditions.

Design of Structural Features

Cylinders. Large marine-engine cylinders are very commonly made with liners, thus securing a working barrel and at the same time a jacket space between outer and inner barrels. For thickness, t, of liner and other cylinder dimensions see p. 762.

The **cylinder end** may be made with either a single or double shell, in either case with supporting ribs. For a single cylinder end, take the thickness $= 0.9t$ to t, and for a double cylinder end $0.8t$ to $0.9t$. The ribs are made of about the same thickness as the end, and of depth 5 to 6 times the thickness. They must be so spaced that the intermediate flat surfaces will fulfill the conditions for strength as given by the formula $t = b\sqrt{p}/100$, where t = thickness of flat plate and b = distance between ribs, both in in., and p = gage pressure, lb. per sq. in.

Cylinder Covers. (See also p. 762.) For flat single-shell cover of cast iron the thickness $= 0.9t$; for conical single cover of cast iron, $0.8t$; for double-shell cover of cast iron $= 0.75t$; for steel covers the form is usually single and the thickness $= 0.5t$, where t is the thickness of cylinder barrel. In any case the surface must be supported by ribs of dimensions and spacing similar to those for the cylinder end.

Pistons (see also p. 763) are usually of cast steel, dished or conical in form and made of a single thickness of metal. The various pistons of a compound or triple-expansion engine should, as a rule, be made of the same total depth. This gives a steep angle to the high-pressure and a flat angle to the low-pressure piston. The latter should not be less than about 1 : 5. The **thickness near boss** may be obtained from the formula $t = 0.004\ (d + 10\sqrt{p})$, where d = diam. in in., and p = maximum effective difference of pressure on two sides, lb. per sq. in. The **thickness near the edge** may be taken about 0.6 that near the boss. The **thickness of** the **wall of boss** for the piston rod should be about the same as that of the piston near boss, as given by formula above. The **height of boss** should be made 1.10 to 1.15 times the diam. of the piston rod (see below).

Piston Rods. The average piston load with suitable empirical factors may be used in the determination of many of the moving parts of the engine. This is defined as follows: If H = i.h.p. developed in one cylinder of engine, L = length of stroke, ft., N = r.p.m., and $2LN$ = piston speed, ft. per min., $= S$, then **mean piston load** is proportional to H/S, and the **diameter** d **of** the **piston rod** (in in.) may be obtained from $d = 5\sqrt{H/S}$.

When the rod is secured by threaded fastenings at the ends, the diameter at the root of the thread should be such as to insure a stress not exceeding 3000 lb. per sq. in. based on *maximum* piston load as defined by pA, where p = maximum difference of pressure between the two sides (lb. per sq. in.) and A = area (sq. in.)

Connecting Rods. The length of the connecting rod is usually from 4½ to 5 times the length of the crank, and between these limits the relation of the connecting rod to the piston rod may be determined on an empirical basis in accordance with the following proportions: Diam. of connecting rod at upper end = diam. of piston rod; and area of section of connecting rod at lower end = 1.2 to 1.3 times that of piston rod.

If the usual form of section is employed with the fore-and-aft dimension nearly constant from top to bottom of rod and transverse dimension increasing as above, then the section modulus for cross breaking at the lower end will be some 40 to 60 per cent. in excess of that at the upper end, and sufficient stiffness and strength will be secured.

Crank Shafts. The design of the crank shaft may be conveniently related to the mean turning moment (M) given by the equation: $M = 33{,}000 \times H \times 12/2\pi N = 63{,}000H/N$, where H = total indicated horse power, and N = rev. per min.

For a **solid shaft,** $D = 1.72\sqrt[3]{eM/T}$, where D = diam., in., M = moment as above, T = shearing stress allowed, usually from 8000 to 10,000 lb. per sq. in., and e = factor intended to relate empirically the mean to the maximum turning moments, and usually with values of from 1.2 to 1.5.

For a **hollow shaft,** $D = 1.72\sqrt[3]{(eM/T)/[1 - (d^4/D^4)]}$ where d = diam. of hole, in., other notation as above.

Only that section of the shafting which is aft of the after crank is required to transmit the entire turning moment. Usually, however, in order to secure uniformity of size in the bearings, all parts of the crank shaft are made of the same diameter.

The diameters of shafting may also be found by the following empirical rules:

Crank Shafts for Compound and Multiple-expansion Engines.

$$C = \sqrt[3]{pD^2L/K[(D^2/d^2) + 2.4]}$$

where C = diam. of shaft, in.; p = gage pressure at boilers, lb. per sq. in.; D = diam. of l.-p. cylinder, in. (if there is more than one l.-p. cylinder, then for D^2 use the sum of the squares of the diameters); d = diam. of h.-p. cylinder, in. (if there is more than one h.-p. cylinder, then for d^2 use the sum of the squares of the diameters); L = length of stroke, in., and K = factor having the following values:

Type of engine	Number of cranks	Angle between cranks, deg.	Value of factor K
Compound	2	90	1450
Compound	2	180 or 0	1200
Compound (3-cyl.)	3	120	1500
Triple	3	120	1700
Triple (4-cyl.)	4	90	1600
Quadruple	4	90	1800
Quadruple (5-cyl.)	5	72	2100

In four-crank engines with unequal spacing of cranks, K must be decreased as follows: If the smallest angle lies between 75 deg. and 85 deg., decrease K by 100; if between 65 deg. and 75 deg., decrease K by 200; and if between 55 deg. and 65 deg., decrease K by 300.

Crank Shafts for Single-expansion Condensing Engines.

$$C = \sqrt[3]{pD^2L/3K},$$

where C, p and L are the same as in the preceding paragraph, D = diam. of cylinder, in. (if there is more than one cylinder, then for D^2 use the sum of the squares of the diameters), and K is a factor having the following values:

Number of cranks	Angle between cranks, deg.	Value of factor K
1	...	1000
2	180	1000
2	90	1225
3	120	1320
4	90	1225

The diameter of the **propeller shaft** should be made equal to 1.06C; the diameter of the **tunnel shafting** may be taken as 0.95C. The diameters of **paddle-wheel crank shafts** may be found by the preceding formulæ and rules according to the type of engine employed. For simple beam engines and smooth-water navigation, however, the value of K may be multiplied by 2.5, while for other types of engine and smooth-water navigation the values of K may be multiplied by 1.7.

Bearing Pressures. Let W = i.h.p. developed by any given cylinder; S = piston speed, ft. per min.; a = length of crank and b = length of connecting rod, both in in. Then, **area of cross-head slipper** in sq. in. = 33,000 Wa/B_1Sb, where B_1 may vary from 15 to 20. In multi-stage engines all **guides** are made equal in area. The area for taking the load when backing may be made from 0.50 to 0.70 that for going ahead. See also p. 767.

The **projected area of engine bearings** in sq. in. = 33,000 W/B_2S, where

B_2 may range from 240 to 300 for the **cross-head pin**, from 100 to 120 for the **crank pin**, and from 65 to 80 for the **main bearings**.

The **area of the thrust bearing** in sq. in. = 220 H/B_3U, where H = total i.h.p., U = speed in knots, and B_3 ranges from 50 to 70.

The Problem of Balance

Unbalanced Forces in Ships. A ship is an elastic structure with natural principal and secondary periods of vibration and will respond in varying degrees to unbalanced forces in the engine. In case the periodicity of the applied disturbing forces agrees or nearly agrees with the natural period of the ship, vibrations of a serious character may develop. Two **types of disturbing action** are noted:

1. The resultant of the forces due to reciprocating and rotating parts, which with vertical engines have maximum values in the vertical direction and usually produce maximum disturbance in the same direction. These forces tend to throw the ship into **lateral** (usually vertical) **vibration,** either in a primary or some higher period.

2. A rocking moment tending to rock the engine bed plate in a vertical fore-and-aft plane, due to the periodic application of the forces (1) at any one instant with components in opposite directions and thus developing periodic **rocking moments.** The maximum values of such moments are usually with the forces vertical, and hence the induced vibrations are usually vertical in direction.

The forces (1) will be most effective when they are applied near the middle of a loop of the vibrating system which the ship may be considered as constituting. The rocking moment (2) will be most effective when applied near a node of the same vibrating system.

Means Available for Balancing. The following means are available for reducing the effects due to the action of these unbalanced forces:

1. The application to each **crank** of **counterbalance weights** to counteract the vertical first-order forces.

2. The **variation of** the fore-and-aft **distances between crank centers** for the purpose of controlling or reducing the resultant rocking moment, the individual forces of which are assumed to be applied at the crank centers. Usually, the best results are realized by such adjustment of weights as shall place the smaller forces at the ends and the greater forces between. Also, with four cranks, the two inner cylinders should be placed as near together as possible, and the outer ones in such position as to secure the best balance of moments.

3. The **variation of crank angles between** the **successive cranks.** This factor is of special significance in four-crank engines, and in particular with reference to the entire system of forces, including those due to the valves and valve gears. It is found in such case that a marked reduction in the final resultant forces and moments may be realized by suitable spacing of the cranks, departing in some cases 20 or 25 deg. from the conventional 90-deg. arrangement.

In general, it must be recognized that no combination of factors or arrangements as noted in (1), (2) and (3) will give a complete balance. The primary forces alone may be thus balanced, but not those of higher orders. The so-called Yarrow-Schlick-Tweedy system of balance takes full cognizance of these various forces and corrective means (see *Trans. Inst. Naval Architects*, 1893, 1894).

Auxiliaries

Condenser Surface. Surface condensers alone are used in salt-water navigation and are the general rule in all cases. The amount of surface is usually 1 to 1.5 sq. ft. per i.h.p. of the main engines, corresponding to a heat transfer of 200 to 250 B.t.u. per min. per sq. ft. of surface. The **amount of condensing water required** may be taken from 30 to 60 times the amount of feed water or from 60 to 120 gal. per h.p.-hr., (= 1 to 2 gal. per min. per i.h.p.). For cold water and moderate vacuum, the amount will range toward the lower figure; for high vacuum, especially with turbine drive, or with warm water, or both, the amount will range upward toward the higher value.

The **volume displaced by an air-pump plunger** may be taken as follows:

Displacement volume in cu. in. $= C \times (\text{i.h.p.})/N$,

where N = number of displacing strokes per min.

C = 50 to 70 for a triple- or quadruple-expansion engine with independent air pump.

C = 100 to 120 for a triple- or quadruple-expansion engine with air pump driven from the main engine.

C = 75 to 110 for a compound engine with independent air pump.

C = 150 to 180 for a compound engine with air pump driven by the main engine.

Steam Piping. The size of steam pipes is given by $a = vA/V$, where v and V are respectively the piston-speed and steam velocity in ft. per min., a is the cross-sectional area of the pipe and A the piston area, both in sq. in. V may be taken from 5000 to 8000, smaller values being suited to small pipes and high-pressure steam, and larger values to large pipes and low-pressure steam. The size of low-pressure exhaust pipes may be based on a value of V = 4,000 to 6,000.

U. S. Rules for Thickness of Steel and Copper Steam Pipes. Let p = working steam pressure in lb. per sq. in., t = thickness of pipe in in., and d = diam. of pipe in. in. Then for steel pipe, $t = (pd/10{,}000) + 0.125$; for copper pipe, $t = (pd/6000) + 0.065$.

AERONAUTICS

BY

J. C. HUNSAKER

REFERENCES: G. Eiffel, "La Résistance de l'Air et l'Aviation," Dunod et Pinat, Paris (1912 and 1914). L. Marchis, "Cours d'Aeronautique," Dunod et Pinat. G. H. Bryan, "Stability in Aviation," Macmillan. "Technical Report of the Advisory Committee for Aeronautics," 1909–10, 10–11, 11–12, 12–13, H. M. Stationery Office, London. A. Fage, "The Aeroplane," Griffin, London. S. Huppert, "Leitfaden der Flugtechnik," Springer, Berlin. Reber, "An Outline of the Theory of Ballooning," *Jour. Franklin Inst.*, Oct., 1912. Eberhardt, "Theorie und Berechnung von Motorluftschiffen," Berlin, 1912.

Aeronautics embraces all that pertains to the navigation of the air, and includes the use of aeroplanes or heavier-than-air machines (**aviation**) and air ships and balloons or lighter-than-air machines (**aerostation**). In aviation, sustentation is obtained from the dynamic lift of wings, while in aerostation, sustentation is obtained from the buoyancy of a volume of light gas. In either case, propulsion is by means of propellers producing thrust sufficient to overcome the resistance of the air. **Aerodynamics** is the study of the motion of air and its dynamic effects.

Lifting Power of Balloons. Let V = cubic contents of balloon, cu. ft.; $w'(w)$ = density of balloon gas (atmosphere), lb. per cu. ft.; $a = w - w'$ = lifting power per cu. ft., lb. Then gross lifting power A (lb.) = aV. If W = weight of balloon and equipment (lb.), net lifting power available = $A - W$. Let $s = w'/w$; then for temperature T_0 and pressure P_0 of gas and air, $a_0 = w_0 - w'_0 = w_0(1 - s)$, and for any given gas $(w,' P', T')$ and air (w, P, T) conditions, $a = w\,[1 - s(P'T/PT')] = a_0[PT_0/P_0(1 - s)] \times [(1/T) - (sP'/T'P)]$. Taking P_0 = 760 mm., T_0 = 492 deg. abs. (or 32 deg. fahr.), and w_0 for dry air = 0.0807 lb. per cu. ft., the following values hold:

	w'_0	s	a_0
Coal gas	0.0418–0.0281	0.52–0.35	0.0387–0.0524
Hydrogen, pure	0.00559	0.0692	0.0751
Hydrogen, commercial	0.0936	0.12	0.0687

P' is practically always equal to P; T' is often 30 or more degrees higher than T, due to heat from the sun's rays.

Taking gas and air temperatures at 32 deg. fahr., the **height** to which a **balloon will rise** = h (ft.) = 60,350 log (W/a_0V). If V is constant, a decrease of W by an amount W' (*i.e.*, throwing out ballast) will result in the additional ascent h_1 (ft.) = 63,050 log $[1 - (W'/W)]$. For $W' \leq 0.1W$, $h_1 = 26{,}240\ W'/W$, or h_1 = 262 ft. for each per cent. W is lightened. For any values of T' and T, the height to which the balloon will ascend $= h' = h - 53.4(t - 32) + 26{,}240\ [s/(1 - s)] \times [(T' - T)/T]$, where $t = T - 460$. An increase of 1 deg. fahr. in the air temperature will increase the altitude about 55 ft. and the lifting power 0.2 per cent., and *vice versa*. If the gas temperature T' be assumed as 572 deg., the altitude will be approximately increased as follows for each deg. fahr. difference between T' and T: Coal gas (s = 0.435), 37.4 ft.; hydrogen, pure, 3.64 ft.; commercial hydrogen, 6 ft.

Air ships or dirigible balloons are provided with air bags (**ballonets**) within their hulls for regulating the height of ascent. These are pumped full before ascent, emptied while ascending, and refilled when it is desired to descend. The total cubic contents of these air bags when filled = $V' = mV$. Values of m for various heights to which it is desired the air ship should rise, are as follows:

Height, ft.	1,000	2,000	4,000	6,000	8,000	10,000
$m = V'/V$	0.04	0.075	0.141	0.20	0.26	0.318

RESISTANCE OF BODIES OF EASY FORM

Stream-line Bodies. A body of "easy" form (*e.g.*, resembling a fish or torpedo) when moved through air or water at ordinary speeds makes little disturbance, and no turbulent wake is left behind. Air for ordinary transportation speeds is practically incompressible. The resistance to motion through air for such bodies is almost entirely frictional. A body of such easy form that the only resistance to its motion is frictional, is called a "**stream-line body**;" and the motion of the fluid caused by its passage is a steady **stream-line motion.** In practice, the term stream-line body is applied to bodies which give rise to an approximate stream-line motion. The nose of the body may be fairly blunt, with the maximum section well forward of the middle. The after body is very fine. The ratio of length to maximum diameter should be from 4 to 6.

Viscosity Resistance. The viscosity of a fluid is a measure of its strength in shear. Air is a very viscous fluid and, further, tends to adhere to a solid body immersed in it. If this body be in motion a fluid shear or viscous drag is set up. The drag so produced is felt as a resistance to motion R_v, which is a function of the coefficient of kinematic viscosity of the fluid μ/d, the area in shear A_s, and the relative velocity V. $R_v = a(\mu/d)^{0.5}A_s^{0.75}V^{1.5}$, where a is a constant for a given geometrical form.

Density Resistance. In a real fluid, except for very low velocities, some momentum is always imparted to particles of fluid near the moving body. This may be manifest as a wake left behind or as small friction rollers next the skin, and represents work done by the body and hence the overcoming of a resistance to motion which is called density resistance. Its magnitude is given by $R_d = bdAV^2$, where d is the density of the fluid, A some area of the body (usually its projected area normal to the wind), V the relative velocity, and b a constant for a given geometrical form.

Skin Friction (or total resistance of a thin plane surface moving edgewise). In air, a thin plane surface (or board) moving edgewise experiences a viscous drag and also considerable density resistance. For smooth surfaces not longer than 16 ft., Zahm's experiments on air friction lead to the following empirical formula:

$$R = R_v + R_d = 0.0000077 8L^{0.93}V^{1.86}b,$$

where R = resistance for one side of board, lb.; L = length in direction of wind, ft.; b = width, ft.; V = velocity, ft. per sec. The effect of small changes in temperature and barometer are here neglected.

Total Resistance. For solids of revolution of "stream-line form" there may be more or less turbulence in the wake, indicating an augmentation of density resistance beyond that of a plane surface. The degree of turbulence set up is inversely as the excellence of the shape from an aerodynamic standpoint. The total resistance is given by

$$R = R_v + R_d = K_1 d\,(\mu/d)^{2-n}\,A^{n/2}V^n$$

where K_1 is a constant, n an exponent to be found by experiment for every geometrical form, and A is some area on the body. The ratio μ/d is called the coefficient of **kinematic viscosity,** and may be considered nearly constant for air at ordinary temperatures and pressures. The above expression then reduces to $R = KA^{n/2}V^n$. The value of n for six air-ship hulls tested both in air and in water at the National Physical Laboratory, England, varies between 1.84 and 1.96 in an irregular manner, with a mean value of 1.86. The tests are summarised in Table 1, in which K is computed from $K = R/A^{0.93}V^{1.86}$, where R is resistance of the hull (lb.), A the surface area (sq. ft.), and V the velocity (ft. per sec.). The values of K for a round-end and blunt-end cylinder are also given to show the large resistance coefficient for the latter shape.

Table 1. Air-ship Shapes*

Shape

Model	Beta	Gamma	B.F. 36
L/D =	4.18	5.15	5.83
K =	0.0000164	0.0000165	0.0000142

Shape

Model	B.F. 32	Lebaudy	Cylinders	
L/D =	6.0	8.5	7.0	8.0
K =	0.000014	0.0000124	0.0000693	0.0000138

* All values of K are from the British Report (1912–13) except for cylinders (Eiffel 1914). L is the length of the hull.

NOTE. In this and subsequent tables of this section, constants involving density refer to standard conditions, *i.e.*, dry air at 15 deg. cent. (59 deg. fahr.) and 760 mm. (29.92 in.) barometer.

Resistance of Wires and Cylinders. The resistance of long wires or cylinders stretched across the wind increases with the velocity, but with a power less than the square. Consequently, in the formula, $R = KLDV^2$, the coefficient K is not strictly a constant, but increases for high speeds and large cylinders. L is length of wire (ft.), D diameter (ft.), V speed (ft. per sec.), and R resistance (lb.). The variation of K with the product DV is given in Table 2. The coefficient for stranded rope and cable may be taken 20 per cent. greater than the corresponding value for smooth wires and cylinders. The variation of resistance of a wire with varying inclination to the wind is given below.

Inclination of wire to wind, deg.	30	40	50	60	70	80
Per cent. of normal resistance	20	37	54	72	87	97

Resistance of Struts and Bars. To keep head resistance a minimum, structural members of an aeroplane are given a stream-line section. A good

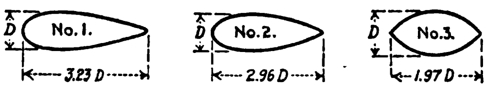

FIG. 1.—Aeroplane Strut Sections.

section is found to have less than one-eighth the resistance of a cylinder with long axis across the wind. The coefficient K for such struts as are used in biplanes decreases with increase in the product DV, where D represents the maximum thickness of the strut section in feet. Values of K for the three struts shown in section in Fig. 1 are given in Table 3. A strut inclined 30 deg. to the wind is there shown to have its resistance materially reduced if it be of poor shape, while the resistance of a good shape is not affected.

Struts give less resistance when more elongated, but a thin strut is structurally weak. In aeroplanes a strut of depth-to-thickness ratio between 3 and 4 is used. Fig. 2 shows the effect of elongating a strut. The coefficients K_x refer to a value of $VD = 2.5$. For larger values of VD, the coefficients will be reduced as in Table 3. The "fineness ratio" is the ratio of depth to maximum thickness of the cross-section. A good cross-section is shown in Fig. 2. The relative thicknesses at each tenth of the depth, starting from the front, are 0.75, 0.94, 1.00, 0.99, 0.96, 0.91, 0.81, 0.69, 0.54, and 0.

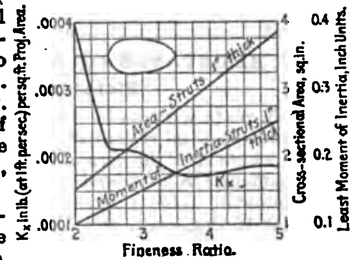

Fig. 2.—Effect of Lengthening an Aeroplane Strut.

Resistance of Miscellaneous Objects. The objects in Table 4 are generally supposed to give rise to such turbulence that density resistance preponderates, and the resistance in pounds may be represented by $R = KAV^2$, where A is the area (sq. ft.) of the projection of the object on a plane normal to the wind. An aeroplane **radiator** of the honeycomb type may be taken as having a resistance of one-half that of a flat plate normal to the wind and of the same projected area.

Resistance of Aeroplane Bodies. The resistance of such an unsymmetrical form as an aeroplane body is estimated from wind-tunnel tests on small models, on the assumption that $R = KAV^2$, where A is the area (sq. ft.)

projected on a plane normal to the wind. Table 5 gives the values of K for three of the best bodies in present use. No. I is a monoplane body, No. II a "tractor" biplane and No. III a "pusher" biplane body. It is to be noted that the resistance of bodies I and III includes that of a propeller not turning. Nos. II and III include the resistance of the heads of the personnel. The value of K given should be less for full size and high speed, but due to the blast from the propeller this saving in resistance should not be counted on.

RESISTANCE OF SHAPES PRESENTING AN EDGE

Plates in Normal Presentation

A thin plate with its face normal to the wind has a turbulent wake in its rear, and the total resistance (almost wholly density resistance) is R(lb.) $= KAV^2$, where A is the area of plate (sq. ft.) and V the velocity (ft. per sec.). The coefficient K is found to increase slightly with the size of the plate. The following table gives values of K for square (or circular) plates (air taken at 15 deg. cent. and 760 mm.).

Side (or diam.) of plate, ft.	0.5	1.0	2.0	3.0	4.0	5.0	10.0
K.....................	0.00125	0.00133	0.00146	0.00148	0.00150	0.00152	0.00152

Aspect Ratio is the ratio of the span of a rectangular plate or wing measured across the wind to the depth measured in the direction of the wind. For high aspect ratios the value of K increases as shown below. The coefficient for a square plate of the same area is taken as unity.

Aspect ratio............	1.0	1.5	3.0	6.0	10.0	14.6	20.0	30.0	50.0
K....................	1.0	1.04	1.07	1.10	1.15	1.25	1.34	1.40	1.47

Inclined Surfaces

When any thin plane or cambered surface is moved through the air so that the direction of motion makes a small angle with the lower side, the fluid motion resulting is unsymmetrical and the resultant pressure of the air is very nearly normal to the plane of the surface. On top of a wing, the flow of air is turbulent and the entire upper surface is under suction. This suction produces a lift which in good wings amounts to more than ⅔ of the total lift. Skin friction on an inclined surface is present only on the face or lower side where there is rubbing, and may generally be neglected. The total resultant force R in pounds for a velocity V ft. per sec. of a wing of S sq. ft. area is given by the formula: $R = K_iSV^2$, where K_i is a coefficient which varies in an irregular manner for different shapes of wing and for different attitudes of the same shape. Since R is a density resistance the coefficient K varies with the density of the air, which is here assumed to be at 760 mm. and 15 deg. cent. The vertical component of R is the **lift** L in pounds, or $L = K_ySV^2$, and the horizontal component of R (along the direction of the wind) is the resistance to motion called **drift**, or $D = K_xSV^2$. Hence $K_i^2 = K_x^2 + K_y^2$, and the direction of the resultant force is defined by the angle between its line of action and the wind, or $\theta = \tan^{-1}(K_y/K_x)$. The coefficients K_y and K_x are called lift and drift coefficients and are characteristic of various surfaces. The angle of incidence is defined arbitrarily as the acute angle between the wind direction and the lower chord of a section of the wing cut by a vertical plane parallel to the wind direction. K_y and K_x vary with the angle of incidence.

Flat Plates. For a smooth, thin flat plate Table 6 gives K_y and K_x for various values of the angle of incidence i and for different aspect ratios. Note in this table that the lift for each plate increases with the angle until a critical angle is reached, called the "**burble point,**" where the lift begins to decrease. For aspect ratio 9 the burble point is about 20 deg., while for aspect ratio 1 it is 35 deg. Rudders should therefore be given a low aspect ratio if large angles are to be used. The lift-drift ratio is not much improved for flat plates by high aspect ratio.

Curved Wings. Aeroplanes obtain a maximum K_y/K_x ratio by the use of wings of curved or arched section. The lift of a good wing is more than double that of a plane, and the K_y/K_x ratio is 18 or 20 as against 6 or 7 for a plane. The K_y/K_x ratio of curved wings is much improved by high aspect ratio. The following table shows the effect of aspect ratio for wings of usual form. An aspect ratio 6 is taken as the standard of comparison. The gain in lift-drift ratio is obtained without change in lift by a decrease in drift at high aspect ratios.

Aspect ratio..................	3	4	5	6	7	8
Drift........................	1.28	1.18	1.08	1.00	0.92	0.89

Camber of the upper surface of a wing is expressed as a fraction of the chord of that surface. In practice, a decrease of camber below 0.05 or increase of camber much above 0.08 is disadvantageous. For the incidence giving maximum lift-drift ratio, the lift for camber 0.08 may be twice as great as for camber 0.05, but the lift-drift ratio is diminished 27 per cent. Also, the burble point comes at 6 deg. instead of about 16 deg. Camber of lower surface made by hollowing out is found to have only a slight effect on burble point and lift-drift ratio. The lift at any angle is increased about 17 per cent. when a flat surface is hollowed out to a camber of 0.06. Camber of lower surface is not very important, and if excessive makes a wing structurally weak. The maximum ordinate of the upper surface should be placed about ⅓ of the chord from the leading edge.

The wing sections whose camber and thickness are given in Table 7 are shown in Fig. 3. Eiffel No. 32 is suitable for a racing machine, having a lift-drift ratio of 20 for small angles. R. A. F. 3 gives a very large lift at large angles and is suitable for a weight-carrying aeroplane or sea plane. R. A. F. 6 is the wing used on British army biplanes and has the great structural advantage of being thick enough to permit the use of large wing spars. Coefficients for these wings are shown in Fig. 3 and refer to an aspect ratio 6. The corresponding angles of incidence are marked along the curves.

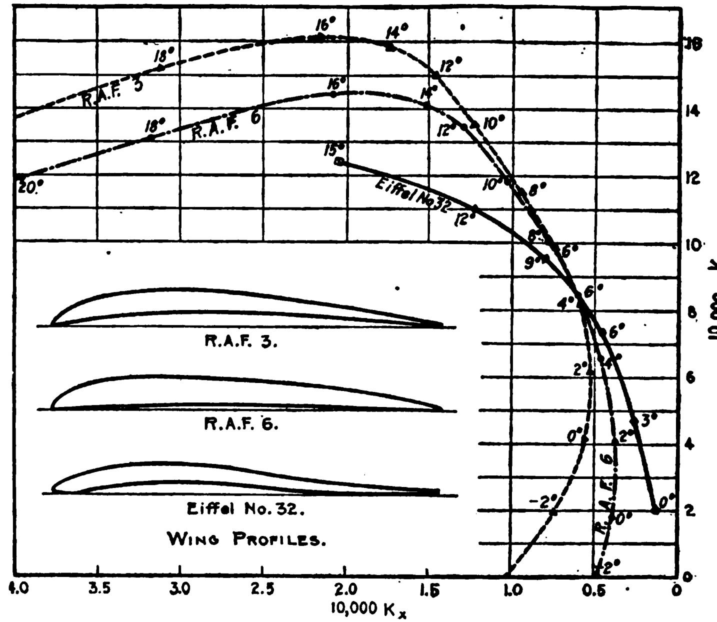

Fig. 3.

Center of Pressure. The intersection of the resultant force with the plane of the chord of the lower surface is called the center of pressure (c.p.).

This center varies with the angle of incidence in a characteristic manner for every wing shape. The center of pressure is located for a given angle of incidence by giving its distance from the leading edge in per cent. of the chord length. Fig. 4 shows the c.p. motion for a flat plate and for the Eiffel No. 32 and R. A. F. 6 wings. The curve for the R. A. F. 3 wing is very close to the R. A. F. 6 wing. The motion of the flat plate is such that for small angles the wind lifts the front edge and at larger angles the rear edge. This gives longitudinal stability if the center of gravity is at an intermediate point. On the contrary, the c.p. motion of the R. A. F. 3 and R. A. F. 6 is unstable, which is the case for most cambered surfaces. The artifice of a reversed curvature near the trailing edge, as in Eiffel No. 32, is seen to hold the c.p. motion nearly constant. This is an advantage, but is obtained at the expense of lift at large angles.

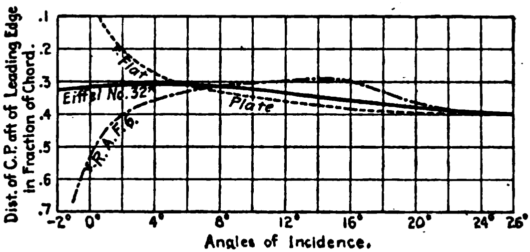

FIG. 4.

Speed and Scale. The coefficients of wings are obtained from wind-tunnel tests on small models. The drift coefficients are lower for the full-scale machines, but the lift coefficients are practically unaffected. By using model coefficients without correction the designer is on the safe side by about 10 per cent.

Interference

Biplane Coefficients. When a pair of superposed wings is used, as in a biplane, the suction on the back of the lower wing is reduced by the interference of the upper wing, and the lift of the lower wing may be reduced 30 per cent. The lift of the upper wing is not affected. The drift of a biplane is somewhat less than that of a monoplane, but the reduction is not important compared with the loss in lift. The **gap** (Fig. 5) is the perpendicular distance between the wings of a biplane. It is usually given in terms of the chord length. To obtain biplane coefficients from the known coefficients for a monoplane wing, use the following multiplying factors.

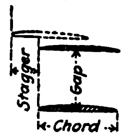

FIG. 5.

Ratio of gap to chord	0.40	0.80	1.00	1.20	1.60
Factor for K_y	0.61	0.76	0.81	0.86	0.89
Factor for K_y/K_x	0.75	0.79	0.81	0.84	0.88

The usual case in practice is for biplane wings to be equal in area, parallel, and with gap equal to the chord. A **staggered biplane** (Fig. 5) is a biplane in which the upper wing is not directly over the lower wing. A slight improvement may be made by making the lower wing, which is less effective, of smaller area than the upper. In this case the coefficients are to be obtained by considering the overhanging portions of the upper wing as monoplane surface.

The center-of-pressure motion for ordinary biplanes is not sensibly different from that for a monoplane of the same section. Efforts to make center-of-pressure motion zero by inclining the upper and forward wing of a staggered biplane 3 or 4 deg. away from the lower wing involve a loss of lift-drift ratio of 5 per cent.

A horizontal fixed **tail** surface is usually flat, of area about $\frac{1}{10}$ the wing area, and placed to the rear of the after edge of the wing a distance equal to the half-span of the wings. Such a tail, if placed parallel to the axis of the body (or propeller shaft), will be inclined to the wing chord by 3 or 4 deg., making what is known as the "longitudinal vee," which insures longitudinal stability. The tail surface is in the wash of the wings, which deflect the air downward by an angle $\alpha = 1 + \frac{1}{2}i$, where i is the incidence of the wings. This air, when the body is horizontal, strikes the tail on the top with an incidence α, and from a knowledge of the coefficients of the tail surface the moment of the air forces about the center of gravity of the aeroplane can be computed. Combine this moment with moment of the wings. The resultant moment should provide a righting moment tending to turn the machine back to the horizontal if it tends to pitch.

THEORY OF AEROPLANE DESIGN

Lift and Power Equations. The aeroplane in horizontal flight is sustained in the air by the lift of the wings. The lift $W = K_ySV^2$, where W is the total weight (lb.), K_y the wing coefficient for a particular incidence, S the effective area of the wings (sq. ft.), and V the relative velocity of the wings through the air (ft. per sec.). In order to maintain the speed necessary for sustentation, the propeller must overcome the resistance to forward motion at this speed. The **horizontal force on the wings** is $R_w = K_xSV^2$. The resistance of the wing bracing, body, radiator, landing carriage, etc., is called "parasite" resistance, since no lift is obtained from these parts. Their resistance is $R_b = K_bV^2$, where K_b is a constant characteristic of the machine and is independent of the incidence.

The **propeller thrust** T (lb.) is then $T = R_b + R_w = (K_xS + K_b)V^2$. If the efficiency of the propeller is e, the **brake horse power required** for flight at speed V is given by: $P = TV/550e = (K_xS + K_b)\ V^3/550e$.

In this equation K_x is the drift coefficient corresponding to K_y of the lift equation, and both are functions of the incidence. The lift and power equations must be satisfied simultaneously by a concordant set of values of W, S, V, P, e, K_b, K_x and K_y. In a design W, S, V, e, K_b are known by assumption or calculation, and it is required to determine P, K_x and K_y for a series of values of V. Since K_x and K_y are functions of i, there are only two independent variables, i and P, to be found.

Weight. The final weight of the machine is estimated from the plans, but a preliminary estimate must be made from similar machines. The useful load the aeroplane is required to carry is the weight of fuel, oil, passengers, etc. This useful weight may be taken as 45 per cent. of the total weight in the air for light monoplanes, and 30 per cent. for heavy military biplanes. In practice, racing machines show 15 lb. of total weight per horse power, military machines 20, and flying boats over 25. The former are said to be "overpowered" and the latter "underpowered."

The **motor weight** is estimated by taking t = duration of flight in hours; P = b.h.p. of motor; a = gross weight per b.h.p. of motor and accessories, lb; c = fuel and oil per b.h.p.-hour, lb.; and tanks and oil pipes = $\frac{1}{6}$ weight of liquid carried. Whence, total supply weight = $\frac{7}{6}tPc$; total motor weight = Pa; and total power-plant weight = $P(a + \frac{7}{6}tc)$.

For rotary air-cooled motors, $a = 3$ and $c = 0.9$; for water-cooled four-cycle fixed-cylinder motors, $a = 5$ and $c = 0.6$, including water, radiator, pump, piping, magneto and all accessories. With these values for a flight of more than 5 hours, the fixed-cylinder motor is the lighter. Figures for a and c are for the best motors of their type in the year 1917.

Wing Weight. The weight of wings may be estimated at about ¾ lb. per sq. ft., not including external struts and wires. Where the latter are included, allow 1 lb. per sq. ft.

The area of wings is roughly such that the air load is from 4 lb. per sq. ft. on large biplanes to 8 on small monoplanes. Above 300 sq. ft. wing area the biplane arrangement is structurally preferable to the monoplane.

The following table shows the upper limits of present practice. The loads there given should be approached with caution.

Area of wings, sq. ft.	150	200	250	300	400	500	600	700
Load per sq. ft. of wing, lb.	9.4	8.1	7.4	6.8	6.2	5.7	5.4	5.1

The following table gives the weights of a typical military aeroplane (125 b.h.p.) in per cent. of the total weight (2438 lb.).

Useful load		Structural weight	
Personnel and equipment	13.1	Fuselage or body	8.2
Gasoline and oil, 6 hr.	19.8	Landing carriage	8.2
Motor weight		Directive surfaces	4.1
Tanks and pipes	3.3	Wings	16.5
Motor and accessories	17.9	Wing bracing	4.0
Radiator (empty)	2.2	Useful load	32.9
Cooling water	1.7	Motor weight	26.1
Propeller and hub	1.0	Structural weight	41.0

Principal Dimensions. The **wings** of a monoplane have an aspect ratio from 4 to 6; for a biplane, 6 to 10 for each wing. From the assumed area S the span of the wings can be estimated. Place the tail surfaces in rear of the rear edge of the wings a distance about equal to half the span. The overall dimensions of the motor fix the **diameter of the body**, and if the motor and propeller are mounted in front, the body will extend to the tail surfaces, giving a length somewhat over ¾ span. The body is placed between the wings of a biplane so that a propeller of 8 or 9 ft. diameter may be swung. The **chassis** or landing-carriage height is fixed by the propeller clearance desired. The wheels of the chassis should be 24 in. or 26 in. for rough ground, with 4-in. tires for machines weighing over 2000 lb. The center of gravity (c.g.) of the whole machine should be near the propeller axis and about 1 ft. to the rear of the wheels of the landing carriage. The gasoline tank should be near the c.g., so that as fuel is consumed balance is not altered.

The **horizontal rudder** is about equal in area to the fixed **horizontal tail** surface. Let the sum of these areas be Q, l the distance of their center from the center of gravity of the aeroplane, S the total wing area, and b the chord length of the wings. Then a coefficient $c = Ql/Sb$ can be used to estimate Q or l from present practice, which indicates that machines which are easily controlled have c between 0.45 and 0.65. The former figure is for fast monoplanes and the latter for slow biplanes. Flying boats have such great wing area that c is often as low as 0.3.

In a similar manner let s be the span of the wings and V the total area of **vertical fin and rudder**. Then $f = Vl/Ss$. The coefficient f has a value of about 0.02. The vertical fin is not in general necessary on long-body machines, but in pusher-type machines when the body extends far in advance of the center of gravity, a fixed fin aft is often fitted to give better steering.

It is rarely more than 25 per cent. of the rudder area. **Ailerons** or **wing flaps** are hinged to the rear edge of the wings so that by pulling down on one side and up on the other, the air forces on the ailerons produce a rolling moment on the machine. Let a be total aileron area, S the wing area and s the wing span. In practice, $a/S = x = 10$ to 20 per cent. The product sx is 650 for hydroplanes and 500 for military aeroplanes. **Warping** the rear outer portion of the wings gives a more powerful control than ailerons, but is structurally undesirable. Six degrees is normal warping.

Characteristic Aeroplane Curves are used to predict the probable performance of the designed aeroplane. From the given corrections to be applied to the K_x, K_y coefficients to take account of biplane gap, aspect ratio, etc., plot curves of K_x and K_y for the selected wing section against incidences i as abscissæ. From the lift equation $W = K_ySV^2$ compute K_y for a series of speeds. For these values of K_y take from the wing-coefficient curves corresponding values of i and K_x. Compute R_w, R_b and T at each speed. The **effective horse power** required at each speed is then e.h.p. $= TV/550$. The efficiency of the propeller is a maximum at full speed and falls off rapidly at low speeds. If P is the b.h.p. of the motor selected, then eP at each speed is the **propeller horse power** (p.h.p.) available. Flight is possible over the range where the p.h.p. exceeds the e.h.p.

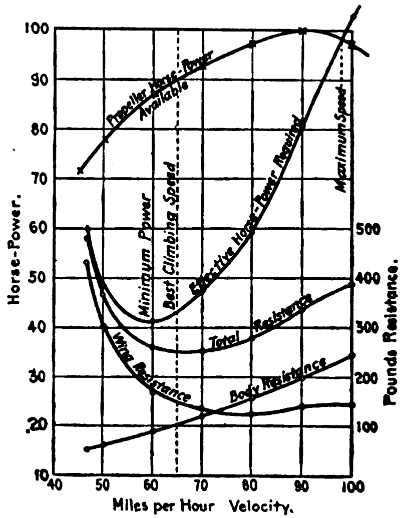

FIG. 6.—Characteristic Aeroplane Curves.

The characteristic curves of Fig. 6 are for the 125-h.p. machine whose weights were given above. The maximum speed is 97 miles per hour, the speed of minimum power required is 60 miles, which is also the minimum safe speed. Speeds between 47 and 60 miles are in the region of reversed controls and not considered safe (see Alex. Sée; "Les Lois Expérimentales de l'Aviation," Paris, 1912, p. 200). The greatest margin of power available over power required is 47 h.p. at 65 miles. This is the **best climbing speed,** for if the throttle be opened out, the machine will climb at a rate $47 \times 33{,}000/W = 650$ ft. per min. A machine whose curves showed no margin of power available for climbing could fly at only one speed. However, it never could get off level ground because it could not climb. Variable speed is obtained by over-powering and by the use of large wings of light loading per sq. ft. and a wing section giving a high value of K_y at the burble point.

Stability

Aeroplane Control. An aeroplane is controlled in flight by impressing on it yawing, pitching or rolling moments by manipulation of the vertical or horizontal rudders, or by use of wing warping or ailerons. This is the **three-rudder system** in almost universal use. Controllability is quite independent of stability. The aeroplane may be made automatically stable by gyroscopic or other devices which actuate the controls mechanically; it is inherently stable if, on deflection by any accidental cause, the aerodynamic forces introduced are such as to produce restoring moments tending to return the aeroplane to its original state of motion.

Stability may be either **static** or **dynamic.** The aeroplane is statically stable if the restoring moments tend to turn the machine back to its original equilibrium position. It is dynamically stable in addition if the oscillation produced by these restoring moments is rapidly damped out. The aeroplane is dynamically unstable if an oscillation tends to increase in amplitude with time. Static stability or **stable equilibrium** is necessary to obtain dynamic stability in oscillation, but is no guarantee of obtaining it. For small oscillations, **symmetric or longitudinal stability** may be considered independently of **asymmetric or lateral stability.** The former deals with **pitching,** and involves change of forward and upward components of velocity and angular motion of pitching. Lateral stability involves changes of lateral component of velocity or side-slipping (**"skidding"**) and angular velocities of roll and yaw. The term **"directional" stability** as used for ships to designate a tendency to persist on a course without yawing, is intimately bound up with the rolling and side-slipping and cannot be considered separately.

The righting moments due to the combination of wings and tail (see p. 1254) may be plotted on angle of pitch. If this curve of statical righting moments is too steep, the machine is stiff and difficult to control; it is too stable. The **righting moment** at any angle of pitch must always be less than the moment which the pilot may produce with his horizontal rudder. Dynamic stability in pitching is practically always secured when the machine is statically stable longitudinally. A large tail makes pitching slow and easy to control.

Rolling does not in general produce a marked center-of-pressure motion on the wings, and hence there is no restoring moment. However, if an aeroplane tilts to one side, it starts to skid or side-slip toward the low side. If a **fin** or its equivalent be placed above the center of gravity, a **lateral restoring moment** will be produced as soon as side-slipping starts. This will correct the roll and stop the side-slip. Such a fin is made by raising the wing tips or by broadening the tops of the struts. A strong moment is produced in an ordinary machine by inclining the wings upward and outward 2 or 3 deg. A greater dihedral angle than this (174 or 176 deg.) may make the aileron control too weak, and may accentuate the rolling oscillation.

When the aeroplane side-slips, if there be more vertical surface forward of the center of gravity than aft, a yawing couple is produced which tends to throw the nose of the machine up and away from relative wind; if the fin surface aft preponderates, the aeroplane may dive on a side-slip. The latter is preferable to the former condition, but as near a balance as possible should be attempted in the longitudinal distribution of fin surface. In some machines it is necessary to fit a small fin on the tail to balance a forward projecting body, skids, covered wheels and propeller. Curves of rolling and yawing moment are best obtained from wind-tunnel tests on a complete model.

When the side-slip resulting from a roll creates a righting moment without introducing an appreciable yawing moment, **static lateral stability** is obtained. If the fin surface, or the equivalent, be excessive, the aeroplane rolls badly in side gusts and may be difficult to control when landing. Too much fin aft causes the machine to turn from her course to head into side gusts. **Dynamic lateral stability** is not assured by the existence of static stability. An oscillation in roll alone is heavily damped by the wide-spreading wings, and the majority of modern aeroplanes if given proper fin disposition are unlikely to permit an oscillation in roll to increase. If the vertical rudder be large it acts as a fin and causes the machine to yaw toward the low side on a side-slip, or to dive. The first effect of this angular velocity in yaw is to cause a greater lift on the outer and more swiftly moving wing than on the inner one. The difference in lift on the two wings is an upsetting moment, tending to augment the side-slip. The result may be a **"spiral dive"**—the most common form of lateral instability.

A tendency toward spiral instability may be removed by the following alterations in a machine: (1) Provide a slight preponderance of fin surface above the center of gravity. (2) Reduce the rolling moment due to angular velocity of yaw by shortening the span of the wings. (3) Correct the undesirable preponderance of fin surface aft by fitting a smaller rudder or by fitting fin surface forward. (4) Damp any oscillation in yaw by balanced fin surface forward and aft. Thus a deep flat-sided body with a fin aft and another forward will damp an oscillation in yaw. A panel between the wings of a biplane, small upward dihedral of wings, or wings swept back in plan like an arrowhead are equivalent means of obtaining a righting moment. A sweep back of about 15 deg. for each wing to right and to left is equivalent to the small dihedral recommended. Neither expedient involves any appreciable loss in efficiency of wing.

For the mathematical theory of the oscillations of an aeroplane and the criterion for dynamic stability based on analysis of the differential equations of motion, see "Stability in Aviation," by G. H. Bryan, MacMillan, London, 1911, and for extension of the theory, determination of aerodynamic constants, and application to a Blériot monoplane, see Report No. 77, "Technical Report of the Advisory Committee for Aeronautics," 1912–1913, H. M. Stationery Office, London.

The above discussion of stability assumes constant power from the motor to maintain speed. In case of sudden stoppage of the motor a sudden pitching moment is produced if the center of gravity be higher or lower than the propeller axis. In **hydro-aeroplanes** with heavy floats the c.g. is low but the propeller must be high to clear the water. Such machines tend to nose up if the motor stops. Headed up the machine cannot climb without power, and speed would be quickly lost if the pilot did not head down into a glide at once. A stable machine may be "stalled" by an inexperienced pilot, but after a fall of sufficient height it will take its natural gliding path.

Air Propellers

Theory. Air propellers are commonly designed to fit a given motor and aeroplane by application of the theory of similitude to a propeller whose characteristics are known. The characteristics of a given propeller are the following quantities: T, thrust (lb.); Q, torque (ft.-lb.); b.h.p., brake horse power; t.h.p. thrust horse power; e, efficiency = t.h.p./b.h.p. Each of these five quantities is given by an expression involving density of air d, diam. of propeller D, rev. per sec. N, and speed of advance of aeroplane V. For a family of **geometrically similar propellers**, in which size, speed, and revolutions vary,

$$T = dN^2D^4f_1(V/ND) = K_tN^2D^4, \quad Q = dN^2D^5f_2(V/ND)$$
$$\text{b.h.p.} = \pi QN/550 = dN^3D^5f_3(V/ND)$$
$$\text{t.h.p.} = TV/550 = dN^3D^5f_4(V/ND), \quad e = f_5(V/ND).$$

Here f_1, f_2, f_3, f_4 and f_5 are unknown functions of the **slip function** V/ND, and $K_t = df_1(V/ND)$ is the **thrust coefficient**. All the characteristics of a family of propellers vary with the slip function, and from any two of them the rest may be calculated. Knowing the thrust and efficiency for one propeller for a series of values of V/ND, all the characteristics may be computed for a larger or smaller propeller geometrically similar to it, for the same values of V/ND.

The thrust coefficient and efficiency calculated from tests on a particular propeller may be applied to similar propellers for corresponding values of slip function by use of the above equation for thrust. The error should be within 3 per cent.

Construction. Air propellers are usually made of about six black-walnut or mahogany planks glued together. Two blades are commonly employed, but where great power on small diameter is required, four blades may be desirable. The thrust of a four-bladed propeller may be taken as nearly twice that of a two-bladed propeller of the same diameter and blade shape. If the blades are not broad, the efficiency is the same for two and four blades. As a general rule, the blades of a two-bladed propeller may be given a rectangular plan form of width ⅙th of radius. For four-bladed propellers the width should be about ⅛th of the radius. Experiments show that the plan form of the blade has little effect on efficiency.

The sections of the blades should be similar to the aeroplane wing section

R. A. F. 6, Fig. 3, near the tip. As the hub is approached, the blades must be thickened up for strength. The useful part of the blade is the outer three-quarters, hence the size of hub is not important and the blades may be thickened up in an arbitrary manner near the hub.

Strength. Any section of a blade is subject to centrifugal tension and to a bending moment due to thrust. A factor of safety of six should be used. The bending moment due to thrust may be computed by considering that the thrust of the blade is a single force acting at a point ¾ of the radius from the hub.

Efficiency. The efficiency of good aeroplane propellers at best speed V is about 80 per cent. The efficiency should usually be a maximum for the normal speed of the aeroplane. At 10 per cent. excess speed, for the same r.p.m. the efficiency of an 80-per cent. propeller may be 70 per cent. or less. At 10 per cent. below normal speed the efficiency may be 78 per cent. At 50 per cent. of normal speed, the efficiency may be about 50 per cent.

Thrust. A propeller is designed to give a thrust equal to the resistance of the aeroplane at normal speed, and to turn at the r.p.m. corresponding to full power of the motor. Gasoline motors develop practically constant torque and hence the b.h.p. varies directly as the r.p.m. For reduced power, the thrust delivered by the propeller at the reduced revolutions may be estimated by selecting values of K_t corresponding to the new values of slip

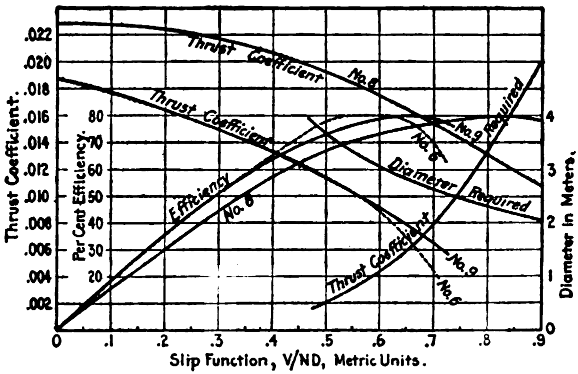

FIG. 7.—Thrust-coefficient and Efficiency Curves of Aeroplane Propellers.

function V/ND computed from assumed values of N and V. Thus curves of thrust plotted on V may be constructed for several revolution speeds of the motor. Such curves will intersect the curve of aeroplane resistance on speed, and these intersection points will indicate the motor revolutions necessary to make the corresponding speeds.

Full-size tests on three aeroplane propellers at the University of Paris ("Bulletin de l' Institut Aerotechnique de l' Université de Paris," Paris, 1913) give curves of thrust coefficient and efficiency as shown in Fig. 7. (Metric units are here used: thrust in kilograms, diameter in meters, velocity in meters per sec.)

Example. An aeroplane requires a thrust of 380 lb. (or 172 kg.) at 90 miles per hour (40.2 meters per sec.), and has a motor which delivers 125 b.h.p. at 1300 r.p.m.

($N = 21.66$ rev. per sec.). From $S = V/ND$ and $D = V/21.66\,S$, compute for various values of S the diameters required to preserve similitude. A curve of D required is plotted on Fig. 7. The thrust must be 172 kg., or $T = K_t N^2 D^4$ and $K_t = 172/(21.66)^2 D^4$. For every value of D, K_t is determined, so also is D determined by S. Hence K_t varies with S and is so plotted on Fig. 7. The intersection of the curve of K_t required with the curve of K_t for any propeller is a possible solution. For propeller No. 6, the intersection is at $V/ND = 0.66$. The corresponding efficiency is 77 per cent.; the diameter required is 2.75 meters (9 ft.), probably too large. Propeller No. 8 gives the best solution. The intersection of the K_t required curve takes place at $V/ND = 0.795$, efficiency being 80 per cent. and diam. 2.3 meters (7.54 ft.).

The propeller (No. 8) for which the curves in Fig. 7 were obtained had a diameter of 2.596 meters and was run at 700 r.p.m. The propeller just selected, if made of the same material as the model and geometrically similar, will be relatively weaker in the proportion of $N_1^2D_1^2/N_2^2D_2^2 = 1300^2 \times 2.3^2/700^2 \times 2.596^2 = 2.7$, or roughly one to three.

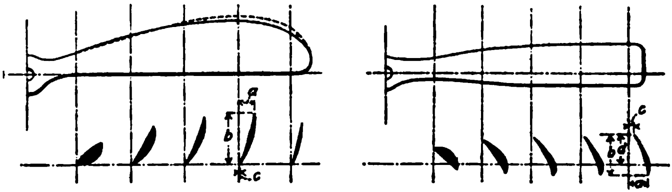

FIG. 8.—Aeroplane Propeller Blades.

The factor of safety in the original design is thus cut down to one-third. Since the centrifugal force and bending moment are important only for sections near the root of the blade, it is necessary to thicken up only those sections materially. Such thickening of the root will have very little effect on the functioning of the propeller, as the major part of the work is done by the outer half of a blade.

In very light propeller blades the distortion at high speeds is considerable and may have an important effect on efficiency. To preserve the same efficiency, a geometrically similar propeller must be run with N^2D^2 constant, so that the distortions, or the stresses which cause them, shall be the same.

The propellers used in Fig. 7 as prototypes are all two-bladed wood propellers. Their principal features are shown in Fig. 8 and Table 8. The pitch of the blade face increases toward the tip in each case and the propeller with greatest pitch (No. 8) gives the greatest thrust coefficient. It is possible to make anything that looks like a standard propeller of pitch equal to diameter with assurance that the efficiency will be at least 60 per cent. However, it may not allow the motor to turn at its required revolutions and may otherwise not fit the aeroplane.

LIONEL S. MARKS

FOUNDATIONS

Bearing Pressure of Soils. The bearing pressure which may be allowed on soil may vary over a large range. Where borings have not been made, tests should be carried out in the open trenches or in test pits by applying a concentrated load of known weight upon a limited area of the bearing soil and making daily level readings of the supported load. Table 1 (from Baker's "Treatise on Masonry Construction") gives a general classification of soils and the safe pressures which they may support.

Table 1. Safe Bearing Power of Soils

Nature of Soil	Safe Bearing Power, Tons per Sq. Ft. Min.	Max.
Rock, the hardest, in thick layers in native bed	200	..
Rock, equal to best ashlar masonry	25	30
Rock, equal to best brick masonry	15	20
Rock, equal to poor brick masonry	5	10
Clay, in thick beds, always dry	4	6
Clay, in thick beds, moderately dry	2	4
Clay, soft	1	2
Gravel and coarse sand, well cemented	8	10
Sand, compact and well cemented	4	6
Sand, clean, dry	2	4
Quicksand, alluvial soils, etc	0.5	1

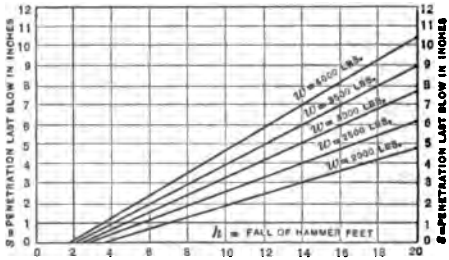
These values are somewhat higher than are customarily used in foundation work for low buildings, that is, for five stories or less, where preliminary exploratory work has not been made, and are higher than most building laws allow. The foundation for a building housing heavy vibrating machinery such as steam hammers, heavy punches, shears, etc., should receive some allowance for possible compression and rearrangement of soil due to the vibrations transmitted through it. The foundation for a tall chimney should be designed with a comparatively low pressure upon the soil, because of the disastrous results which might occur from local settlements.

Footings. The purpose of footings is to spread the concentrated loads of building walls and columns over an area of soil so that the unit pressure will come within the allowable limits. Footings are usually constructed of either concrete or stone. Brick is occasionally used, especially in the South, but is generally more expensive than concrete. Stone, where available in quantity and of the proper quality, can often be used economically, but concrete is the customary footing material (see p. 1314). This material is either used plain in mass, or reinforced with steel rods. The offset on each side of the footing for each successive course is determined by figuring the overhanging portion as a cantilever. For plain footings of 1 : 2½ : 5 (or better) concrete and soil pressures of 2 tons per sq. ft. (or less) a good all-around rule is to make the offset 0.6 of the thickness. The center of pressure should always pass through the center of the footing.

Pile Foundations. Where satisfactory bearing soil is not to be had at a reasonable depth, piles become necessary. Piles are either of wood or of concrete. **Wood piles,** barring the presence of marine borers or other animal destroyers, are as permanent as stone when continually submerged in water. Marine borers will not attack them below the mud line. A subsequent lowering of the ground-water level, however, may be disastrous, because when alternately wet and dry they will rot. **Concrete piles** are indestructible, and hence are adaptable to many conditions. Wood piles are usually designed to carry from 8 to 12 tons per pile. They should be straight and not less than 6 in. in diameter under the bark at the tip. With a concrete pile, from 25 to 35 tons are carried, 30 tons being a fair average.

Methods of Driving Wood Piles. The drop hammer and the steam hammer are usually employed in driving wood piles. The steam hammer, with its comparatively light blows delivered in rapid succession, is of advantage in case of an elastic soil, the speed with which the blows are delivered preventing the readjustment of the soil. It is also of advantage in soft soils where the driving is easy. The water jet is used in sandy soils and in mud. Water supplied under pressure at the point of the pile through a pipe or hose run alongside it erodes the soil, allowing the pile to settle into place.

Determination of Safe Loads for Piles. Piles may obtain their supporting power from friction of the surrounding soil or from columnar action. In the latter case, the bearing power is limited only by the strength of the pile, considered as a column, and since it is supported against deflection sideways, the load that can be carried is very nearly equal to the crushing strength of the pile. In the former case no precise determination of the bearing power can be made. Many formulæ have been developed for determining the safe bearing power in terms of weight of hammer, the fall, and the penetration of the pile per blow, the most generally accepted of which is that known as the *Engineering News* formula, namely, $L = 2wh/(s + 1)$, where L = safe load, lb.; w = weight of hammer, lb.; h = fall of hammer, ft.; s = penetration of last blow, in. A factor of safety of six is assumed. This formula and similar ones are based on the determination of the energy in the falling hammer, and from this the pressure which it must exert on the top of the pile. It is a wise practice to drive test piles and determine their bearing value before proceeding with the final designs of important structures to be supported on piles. The designs are then based upon the safe bearing power so determined, and the piles are driven to the penetration which the above formula shows necessary to give the bearing power for which they were designed. Fig. 1 shows the relation between penetration and fall for weights of different sizes driving a pile equal to supporting a load L of 14,000 lb. Diagrams are easily constructed for other loads.



NOTE: THE LAST FIVE BLOWS SHOULD BE MADE WITH A FALL OF HAMMER OF BETWEEN 8 AND 12 FT.
THE FORMULA IS BASED ON A FREE FALL OF THE HAMMER; A SUITABLE REDUCTION SHOULD BE MADE IN THE ACTUAL WEIGHT OF THE HAMMER TO ALLOW FOR FRICTION IN THE FALL ROPE.

FIG. 1.—Relation Between Penetration and Fall of Hammer in Pile Driving.

Concrete Piles may be broadly divided into two classes: (1) Those molded in place, and (2) those molded, cured and driven. The first of these classes (Raymond) is made by driving a mandrel into the ground and filling the hole so formed with concrete. In one well-known pile of this type, a thin steel sheet is fitted over a tapered mandrel before driving. This shell, which is left in the ground when the mandrel is withdrawn, is filled with concrete and left to rust away. Another well-known pile (Simplex) of the molded-in-place type uses a hollow cylindrical mandrel which is filled with concrete after having been driven to the desired depth and raised a few feet at a time, the concrete flowing out at the bottom and filling the hole in the earth. Most separately molded and many molded-in-place piles are reinforced with steel. Jetting is used extensively in placing separately molded concrete piles, but most are driven into place. Jetting is not often practical or safe in city work on account of danger to the foundations of adjoining buildings. Driving by hammer necessitates a cushioned driving head. The choice of type of concrete pile should be governed by considerations such as whether the pile derives its supporting power from skin friction or column action, the character of the soil, presence of stones, springs, etc.

Spacing of Piles. Wood piles are preferably spaced not closer than 2½ ft. or 3 ft. on centers. If driven closer than this, one pile is liable to force another up; piles relying on skin friction lose some of their bearing power when driven too close together. Occasions arise, however, when closer spacing is inevitable. Twenty-one inches is probably a minimum center distance.

Capping of Piles. Wood piles are capped with timber or concrete. The former is used where stonework is to be supported, and sometimes with concrete. Where concrete is used it is customary to omit the timber platform and place the concrete directly around the pile heads. Concrete placed in this way necessarily gets a bearing on all piles. The piles should be embedded 6 in. in the concrete.

Cost of Piles. Concrete piles cost from $1.00 to $1.10 per lin. ft.; wood piles from $0.25 to $0.30 per ft.

MASONRY CONSTRUCTION

Brickwork. Building walls are built of hard, well-burned brick. Hard-burned or arch brick may be laid in the core of the walls only; soft-burned or salmon brick should never be used on important work. Strong brick masonry is laid up in mortar composed of one part Portland cement to three parts of clean, coarse, sharp sand, tempered with one part of slaked-lime paste. For work of less importance the mortar is made cheaper by decreasing the amount of cement and increasing the amount of sand. An average mortar consists of one part cement, one part lime paste and six parts sand (see p. 569). The poorest mixture that should be used is one part lime to six parts sand. Brick should be laid in a full bed of mortar and shoved into place in order to secure a solid bearing and a joint of even thickness.

Laying and Bonding Brickwork. Brick laid with the long dimension parallel with the wall are called stretchers, and when laid with the long dimension across the wall are called headers. In order to tie or bond brickwork together, the various bonds shown in Fig. 2 are used. Arches over windows are laid in consecutive rings one-half brick high with small joints, and each ring is plastered over before the next ring is placed. Adjacent rings should break joints. Radius of arch should be from one to one and a quarter times the width of the opening. Before laying, all brick should be thoroughly wetted if the weather is warm, but should be kept perfectly dry in freezing weather. The **cost of labor in laying brickwork** in ordinary manufacturing buildings is about $8.00 per 1000 brick.

Strength of Brickwork. The safe working stress for brickwork, including walls and piers, with heights less than six times the least dimension, is 8 tons per sq. ft. if laid in lime mortar (1 lime, 6 sand). If laid in 1 : 3 cement mortar, 20 tons is allowed by the New York and Boston building laws. In isolated piers in which the height is from 6 to 12 times the least dimension, the stresses should be taken as 12 and 7 tons per sq. ft., respectively.

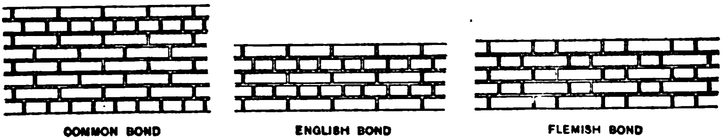


Fig. 2.—Bonds Used in Bricklaying.

Stone Work. Stone masonry is divided into two general classes, viz., rubble and ashlar (see Fig. 3). **Rubble masonry** work is built up of rough stone of irregular shape and size, coursed and uncoursed. Rubble work is used principally for retaining walls, and is sometimes laid up without mortar. Mortar, when used, occupies from 1/5 to 1/3 of the mass, the amount increasing as the stones are smaller. **Ashlar masonry** is built of up stones of rectangular shape on the exterior face of the wall, and is further classified into coursed and broken ashlar, depending on whether the stones of the same course are of the same height or of different heights.

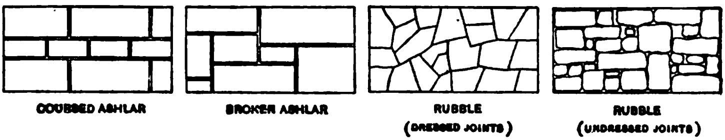

Fig. 3.—Ashlar and Rubble Masonry.

Allowable Working Compressive Stresses on Masonry in tons per sq. ft. according to the building laws of the principal American cities, range as follows:

Granite ashlar	60–170	Rubble in lime	4–6
Limestone ashlar	40–166	Brickwork in Portland cement	15–18
Marble ashlar	40–86	Brickwork in natural cement	12–15
Sandstone ashlar	30–115	Brickwork in lime and cement	10–12
Rubble in Portland cement	12–20	Brickwork in lime	8
Rubble in natural cement	7–12	Concrete, Portland cement, 1 : 2 : 4	15–29
Rubble in lime and cement	8–12	Concrete, natural cement, 1 : 2 : 4	8–9

Retaining Walls. A wall used to sustain the pressure of earth behind it is called a retaining wall. The proportion generally used for walls with fill level at the top is to make the thickness four-tenths of the height, the faces of the wall being plumb. An additional factor of safety is obtained by building the face on a batter. Care should be taken in the design of a wall that the allowable soil pressure is not exceeded, and that drainage is provided for the back of the wall. The foundation should be at least 4 ft. below the ground level where frost is expected.

It is impossible to derive formulæ for the earth pressure on the back of the wall which will take account of all the actual conditions. Assuming the earth to be a loose, homogeneous, granular mass, and the coefficient of friction to be independent of the pressure, Rankine deduced the following formula:

$$P = (\tfrac{1}{2}wh^2 + vh)\tan^2(45° - \tfrac{1}{2}a)$$

the center of pressure being at a height $\tfrac{1}{3}h(wh + 3v)/(wh + 2v)$ above the base, where P = earth pressure per lin. ft. of the wall, lb.; h = height of the wall, ft.; w = weight of earth per cu. ft., lb.; v = weight of superposed load per sq. ft. of surface, lb., and a = angle of repose of the earth, deg. (For values of a see p. 232.) The retaining wall should have sufficient thickness at the base so that the resultant of the earth pressure, P, combined with the weight of the wall, will fall within the middle third of the base. If this resultant falls at the outside edge of the middle third, the maximum vertical pressure on the foundation (at the outer edge of the base) will be equal to $2W/T$ lb. per sq. ft., where W is the weight of 1 lin. ft. of the wall, and T the thickness of the wall at the base, ft.

Building Walls. The following table gives the thickness in inches of brick, stone or solid concrete walls as specified in the Chicago Building Ordinances as amended to September, 1912: Walls less than 50 ft. long from end to end or between cross walls may be 4 in. thinner, but not less than 12 in. thick, and walls of dwelling houses may be 8 in. for a one-story house, and 8 in. in the second story of a two-story house with a story height of less than 14 ft.

Stories	Basement	1	2	3	4	5	6	7	8	9	10	11	12
One story	12	12											
Two stories	16	12	12										
Three stories	16	16	12	12									
Four stories	20	20	16	16	12								
Five stories	24	20	20	16	16	16							
Six stories	24	20	20	20	16	16	16						
Seven stories	24	20	20	20	20	16	16	16					
Eight stories	24	24	24	20	20	20	16	16	16				
Nine stories	28	24	24	24	20	20	20	16	16	16			
Ten stories	28	28	28	24	24	24	20	20	20	16	16		
Eleven stories	28	28	28	24	24	24	20	20	20	16	16	16	
Twelve stories	32	28	28	28	24	24	24	20	20	20	16	16	16

Curtain Walls. When the entire weight of a building is sustained on a steel or concrete framework, the walls may be thin, since they have to support only their own weight in each story. Such walls are called curtain walls, and should be at least 12 in. thick for an 18-ft. height, 16 in. for a 24-ft. height, and 20 in. for a 30-ft. height.

Partitions or thin walls used to subdivide a building into rooms, are of various types, the principal ones being wooden or stud partitions (see Table 14, p. 1279), terra cotta tile, concrete block, and metal lath and plaster. **Terra cotta partitions** are formed of hollow cellular tile, usually 12 in. square and 3, 4 or 6 in. thick, and are laid up with lime mortar like ordinary brickwork. The outside of the tile is then plastered in the usual way for finish. Partitions constructed in this way are both fire- and sound-proof. A safe height for 3-in. block partitions is 12 ft.; for 4-in., 16 ft; and for 6-in., 20 ft. The unsupported length should not exceed the safe height. The crushing strength of solid terra cotta is from 6000 to 7000 lb. per sq. in. **Concrete block partitions** are made up in the same manner as terra cotta, and serve the same purpose. They are much heavier, and for this reason not so generally used. Common practice, shown by the building laws of Philadelphia and Buffalo, allows hollow spaces in the blocks equal to

¼ the cross-section, and working stresses of from 100 to 150 lb. per sq. in. of solid concrete, excluding the area of the hollow spaces. **Metal-lath partitions** are much used, on account of their lightness and economy of space. They are usually formed of ⅞-in. or 1-in. steel channels fastened to the floors and ceilings and spaced 12 in. on centers for spans of over 10 ft., and up to 16 in. apart for smaller spans. These channels are then covered with wire fabric or expanded metal wired on, and plastered over on both sides, usually with two coats of mortar and a finish coat on each side of hard-setting mortar, with a total thickness of 2 in.

Terra Cotta Floor Construction. The floors and roofs of steel-frame buildings are often constructed with terra cotta hollow-tile arches, spanning between and protecting the steel beams. These arches are of two classes,

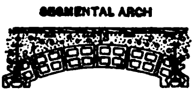

FIG. 4.

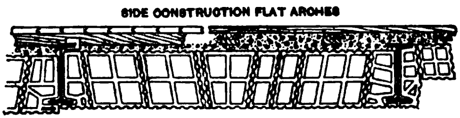

FIG. 5.

Terra Cotta Floor Construction.

segmental (Fig. 4) and flat (Figs. 5 and 6), the latter being of end construction or side construction. The segmental arch is the cheapest and strongest and is well adapted to factories, warehouses and locations where a flat ceiling is not required. The end-construction type of flat arch is nearly 50 per cent. stronger, for the same weight, than the side construction. Proper protection of the bottom flange of the steel beams should be provided for all

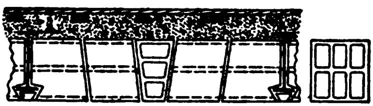

FIG. 6.—Terra Cotta Tile Floor Arch, End Construction.

types of this construction and the beams securely tied together with rods to resist thrust. All blocks should be set in Portland cement mortar. Cinder concrete filling is placed on top of the arches and leveled off to receive flooring. If wood flooring is used, nailing strips are bedded in the concrete and the flooring nailed to these strips, the strips being anchored to the tops of steel beams. Table 3 gives the spacing (in ft.) of ¾-in. tie rods to provide a sufficient cross-section to withstand the thrust of the arch with a total load on the arch of 100 lb. per sq. ft. For other loadings, multiply the tabular values by 100 and divide by the loading to be used. Tie rods should be placed in the line of thrust if possible, usually 3 in. above the bottom of the beam. In segmental arches the effective rise is equal to the vertical distance between the highest point of the concave surface and the springing line or chord; the effective rise of a flat arch may be taken at 2.4 in. less than the arch depth. Tables 4 and 5 give safe loads for end-construction flat arches and segmental arches. The weights of the arches themselves are included in the safe loads in Table 4, and may be computed at 0.06 lb. per cu. in. of solid terra cotta.

Table 3. Spacing of 3/4-in. Tie Rods for Terra Cotta Tile Arches

(Spacing in feet from center to center of rods for total load on arch of 100 lb. per sq. ft. For any other loading W, multiply tabular values by 100 and divide by W)

TIMBER CONSTRUCTION

Holding Power of Nails, Spikes and Screws in Wood. The **holding power of nails and spikes** is given in Table 6 and that of **lag screws and wood screws** in Table 7. The resistance of a lag screw increases about as the square root of the diameter; the size of the hole bored apparently has but little influence on the resistance.

Table 6. Holding Power of Nails and Spikes, in Lb. per In. of Penetration

(Tests at Watertown Arsenal, 1884)

	White pine	1	6½	1580(*a*)	No hole.
	Douglas fir	....	....	....	(½ values given for white oak.)

Lateral Resistance of Nails in Wood. According to W. K. Hatt (*Ind. Eng. Soc.*, 1900) the load in pounds supported by a nail when it fastens two boards together and is subjected to a transverse load, is $P = cd$, where d is the pennyweight designation of the nail and c has the following values:

	Common Nails		Finish Nails		Fence Nails	
	Cut	Wire	Cut	Wire	Cut	Wire
Oak	82	70	49	52	100	..
Yellow pine	50	48	42	32	90	84

The joints will slip at about 60 per cent. of these loads. The **resistance of common railway spikes** (W. K. Hatt, *Proc. Am. Ry. Eng. Assn.*, 1910) is as follows:

Resistance against	Red oak	Short-leaf pine	Long-leaf pine	Lob-lolly pine	Red gum	Screw spikes are stronger by
Direct pull, lb.	7639	4359	3955	3930	3883	1.7 to 3.8 times
Lateral pull, lb.	2026	1704	1650	1633	1619	1.2 to 2.4 times

The ultimate **pulling resistance of drift bolts** perpendicular to the grain of the wood, in lb. per lin. in., is as follows (Watertown Arsenal, 1902): 1-in. bolt driven in a 15/16-in. hole: yellow pine, 375; white oak, 3250; Douglas fir, 2250. 1-in. bolt in 13/16-in. hole: yellow pine, 740; white oak, 1300; Douglas fir, 886. Douglas fir: ¾-in. bolt in 11/16 hole, 800; in 9/16-in. hole, 1000; ½-in. bolt in 7/16-in. hole, 374; do., in 5/16-in. hole, 1000. The resistance is only about half these values when driven parallel to the grain. The holding power varies directly with the area of contact and with the compressive strength of the wood. Square drift bolts have the same resistance as round drift bolts of the same diameter.

Floors (See also p. 1329 for factory floors). The framing of wooden floors may be divided into two general types: joist construction, and solid or mill construction. The first consists of **joists** 2 or 3 in. wide, of the necessary depth, and spaced about 12 in. to 16 in. on centers. The wall ends should be built solidly into walls, and the interior ends carried by a line of girders on columns. These joists should be securely cross-bridged in each span to prevent twisting and to assist in distributing concentrated or suddenly applied loads. The floor is formed of a thickness of rough boarding on which the finish flooring is laid. **Solid or mill-construction floors** are designed to do away with the small pockets which exist in joist construction and thus reduce the fire hazard. They are generally framed with beams spaced from 8 to 11 ft. on centers and spanning from 20 to 25 ft. The wall ends of beams are built into and anchored to the wall, and the interior ends carried on columns and tied together to form a continuous tie across the building. In all cases care should be taken to provide sufficient bearing at the points of support so that the allowable intensity of compression across the grain, as given in the tables on p. 593, is not exceeded. In case it is desirable to omit columns, or the floor load requires a closer spacing of beams, girders are run lengthwise of the building over the columns to take the beams, the ends of which are hung in hangers or stirrup irons and tied together over or through the girders. This is called **intermediate framing.** Steel beams are sometimes used in place of wooden beams in this type of construction, in which case a wooden strip is secured to the top flange of the beam to take the nailing of the plank, or the plank is laid directly on top of the beam and secured by spikes driven from below and clinched over the flange. The floor is formed of 3- or 4-in. plank, grooved in each edge and put together with splines and securely spiked to beams. On top of the plank is laid an intermediate or top flooring having a layer of sheathing paper between the plank and flooring. In case the floor loads require an excessive thickness of plank, or in localities where heavy plank is not easily obtainable, the flooring is built up of 3 × 4-in., 4 × 6-in., or other sized pieces, placed on edge and securely nailed together.

Floor Loads are regulated by the building laws in all municipalities, and vary slightly in different localities. For districts not thus regulated, the following values will serve as a guide for live loads (lb. per sq. ft.): Cotton mills, 75 to 100; machine shops, 125 to 250; foundries, 200 to 300; roof loads (flat), 40 to 50, depending on locality and snowfall.

Table 8 gives the properties of mill floors made of matched and dressed plank, and of laminated floors made of planks on edge, laid close. For the meanings of "coefficient of strength" and "coefficient of deflection" see the following two pages.

Table 8. Properties of Yellow Pine Floors per Foot Breadth

* Use for 2½ × 6, 3 × 6, and 6 × 6 pieces; for 2 × 6 and 6 × 6, use values for mill floors.

Beams

Properties of Wooden Beams. Table 9 is adapted from the "Yellow Pine Handbook" for 1913. The "nominal size" of a timber is indicated by the breadth and depth of the section in inches. The "actual size" indicates the size of the dressed timber, and these sizes are dressed as indicated. "S1S1E" indicates that the piece is "dressed on one side and one edge," "S4S" indicates that the piece is "dressed on four sides." The moment of inertia and section modulus are with the neutral axis perpendicular to the depth at the center. The **coefficients of strength** are given for the fiber stress of 1000 lb. per sq. in. and are the safe loads in pounds uniformly distributed, including its own weight, for a beam 1 ft. long. The safe load

for any span is obtained by dividing the proper coefficient by the length of the span in feet, and multiplying by the ratio of the fiber stress it is desired to employ to 1000 lb. per sq. in.

To select a **beam to support a given uniformly distributed load** on a given span, find the coefficient of strength required as follows: Multiply the given uniformly distributed load in pounds by the span in feet, and by the ratio of 1000 lb. per sq. in. to the fiber stress it is desired to employ, and refer to the table for a beam having that coefficient. To select a beam for supporting a **load concentrated at the center of** the **span**, multiply the concentrated load by 2 and consider the result an equivalent uniformly distributed load. If the loads are not applied as above, the necessary size must be found from the section modulus, as explained on p. 404. A beam whose span is less than from 10 to 15 times its depth is likely to have its safe load limited by the longitudinal shearing stress, and the safety of such beams should always be examined.

The **coefficients of deflection** given are the deflections in inches of beams 1 ft. in span with a uniformly distributed load of 1000 lb., the modulus of elasticity being taken at 1,620,000 lb. per sq. in., which is a reasonable value for yellow pine under loads not long continued. For continuous dead loads, the tabular coefficient of deflection should be multiplied by 2. For other woods than longleaf yellow pine, multiply the tabular coefficient of deflection by the ratio of 1,620,000 to the modulus of elasticity of the wood used. (See the table of the properties of different varieties of structural timber, p. 591.) The deflection of a beam of a given span under uniformly distributed load is obtained by multiplying the coefficient of deflection of the beam by the cube of the span in feet and by the number of 1000-lb. units in the given load. Coefficients of deflection under concentrated loads applied at the middle of the span may be obtained by multiplying the values in the table by 1.6.

Safe Loads for Wooden Beams. Table 10 is based upon the working unit stresses adopted by the American Railway Engineering Association (see p. 593), and gives the uniformly distributed safe loads for rectangular sections 1 in. thick; the safe load for a beam of any thickness is found by multiplying the tabular value by the thickness of the beam in inches. The safe loads include the weight of the beams and are computed on the assumption that the beams are braced against lateral deflection. The table also gives minimum and maximum spans and coefficients of deflection.

The maximum safe loads as limited by the allowable shearing stresses along horizontal axes of beams have been calculated from the formula: Maximum safe load = $\frac{4}{3}$ × area of section × safe unit stress for longitudinal shear. These limits should not be exceeded to avoid failure of the beam by horizontal shear. The deflection in the center of the span for uniformly distributed and permanently applied loads is obtained from the coefficients of deflection by dividing the depth of the beam, in inches, into the corresponding coefficients; the results are only approximate, as the modulus of elasticity varies with the moisture content of the wood.

The deflection of beams intended to carry plastered ceilings should not exceed $\frac{1}{360}$ of the span; the table gives the maximum spans for this limit and for uniform and permanently applied loads.

For loads concentrated in the center of the span, use one-half the values for the tabular loads and four-fifths of the coefficients of deflection. For special cases of loading, see Table 12*b*, p. 403.

Columns

Wooden Columns are usually of hard pine, either square or round, should have cast-iron caps for supporting the beams and rest on cast-iron pintles which carry the load down to the iron column cap or base plate below. In place of pintles, the columns are often run down and rest directly on the cap or plate. For hard-pine columns whose length is not more than twelve times the diameter or least side, the safe load may be found by multiplying the sectional area in square inches by 1000; when the length exceeds the above ratio, the column is liable to bend. For safe loads for square columns with a unit stress of 1000 lb. per sq. in., see Table 28, p. 438. The **working unit stresses for wooden columns** adopted by the American Railway Engineering Association are given in Table 11 for ratios of l/d ranging between limits of 15 and 30.

Table 11. Unit Working Stresses for Wooden Columns, Lb. per Sq. In.

l = effective length of column, in inches; d = least side or diam., in inches; unit working stress = $K[1 - (l/60d)]$

Cast-iron Columns are often used in place of wooden columns on account of the saving in size. Building laws generally limit the stresses and ratio of length to diameter of this type of column. Table 12 gives allowable loads according to the New York Building Law formula, $p = 9000 - (40\,l/r)$, r being the least radius of gyration and l the length—both in the same units—and p the allowable load in lb. per sq. in. of cross-sectional area.

Table 12. Round and Square Cast-iron Columns

(Allowable Loads in Thousands of Pounds)

ROUND CAST-IRON COLUMNS

Wrought-iron Pipe is often used for columns under light loads. Table 13 gives the safe loads on Standard size pipes used as columns, according to the New York building laws. For Extra Strong and Double Extra Strong pipe used as columns, the safe loads will increase in the same proportion as the weight per foot.

Table 13. Standard Pipe Columns

(Loads in tons of 2000 lb., based on New York Building Code.)

$S = 15{,}200 - (58\,l/r)$

S = allowable compressive stress for steel, lb. per sq. in.;
l = length of column, in.;
r = least radius of gyration, in.

Length, ft.	Size of pipe, in.												
	3	4	5	6	7	8	9	10	11	12	13	14	15

NOTE.—Loads above or to the left of the zigzag line correspond to values of l/r greater than 120.

Stud Partitions as Columns. Table 14, taken from the "Yellow Pine Handbook," gives the safe load in pounds per lin. ft. of partition, based on the formula: allowable stress $= 1000[1 - (l/80\,d)]$; it is assumed that the partition is bridged midway in height.

Table 14. Safe Loads on Stud Partitions

(Based on studs being bridged at center)

Nominal size of studs, in.	Distance on centers, in.	Height, ft.	Per lineal foot of partition			Nominal size of studs, in.	Distance on centers, in.	Height, ft.	Per lineal foot of partition		
			Safe load, lb.	Weight, lb.	Board feet				Safe load, lb.	Weight, lb.	Board feet
2×4	12	8	3,723	16.30	6.66	2×6	16	8	4,326	20.24	8.00

Stairs. The sum of the rise and run should be equal to from 17 in. to 17½ in. In case of greater rise the tread should narrow accordingly, or *vice versa.*

Roofs

The roofs of buildings of joist and mill construction are framed in a manner similar to the floors of each type, and should be securely anchored to the walls and columns. In case columns are not desired in the top story, trusses of either steel or wood of any of the regulation types are used. For spans up to 35 ft. trussed beams can often be used to advantage.

Loads on Roofs. Where **snow** is likely to occur, the minimum load should be 25 lb. per horizontal sq. ft. of roof for slopes up to 20 deg., and 1 lb. less for each additional degree up to 45 deg. In severe climates this load must be increased. Table 15 gives the **wind pressure** in lb. per sq. ft. normal to the roof, according to Hutton's formula $P_n = P \sin a^{1.84 \cos a - 1}$ where P is the normal pressure (assumed to be 30 lb.) per sq. ft. on a vertical surface, and a is the inclination of the roof surface to the horizontal, in degrees. For other pressures than 30 lb. per sq. ft., the values change in proportion. For slopes over 60 deg. the values given in the table for 60 deg. are applied.

Table 15. Normal Wind Pressure, Lb. per Sq. Ft.

Slope a, deg.	Pressure, P_n, per sq. ft., lb.	Slope a, deg.	Pressure, P_n, per sq. ft., lb.	Slope a, deg.	Pressure, P_n, per sq. ft., lb.	Slope a, deg.	Pressure, P_n, per sq. ft., lb.
5	3.9	20	13.8	35	22.6	50	28.6
10	7.2	25	17.0	40	25.0	55	29.6
15	10.7	30	19.9	45	27.0	60	30.0

Dead Loads. Table 16 gives the approximate weight per sq. ft. of the roofing materials commonly used.

Table 16. Approximate Weights of Roofing Material

Roofing Material	Weight per sq. ft., lb.
Copper, No 22 B. W. G.	1¼
Corrugated galvanized iron, No. 20 B. W. G. (No. 26 B. W. G)	2¼ (1¼)
Felt, 2 layers	½
Felt and asphalt or coal-tar	2
Glass, ⅛ in. thick	1¾
Lath and plaster ceiling	6–8
Lead, ⅛-in. thick	7½
Mackite, 1 in. thick, with plaster	10
Sheathing, hemlock, 1 in. thick (white pine, spruce) [yellow pine]	2 (2¼–2½) [3½]
Shingles, 6 × 18 in. 6 in. to weather	2
Skylight, glass 3/16 to ½ in. including frame	4–10
Slag roof, 4-ply, with cement and sand	4
Slate, ⅛ in. thick, 3-in. double lap (3/16 in. thick)	4½ (6¾)
Terneplate, IC (IX)	½ (⅝)
Tiles (plain), 10½ × 6¼ × ⅝ in., 5¼ in. to weather	18
Tiles (Spanish), 14½ × 10½ in., 7¼ in. to weather	8½
Zinc, No. 20 B. W. G	1½

Combined Roof Loads. In climates corresponding to that of Pittsburgh, ordinary roofs up to 80 ft. span should carry the minimum loads given in Table 17 per sq. ft. of exposed surface, applied vertically, to provide for dead, wind and snow loads combined. For roofs in climates where no snow is likely to occur, reduce these loads by 10 lb. per sq. ft., but no roof or any part thereof should be designed for a total live and dead load less than 40 lb. per sq. ft. The weight of the jack rafters, purlins, and supporting trusses must be added (see p. 1283 for empirical formulæ giving the weights of roof trusses).

Table 17. Combined Roof Loads

Roof Covering		Roof load per sq. ft., lb.
Gravel or Composition Roofing	on boards, flat slope, 1 to 6 or less	50
	on boards, steep slope, more than 1 to 6	45
	on 3-in. flat tile or cinder concrete	60
Corrugated sheeting on boards or purlins		40
Slate	on boards or purlins	50
	on 3-in. flat tile or cinder concrete	65
Tile on steel purlins		55
Glass		45

Timber Trusses

Stresses in Trussed Beams. Referring to Fig. 7, for a uniformly distributed load of W lb., assuming that the load is carried by the members as a simple truss (without allowance for the continuity of the beam) and writing $h = \sqrt{d^2 + l^2/4}$.

	In Fig. 7a	In Fig. 7b
Tension in rod	$= Wh/4d$	$= Wh/3d$
Compression in strut	$= W/2$	$= W/3$
Compression in beam	$= Wl/8d$	$= Wl/9d$

For a single concentrated load, W, in the middle of the truss in Fig. 7a, the above stresses will all be doubled. For a concentrated load $W/2$ on each of the vertical struts of Fig. 7b, the above stresses should be multiplied by 1.5

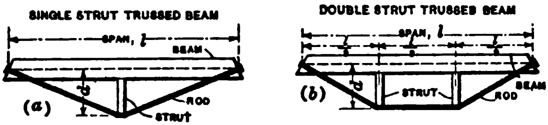

Fig. 7.—Trussed Wooden Beams.

The beam should be large enough so that the unit stress found by adding the unit stress due to the direct compression to the compressive stress caused by bending (considering the length between the strut and the support as a simple beam) shall not exceed the allowable compressive stress for the kind of wood used.

Stresses in Timber Trusses. The most common types of trusses involving wooden compression members are shown in Figs. 8–17 (from Godfrey on "Buildings"). For the **roof trusses** with sloping top chords, Figs. 8–11, the stress in any member may be found by multiplying the coefficient from Tables 18–21 by the total load on the truss (lb.), if the load is vertical and uniformly distributed. The − signs indicate tensions; the + signs, compressions. For other loadings, it will be necessary to draw a stress diagram. For members under both axial and flexural stress, see preceding paragraph.

For trusses with parallel chords shown in Figs. 12–17, the stress in any member is written next to the member, in the figure, in terms of the load on each panel point, for equal vertical loads on each panel point. For other loadings, a stress diagram should be drawn.

* 30 deg. pitch.

For a tabulation of coefficients for **Stresses in Steel Roof Trusses**, see the Carnegie Steel Co.'s "Pocket Companion," 16th edition, pp. 308–310.

Weights of Trusses. For **trusses with wooden compression members and steel tension rods**, the **approximate weight** of the truss, in lb. per sq. ft. of the area of the horizontal projection of that portion of the roof supported by one truss, may be taken as w = (span/25) + (span^2/6200), where the span is measured in feet. For **steel trusses**, for a roof load of about 40 lb. per sq. ft. and span L (ft.), the approximate additional load due to the weight of the truss itself will be $\frac{1}{3}(\sqrt{L} + \frac{1}{3}L)$ lb. per horizontal sq. ft. For greater loads, multiply by the ratio: load per sq. ft./40.

Joints for Timber Trusses. A plain butt joint (Figs. 18 and 19) with steel splice plates is probably the best way to join two members whose axes lie in the same straight line. By extending the splice plates, three or more members may be securely joined. The splice plates are often pieces of plank, in which case h should equal ½b. Special cast-iron pieces (Fig. 20) are often used to join web members and chords. For timber roof trusses, a satisfactory end joint is that shown in Fig. 21.

Choice of Roof Trusses. Wooden Trusses. For pitched roofs with span $L \leq 20$ ft., the simple king-post truss (Fig. 4, p. 225) may be used, and for $L \leq 40$ ft., the type shown in Fig. 10, p. 228. When $L = 40$ to 80 ft., a triangular truss with six vertical struts and a center tie rod, equally spaced, with a tie rod running from the bottom of each strut to the top of the next inner one and from the bottoms of the two inner struts to the peak, is an approved construction. For flat roofs the Howe truss (Fig. 14) may be used up to $L = 130$ ft. The top chord is then made to extend at each end to the full length of the

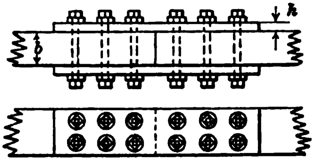

Fig. 18.

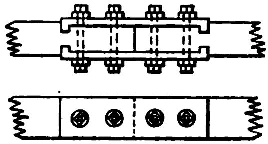

Fig. 19.

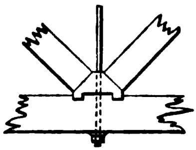

Fig. 20.

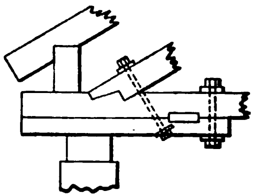

Fig. 21.

Joints for Timber Trusses.

truss, the ends being supported by struts or built into the walls, and may be slightly inclined to the bottom chord for drainage (see Fig. 10, p. 1327). Depth of truss, $\leq 0.1L$; length of each panel, $\leq 0.1L$; spacing of trusses, 10 to 15 ft. apart. Steel Trusses. For pitched roofs, trusses of the types shown in Figs. 8, 9 and 10 are the most satisfactory, Fig. 8 being suitable for $L < 40$ ft., Fig. 9 for $L \leq 50$ ft., and Fig. 10 for $L \leq 90$ ft. For flat roofs, latticed girders (*i.e.*, two superposed and staggered Warren trusses, Fig. 7, p. 227) and Howe trusses may be employed. Spacing of steel trusses, 20 to 25 ft. For various types of trusses suitable for spans up to 200 ft., see *The Brickbuilder*, Mar., 1915.

STEEL FRAMED STRUCTURES

(For loads allowed by various city ordinances, see p. 388)

Specifications. The following excerpts are taken from the American Bridge Co. specifications.

Design

Loads. For structures carrying traveling machinery, such as cranes, conveyors, etc., add 25 per cent. to the stresses resulting from the live load, to provide for the effect of impact and vibrations.

Wind Pressure (assumed to act horizontally in any direction). For finished structures, 20 lb. per sq. ft. on the sides and ends of buildings and on the vertical projection of roof surfaces. For buildings in process of construction, 30 lb. per sq. ft. on vertical surfaces and the vertical projection of inclined surfaces of all exposed metal or other framework.

Unit Stresses. For allowable unit stresses according to the building laws of various cities, see Table 7, p. 388. All parts of structures to be proportioned so that the sum of the dead and live loads, together with the impact, if any, shall not cause the stresses to exceed the following amounts in lb. per sq. in.

Tension, net section, rolled steel	16,000
Direct compression, rolled steel and steel castings	16,000
Bending, on extreme fibers of rolled shapes, built sections, girders, and steel castings	16,000
Bending on extreme fibers of pins	24,000
Shear on shop rivets and pins	12,000
Shear on bolts and field rivets	10,000
Shear—average—on webs of plate girders and rolled beams, gross section	10,000
Bearing pressure on shop rivets and pins	24,000
Bearing on bolts and field rivets	20,000

The pressure per linear inch on expansion rollers shall not exceed 600 times the diam. of rollers in inches.

Axial compression of gross sections of columns, for ratio of l/r up to 120, 19,000 − (100 l/r), with a maximum of 13,000, where l = effective length of members, and r = corresponding radius of gyration of section—both in inches. For ratios of l/r up to 120, and for greater ratios up to 200, use the amounts given in the following table. For intermediate ratios, use proportional amounts.

Ratio	60	70	80	90	100	110	120
Amount	13,000	12,000	11,000	10,000	9,000	8,000	7,000
Ratio	130	140	150	160	170	180	190
Amount	6,500	6,000	5,500	5,000	4,500	4,000	3,500

For bracing and combined stresses due to wind and other loading, the permissible working stresses may be increased 25 per cent.—provided the section thus found is not less than that required by the dead and live loads alone.

Proportion of Parts

General. The effective or unsupported length of main compression members not to exceed 120 ×, and for secondary members 200 ×, the least radius of gyration.

In proportioning columns, provision to be made for eccentric loading. In proportioning tension members, net section to be used. Rivet holes deducted to be taken ⅛ in. larger than the nominal size of rivets.

Members subject to the action of both axial and bending stresses to be proportioned so that the greatest fiber stress will not exceed the allowed limits in that member. Members subject to alternate stresses of tension and compression to be proportioned for the stress giving the largest section, but their connections to be proportioned for the sum of the stresses.

Girders. Rolled I-beams and channels and built-up members used as beams and girders to be proportioned by their moments of inertia. Plate-girder webs to have a thickness not less than 1/160 of the unsupported distance between flange angles. Webs to have stiffeners, generally in pairs, over bearings, at points of concentrated loading, and at other points where the thickness of the web is less than 1/60 of the unsupported distance between flange angles, generally not farther apart than the depth of the web plate, with a maximum limit of 6 ft.

Lateral unsupported length of beams and girders not to exceed 40 × the width of compression flange. When the unsupported length (l) exceeds 10 × the width (b) of compression flange, the stress per sq. in. in the compression flange shall not exceed 19,000 − (300 l/b).

Details of Steel Construction

General. Adjustable members in any part of structures preferably to be avoided. Sections preferably to be made symmetrical. No connection, except lattice bars, to have less than two rivets. Trusses preferably to be riveted structures. Heavy trusses of long span, where the riveted field connections would become unwieldy, or for other good reasons, may be designed as pin-connected structures.

Abutting joints in compression members faced for bearing to be spliced sufficiently to hold the connecting members accurately in place. All other joints in riveted work whether in tension or compression, to be fully spliced.

Lateral, longitudinal and transverse bracing in all structures preferably to be composed of rigid members, and designed to be sufficient to withstand wind and other lateral forces when building is in process of erection as well as after completion.

Girders. Two or more rolled beams used to form a girder are to be connected by bolts and separators at intervals of not more than 5 ft. All beams having a depth of 12 in. and more to have at least two bolts to each separator. Flange plates of all girders to be limited in width, so as not to extend more than 6 in. beyond the outer line of rivets connecting them to the angles, or 8 × thickness of thinnest plate.

Web stiffeners to be in pairs, and have a close bearing against the flange angles. Those over the end bearing or forming the connection between girder and column to be on fillers. Intermediate stiffeners may be on fillers or crimped over the flange angles. Web plates of girders to be spliced at all points by a plate on each side of the web, capable of transmitting the full stress through splice rivets.

Riveting. Minimum distance between centers of rivet holes to be three diameters of the rivet; but preferably not less than 3 in. for ⅞-in., 2 ½ in. for ¾-in., 2 in. for ⅝-in., and 1¾ in. for ½-in. rivets. Maximum pitch in line of stress for members composed of plates and shapes to be 6 in. for ⅞-in. rivets, 6 in. for ¾in., 4½ in. for ⅝-in., and 4 in. for ½-in. rivets.

For angles in built sections with two gage lines, with rivets staggered, maximum pitch in each line to be twice as great as given above. Where two or more plates are in contact, rivets not more than 12 in. apart in either direction to be used to hold plates together.

Minimum distance from center of any rivet hole to a sheared edge to be 1½ in. for ⅞-in. rivets, 1¼ in. for ¾-in., 1⅛ in. for ⅝-in., and 1 in. for ½-in. rivets; and to a rolled edge, 1¼, 1⅛, 1, and ⅞ in., respectively. Maximum distance from any edge to be 8 × thickness of plate.

Pitch of rivets at ends of built compression members not to exceed four diameters of the rivets for a length equal to 1½ × maximum width of the member.

In transmitting stresses between riveted pieces it is customary to disregard friction and to proportion rivets to the entire stress to be transmitted. They must be of sufficient size and number to resist shear and to afford such bearing area as not to cause distortion of the metal at the rivet holes. In the case of beams which frame opposite and of single-web girders, this latter condition often necessitates a greater thickness of web than required by the shearing stresses.

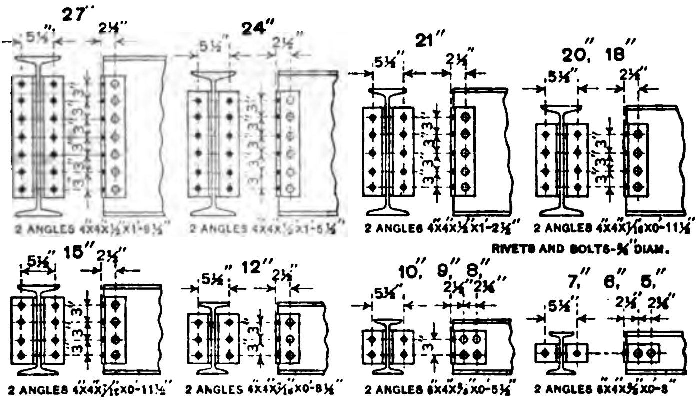
Latticing. Open sides of compression members to be provided with lattice bars, having tie plates at each end and at intermediate points where the lattice is interrupted. Tie plates to be as near the ends as practicable. In main members carrying calculated stresses, end tie plates to have a length not less than the distance between the lines of rivets connecting them to the flanges, and intermediate ones not less than half this distance. Their thickness not to be less than 1/50 of same distance.

Latticing of compression members to be proportioned to resist a shearing stress equal to 2 per cent. of the direct stress. Minimum thickness of lattice bars to be for single lattice, 1/40, and for double lattice, 1/60 of the distance between the end rivets. Minimum widths as follows. For 15-in. channels, or built sections with 3½- and 4-in. angles, 2½ in. (⅞-in. rivets); for 12-, 10- and 9-in. channels, or built sections with 3-in. angles, 2¼ in. (¾-in. rivets); for 8- and 7-in. channels or built sections with 2½-in. angles, 2 in. (⅝-in. rivets); for 6- and 5-in. channels, or built sections with 2-in. angles, 1¾ in. (½-in. rivets).

Inclination of lattice bars with axis of member generally to be not less than 45 deg. When distance between rivet lines in flanges is more than 15 in., if a single rivet bar is used, lattice to be double. The pitch of lattice connections along flange, divided by least radius of gyration of member between connections, to be less than the corresponding ratio of member as a whole.

Pins. Pin holes to be reinforced by plates where necessary. At least one plate to be as wide as the projecting flanges will allow; where angles are used, this plate to be on the same side as the angles. Plates to contain sufficient rivets to distribute their portion of the pin pressure to the full cross-section of the member. Pins to be long enough to insure a full bearing of all parts connected upon the turned-down body of the pin. Members packed on pins to be held against lateral movement.

Table 22. Limiting Values of Beam Connections



I-beams		Value of web connection	Values of outstanding legs of connection angles

10	25	27,900	17,700	7.4	⅜	14,100	9.2	⅝
10	22	20,900	17,700	6.9	⅜	14,100	8.6	⅝
9	21	26,100	17,700	5.7	⅜	14,100	7.1	⅝
8	18	24,300	17,700	4.3	⅜	14,100	5.4	⅝
8	17½	18,900	17,700	4.4	⅜	14,100	5.5	⅝
7	15	11,300	8,800	6.2	⅜	7,100	7.8	⅝
6	12¼	10,400	8,800	4.4	⅜	7,100	5.5	⅝
5	9¾	9,500	8,800	2.9	⅜	7,100	3.6	⅝

t = web thickness, in bearing, to develop max. allowable reactions, when beams frame opposite.

Connections are figured for bearing and shear (no moment considered).

The above values agree with tests made on beams under ordinary conditions of use.

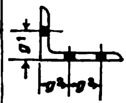
Where web is enclosed between connection angles (enclosed bearing), values are greater because of the increased efficiency due to friction and grip.

Special connections shall be used when any of the limiting conditions given above are exceeded—such as end reaction from loaded beam being greater than value of connection, shorter span with beam fully loaded; or a less thickness of web when maximum allowable reactions are used.

Standard Details and Connections are shown in the figures accompanying Tables 22 and 23. Connections in riveted steel framing (built-up members) are usually made with **gusset plates** (Figs. 22 and 23) and the standard connection angles of Table 22.

Table 23. Gages for Angles, Inches

Leg	8	7	6	5	4	3½	3	2½	2	1¾	1½	1⅜	1¼	1	¾
g1	4½	4	3½	3	2½	2	1¾	1⅜	1⅛	1	⅞	⅞	¾	⅝	½
g2	3	2½	2½	2											
g3	3	3	2¼	1¾											
Max. rivet	1⅛	1	⅞	⅞	⅞	⅞	⅞	¾	⅝	½	⅜	⅜	⅜	¼	¼



For column details, 6 in. leg (½ in. thick or less) against column shaft, g2 = 1¾ in., g3 = 3 in. For diagonal angles, etc., gage in middle, where riveted leg equals or exceeds 3 in. for ¾ in. rivets, 3½ in. for ⅞ in. rivets. Use special gages to adapt work to multiple punch, or to secure desirable details.

Properties of Structural Steel

Safe Loads for I-beams. The coefficient of strength, fiber stress 16,000 lb. per sq. in., given in Tables 25 to 29, is the safe load in pounds uniformly distributed, including the weight of the beam itself, for a beam 1 ft. long. The safe uniformly distributed load for any span, so far as flexural stresses are concerned, is obtained by dividing the proper coefficient by the span in feet. If it is desired to use some stress other than 16,000 lb. per sq. in., multiply the tabular coefficient by the ratio $f/16,000$, where f is the fiber stress to be employed.

To select a beam to support a given uniformly distributed load, multiply the given total load by the span in feet, and by the ratio $f/16,000$, and refer to the table for a beam having that coefficient.

For a given load concentrated at the center of the span, multiply the given concentrated load by 2 and consider the result as an equivalent uniformly distributed load.

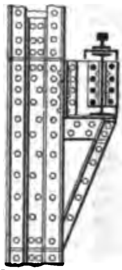


PLATE AND ANGLE COLUMN

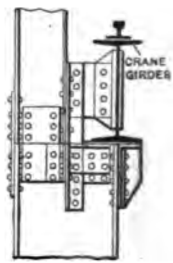
FIG. 22.



BETHLEHEM COLUMN

FIG. 23.

Short beams should be investigated for shear, by dividing the maximum shear, in pounds, by the area of the web, excluding the flanges.

Formulæ for the safe loads and deflections of beams with various methods of support and of loading are given in Tables 12*a* and 12*b*, p. 402.

Deflection of I-beams and Other Structural Shapes. Table 24 gives **coefficients of deflection** for steel shapes under uniformly distributed loads, and is based on the formula: Deflection in inches = $30fL^2/Ed$, the table giving the values of $30fL^2/E$. (f = fiber stress, lb. per sq. in., L = span, ft.; d = depth of section, in.).

To find the deflection in inches of a section symmetrical about the neutral axis, such as a beam, channel, zee, etc., divide the coefficient in the table corresponding to given span and fiber stress by the depth of the section in inches.

To find the deflection in inches of a section not symmetrical about the neutral axis, such as an angle, tee, etc., divide the coefficient corresponding to given span and fiber stress by twice the distance of extreme fiber from neutral axis obtained from table of elements of sections.

To find the deflection in inches of a section for any other fiber stress than those given, multiply this fiber stress by any of the coefficients in the table for the given span and divide by the fiber stress corresponding to the coefficient used.

Table 24. Coefficients of Deflection for Steel Shapes Under Uniformly Distributed Loads

(Am. Bridge Co. For a load concentrated at the center of the span, producing a stress given in the table, use ⅘ of the coefficient given)

Span, ft.	Fiber stress, lb. per sq. in.			Span, ft.	Fiber stress, lb. per sq. in.			Span, ft.	Fiber stress, lb. per sq. in.

* Coefficient of strength in thousands of pounds. Fiber stress 16,000 lb. per sq. in.

Bethlehem Girder Beams from 8 in. to 24 in. in depth, inclusive, have a strength, or section modulus and coefficient of strength, equal to that of two minimum-weight Standard I-beams of the same depth. The girder beam, however, weighs generally 12½ per cent. less than the combined weight of the two Standard beams, not considering the saving in weight of separators needed for assembling the Standard beams into a girder. For example, a Bethlehem 15-in. girder beam, weighing 73 lb. per ft., has a coefficient of strength of 1,256,000. Two Standard 15-in. I-beams, each weighing 42 lb. per ft., have a total coefficient of strength of 1,256,000. Thus, for equal depth and coefficient of strength, the girder beam weighs 11 lb. per ft. less than the two Standard beams. **Bethlehem I-beams** from 8 in. to 24 in. in depth, inclusive, have the same strength, or section modulus and coefficient of strength, as Standard beams of the same depth. Bethlehem beams weigh generally 10 per cent. less than Standard beams of the same depth and strength. For example, a Bethlehem 15-in. I-beam, weighing 54 lb. per ft., has a coefficient of strength of 867,000. The corresponding Standard section is a 15-in. I-beam weighing 60 lb. per ft., having a coefficient of strength of 866,100.

Bethlehem H-Columns are rolled I-sections with heavy, wide flanges. The greater width of flange makes the difference between the maximum and minimum radii of gyration much less than with standard I-beams; these sections are therefore especially adapted for use as columns. The values in Table 31 are selected from those published by the Bethlehem Steel Co.

Table 31. Selected Bethlehem H-Columns

(See Fig. 24)

For D = 16⅞ to 13¾ in., L = 11.06 in. For D = 11½ to 10 in., L = 7.67 in.
For D = 13½ to 11¾ in., L = 9.21 in. For D = 9½ to 8 in., L = 6.14 in.

Plate and Angle Columns. Table 34 gives the dimensions in inches and the properties of columns built up either of a web and four equal angles, or of a web, four equal angles and two plates assembled as in Fig. 26. The safe loads are calculated for an allowable fiber stress of 13,000 lb. per sq. in. for lengths of 60 radii or under; reduced for lengths over 60 radii. Weights do not include rivet heads or other details.

Corrugated Sheets are used for roofs and sides of buildings. They are usually laid directly upon the roof purlins and held in place by means of clips of steel hoops which encircle the purlin and are placed about 12 in. apart. The projecting edges of the corrugated sheets at the eaves and gable ends of the roof should be well secured, otherwise the wind will loosen the sheets.

Corrugated sheets are made in the sizes given in Table 35. The size most generally used has nominally 2½-in. corrugations, (actual width 2⅔ in.) about ½ in. in depth. One corrugation is the double curve between corresponding points; depth of corrugation is the greatest deviation of the curved surfaces from the straight line. The gages frequently used for roofing are Nos. 20 and 22, U. S. Standard Gage.

One and one-half corrugations are allowed for lap in the width of the sheet and 6 in. in the length for the usual quarter-pitch roof; one corrugation in width and 4 in. in the length of the sheet are usually allowed for sidings. Corrugated sheets are furnished in **standard lengths** of 5, 6, 7, 8, 9 and 10 ft. and with a covering width of 24 in., when laid with a lap of either one or one and one-half corrugations.

The weights per 100 sq. ft. given above do not include allowances for end or side laps. The following table gives the approximate number of square feet of sheeting necessary to cover an area of 100 sq. ft., and is based on sheets of standard width, 96 in. long. If longer or shorter sheets are used, the number of square feet required will vary accordingly.

Square Feet of Corrugated Sheets to Cover 100 Sq. Ft.

Side lap	End lap, in.					
	1	2	3	4	5	6
1 Corrugation	110	111	112	113	114	115
$1\frac{1}{2}$ Corrugations	116	117	118	119	120	121
2 Corrugations	123	124	125	126	127	128

By experiment it has been determined that corrugated sheet steel, 5/8 in. deep and 0.035 in. thick, spanning 6 ft., will begin to give a permanent deflection with a load of 30 lb. per sq. ft., and that it collapses with a load of 60 lb. per sq. ft. The distance between centers of purlins should, therefore, not exceed 6 ft. and should preferably be less than this.

Approximately the uniformly distributed **safe load** of corrugated sheets may be obtained from the formulæ

$$W = 25{,}000tdb/l; \quad w = 25{,}000td/L^2$$

where W = total allowable uniform load, lb.; w = allowable uniform load, lb. per sq. ft.; b = width of sheet, in.; l = unsupported length of sheet, in.; L = unsupported length of sheet, ft.; t = thickness of sheet, in., and d = depth of corrugations, in.

Prices of Structural Steel. Standard structural shapes are sold (Aug. 1, 1915) at a **base price** (F.O.B. Pittsburgh) of 1.30 cents per lb. in carload lots (Jan. 1, 1915, 1.05–1.10 cents). This base price applies to beams and channels 3 to 15 in. inclusive, angles 3 to 6 in. on one or both legs and 1/4 in. thick or over, and to zees 3 in. and over. **Extras** to be added to the base price (per lb.) are as follows: For angles over 6 in. on one or both legs, 0.10 cent.; tees, 0.05 cent.; bulb beams and angles, 0.30 cent. For cutting to lengths < 1 ft., 1.55 cents.; 1 to 2 ft., 0.50 cent.; 2 to 3 ft., 0.25 cent; over 3 ft., no charge. Structural rivets in quantity, 1.60–1.75 cents per lb. (Jan. 1,1915, 1.35–1.50 cents). **Freight rates** from Pittsburgh in cents per 100 lb. (carload lots, 36,000 lb. minimum) for structural shapes and fabricated material are as follows: Atlanta, 45; Birmingham, 45; Boston, 19; Buffalo, 12; Chicago, 19; Cincinnati, 16; Cleveland, 11; Denver, 69; Indianapolis, 18; Kansas City, 44; New Orleans, 30; New York, 17; Omaha, 44; Pacific Coast, 80; Philadelphia, 16; St. Louis, 24; St. Paul, 33.

REINFORCED-CONCRETE CONSTRUCTION

BY

SANFORD E. THOMPSON

REFERENCES: Taylor and Thompson, "Concrete, Plain and Reinforced," Wiley. Turneaure and Maurer, "Principles of Reinforced Concrete Construction," Wiley. Marsh, "Reinforced Concrete," Van Nostrand." Taylor and Thompson, "Concrete Costs," Wiley.

Reinforced Concrete is a combination of concrete and steel acting as a unit in consequence of the adhesion between the two materials. Concrete has very low tensile and high compressive strength. Beams of plain concrete fail by tension under very low stresses, but if reinforced with steel in their tensile portion they may be stressed to the compressive working limit of concrete. Reinforced-concrete structures are practically monolithic, more rigid than steel and substantially fireproof. Reinforced concrete is made **use** of in parts of the structure in which tensile and compressive stresses exist, as in beams and slabs, and also in members subject to secondary bending stresses, such as columns and struts. Reinforcement for concrete is also used to prevent cracks due to changes of temperature and shrinkage, as in walls.

Concrete. For reinforced work, only first-class Portland cement concrete must be used, and the aggregates must be carefully selected (see p. 569). The **proportions** are governed by the kind and importance of the construction and by the quality of aggregates (see p. 572). The most common proportions for building constructions are 1 : 2 : 4. For more massive structures proportions of 1 : 2½ : 5 are common. Lean mixtures must be avoided because the adhesion to the steel is small and there is danger of slipping of the rods. A wet consistency, so soft that it will flow sluggishly, but not so wet as to produce a separation of the material in transferring to the work, must be used for all reinforced-concrete work.

Steel. Reinforcing steel is generally in the shape of bars, plain round bars being most extensively used. A number of **deformed bars,** that is, bars with irregular surfaces, have been designed to produce mechanical bond and greater adhesion between steel and concrete. For ordinary beams and slabs, plain bars may be used with safety. Deformed bars are of advantage for short, heavily loaded beams where large bending moments are developed in a short distance, or where the construction is subject to unusual vibration, or to resist temperature stresses. **Fabric reinforcement,** such as triangular mesh, expanded metal, welded wire, etc., is adapted in certain cases for slabs, walls, and partitions. Usually, however, bars are more economical. Angles and structural shapes, either riveted together or loose, are sometimes used as reinforcing material, but are unsatisfactory because of their poor adhesion to concrete. **Mild steel is preferred** by the majority of engineers because, if bought in open market, it is more reliable than high-carbon steel. The latter, however, if properly tested, may be safely used. The steel should comply with the following specifications of the American Society for Testing Materials.

Specifications for Steel for Reinforced Concrete

1. **Manufacture.** Steel may be made by either the open-hearth or Bessemer process. Bars shall be rolled from billets.

2. **Chemical and Physical Properties of Reinforcing Steel.** See p. 460 for the structural steel grade and cold-twisted bars; p. 461 for the hard grade (rail steel). The hard grade will be used only when specified.

3. Number of Tests. At least one tensile and one bending test shall be made from each melt of open-hearth steel rolled, and from each blow or lot of 10 tons of Bessemer steel rolled. In case bars differing ⅜ in. and more in diam. or thickness are rolled from one melt or blow, a test shall be made from the thickest and thinnest material rolled. Should either of these test specimens develop flaws, or should the tensile test specimen break outside of the middle third of its gaged length, it may be discarded and another test specimen substituted therefor. In case a tensile test specimen does not meet the specifications, an additional test may be made.

4. Number of Twists. Cold-twisted bars shall be twisted cold with one complete twist in a length equal to not more than twelve (12) times the thickness of the bar.

Adhesion or Bond Strength is the resistance which the steel bars embedded in concrete offer to longitudinal motion. Tests show that the bond strength is proportional to the area of the surface of steel in contact with the concrete, and varies with the character of the surface and the nature of concrete. The ultimate bond strength for 1:2:4 concrete varies from 350 to 460 lb. per sq. in. of contact surface for plain bars. A length of 50 diameters of embedment is a normal requirement for developing the tensile strength of the bars. Deformed bars give a higher bond resistance, depending upon the nature of deformity.

Table 1. Working Unit Stresses

Kind of stress		No. of formula (see pp. 442 to 445)	Allowable working stress: Percentage of crushing strength at 28 days	Allowable working stress: For 2000-lb. concrete, lb. per sq. in.	Remarks

Shear (as measure of diagonal tension).	Beams without web reinforcement.	(27)	2	$v = 40$	
	Beams with web reinforcement.	(27)	6	$v = 120$	(e)
Bond	Plain bars	(25), (26)	4	$u = 80$	
	Deformed bars	(25), (26)	5 to 6	100 to 120	
Steel in tension.	Structural grade	(4) to (23)	$f_s = 16{,}000$ lb. per sq. in.		
	First-class high-carbon steel.	(4) to (23)	$f_s = 18{,}000$ lb. per sq. in.		

The notation in the fourth column is explained on p. 442.

* Longitudinal steel is to be considered as taking a unit stress equal to nf_c, where n = ratio of moduli of elasticity of steel to concrete.

(a) Height of pier not to exceed 6 diameters; (b) height not to exceed 15 diameters; (c) height not to exceed 10 diameters of core; (d) use in beam formulæ; (e) two-thirds of this stress must be provided for with web reinforcement.

Moduli of Elasticity. For 1 : 2 : 4 concrete the value of the modulus when applied to beams may be taken at the average value of 2,000,000. The modulus of elasticity of steel is practically constant and may be taken as 30,000,000. The ratio of moduli of steel and concrete is of great importance in designing reinforced-concrete structures, and its value may be accepted as 15 for concrete having a strength of 2200 lb. per sq. in. or less. For concrete between 2200 and 2900 lb., use a ratio of 12, and for a strength over 2900 lb., use 10.

Working Unit Stresses. The working unit stresses given in Table 1 have been recommended by the Joint Committee on Concrete and Reinforced Concrete. The third column gives the unit stresses in per cent. of the crushing strength of concrete tested in cylinders 8 in. in diam. and 16 in. long. When a test of the concrete to be used is not available, the expected crushing strength for the concrete of the proportions used may be taken from Table 6, p. 575, at the same time adopting the corresponding ratio of moduli of elasticity of steel to concrete given above. The fourth column in the table gives allowable stresses for 1 : 2 : 4 concrete the strength of which at 28 days is 2000 lb.

UNITS OF CONSTRUCTION

Structures may be divided into the following parts: slabs, beams, columns and footings.

Beams and Slabs

Loads and Spans. The dead and live loads are added together in figuring the allowable stresses. Span lengths of slabs and beams should be taken as the distance between centers of supports, but not to exceed the clear span plus the depth of beam or slab.

Moments for Dead Load and Uniformly Distributed Live Load for Continuous Beams. (*a*) For interior spans of beams and slabs continuous over more than three panels, the maximum positive bending moment at the center and the maximum negative bending moment at the supports should be taken as $M = wL^2/12$, and for end spans at the center and adjoining the support as $M = wL^2/10$. (*b*) For beams and slabs continuous for two spans only, the bending moment at the central support should be taken as $wL^2/8$, and near the middle of the span as $wL^2/10$. (*c*) At the extreme ends of continuous beams the amount of negative moment which will be developed will depend on the conditions of fixedness, but must not be taken at less than $M = wL^2/20$.

Slabs

Slabs supported by steel and by concrete beams respectively are shown in Figs. 1 and 2. In Fig. 3 a part of the tensile portion is replaced by tiles, thus reducing the weight of the slab. Flat slabs supported on columns with flaring heads are also used to a great extent. Slabs are designed by the formulæ on p. 446. The theoretical depth is the distance from center of steel to top of slab. Thickness of concrete below steel should be ¾ in. Shear and bond stresses do not need to be considered for ordinary slabs.

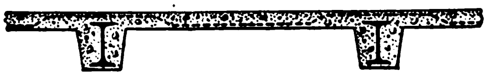

FIG. 1.—Slab Supported by Steel Beams.

Reinforcement of Slabs. Slabs **simply supported** at the ends need to be reinforced at the bottom of the slab only, the principal reinforcement being placed at right angles to the supporting beams. Simply supported slabs, however, seldom occur in construction. **Continuous slabs,** *i.e.*, slabs continuous over several supports, require at each support the same amount of steel placed near the upper surface of the beam as is used at the bottom of slab in the middle of the span. Part of the steel, usually one-half or two-thirds is bent up at a point about one-fifth of the span distant from the support, and carried over the support into the adjoining span. By proper arrangement of bent bars, as regards the lapping of the ends, the required amount of steel at the support may be obtained without introducing extra short bars. To prevent shrinkage cracks, bars of small diameter are placed (preferably in the top of the slab, from 2 to 3 ft. apart) transversely to the principal reinforcement. The **usual reinforcement** of slabs consists of bars, preferably of small diameter, spaced from 4 to 10 in. apart, depending upon the diameter and upon the thickness of slab. **Fabric reinforcement** also may be used for reinforcing slabs.

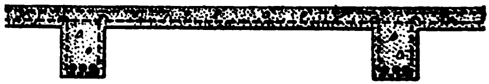

FIG. 2.—Slab Supported by Concrete Beams.

Table 2. Dimensions of Slabs for Different Spans and Loads*

(Based on $M = wL^2/12$; $f_c = 650$ lb. per sq. in.; $f_s = 16{,}000$ lb. per sq. in.; $n = 15$)

† Live load in this table is total load exclusive of weight of slab but inclusive of weight of flooring or granolithic finish.

The cross-sectional area of the strands must be computed to resist the stresses.

Rectangular Slabs. Slabs supported on four sides (when the length does not exceed 1½ times the width) must be reinforced in two directions, and the reinforcement in each direction designed to carry its proportion of the load. For transverse reinforcement, the proportion r for conservative design may be found from the equation $r = (l/b) - 0.5$, where l equals length and b width of slab.

Concrete Floor with Hollow Tile (see Fig. 3) is adapted to certain cases where long spans with flat plastered ceilings between beams are required. The widths of the concrete beams or ribs between the lines of tiles must be determined by shear requirements. The compression portion consists of concrete of sufficient depth above the tiles. The bottoms of the ribs are flush with the bottoms of the tiles. Care must be taken to see that the bond stress does not exceed the allowable working limits. The spacing of the ribs is fixed by the size of the tiles, which are generally 12 in. wide.

Fig. 3.—Concrete Floor with Hollow Tile.

Beams

Reinforced-concrete beams are seldom of rectangular shape. Usually, the rectangular beams are built monolithic with the slab, so that a portion of the latter may be considered as an integral part of the beam, forming the so-called **T-beam.** In practice, the depth of the beam is governed by the rigidity of construction, available head room, and economy. The ratio of length of span to depth is usually restricted to a value of 12. The width of beam, which must be large enough to enable convenient placing of steel, is determined by the shearing stresses. The ratio of depth to width must not exceed four.

For the **design of rectangular beams,** use formulæ (2) to (8), p. 443; for T-beams, formulæ (9) to (18) p. 444. For rectangular beams with steel in top and bottom and for T-beams at the supports, use formulæ (19) to (24) p. 445. The theoretical depth d is the distance from center of tension steel to top of beam. For one layer of bars the center of steel coincides with the center of the bars. For two layers of bars the center of steel is at the center of gravity of the group of bars. To obtain total depth, h, add to the theoretical depth, d, 2 in. or the distance from center of steel to the lowest surface of steel plus 1½ in. Concrete below steel is necessary for fireproofing.

Reinforcement of Beams usually consists of bars placed at the bottom of the beam at the center of the span. Some of the bars are bent in two or more places and carried at the top of the beams, the remaining ones being carried straight. The bent bars help to resist the diagonal tension.

Continuous Beams, *i.e.*, beams continuous over several supports. In these, the bent bars are carried over the support and extend a sufficient length into the beam of the adjoining span to provide anchorage. For 2000-lb. concrete and a working stress of 16,000 lb. in the steel, this requires, by Joint Committee recommendations, a length of embedment of 50 diameters beyond the point of maximum stress. The amount of steel required at the top of the support is substantially the same as at the center of the span. One-half of the bottom steel is generally bent up and carried at the top of the beam and the remainder of the steel required for the negative bending moment is carried over from the adjoining span. If the sum of the cross-sectional areas of the bent bars and the bars carried over from the adjacent span is not large enough, short bars must be used to make up the required area. Fig. 4 illustrates good practice in reinforcing continuous beams. The bars may be either bent and assembled in place in the forms, or unit frames built at the shop may be used.

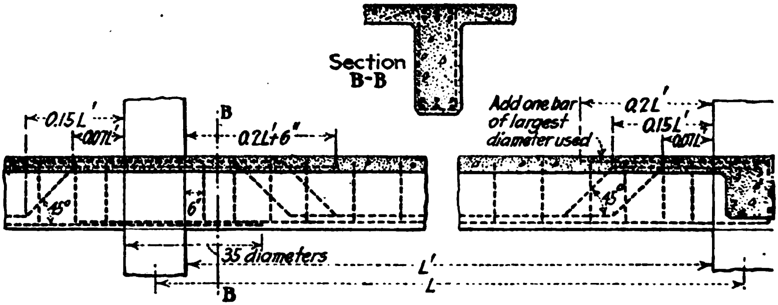

FIG. 4.—Reinforcement of Continuous Beams.

Continuous T-beam at the Support. The compressive area of a T-beam in the middle of the span includes not only the upper part of the web but also a portion of the slab which acts as a flange. At the support, however, the beam is subject to a negative bending moment, so that the flange of the T-beam, which is in tension, is not effective. This reduces the T-beam at the support to a rectangular beam with a compressive concrete area considerably smaller than at the center of the span. To keep the compressive stress in concrete at the support within working limits, the depth of beam must be increased or a sufficient amount of compression steel introduced. In computing, the beam is considered as a rectangular beam with steel in top and bottom. The straight bars in the bottom of the beam at the support are figured to take a part of the compression, and, if necessary, additional short bars may be placed. [See formulæ (19) to (24), p. 445.]

Cantilever Beams must be reinforced with bars placed at the top. The maximum stress in steel is at the support, and the bars must therefore be embedded for a sufficient length to develop this stress or be specially anchored. For steel stressed up to 16,000 lb. per sq. in. and an allowable bond stress of 80 lb. per sq. in., the required length of embedment is equal to 50 diameters.

Diagonal Tension Reinforcement consists of stirrups of U-shaped form. The spacing of stirrups and their sectional area may be found by formulæ (28) and (30), p. 445. Stirrups must be firmly attached to the horizontal bars which are in tension. At the support of continuous beams, since the tension bars are at the top, the attachment must be made to these bars. The ends in the compression part of the beam must be provided with hooks or other means of increasing the bond. Wherever stirrups are necessary, they should not be spaced farther apart than three-fourths the depth of the beam.

Spacing of Bars in Beams. Parallel bars should not be spaced nearer together than 3 times their diameter measured from center to center, nor should the distance from side of the beam to center of the nearest bar be less than 2 diameters. When necessary, two layers of bars may be placed one above the other, with 1 in. clear spacing in between. More than two layers of bars is not advisable. The clear spacing between the lowest layer of bars and the bottom of the beam should be 1½ in.

* Reinforcing bars are arranged in two layers.

† The thickness in this column is the minimum required for compression.

Explanations for T-beam Table (Table 3)

How to Use.

(1) Take span of beam as distance center to center of supports, but not to exceed clear span plus depth of beam.

(2) Find from Table 2 required thickness of slab to support the load.

(3) Compute total live and dead load per linear foot of beam. Dead load to include weight of slab, beam, and granolithic finish or other flooring used.

(4) Note whether beam is an interior span, an end span, or a simply supported beam, and from the table take off the required dimensions and reinforcement.

(5) If there is no table for the span required, use table for the next higher span, but reduce the load in the ratio of required span and span used. For example, when designing a beam for 18 ft. 6 in., use the table for 20 ft. span and multiply the load by 18.5/20.

(6) See that thickness of slab determined for the load is not smaller than minimum thickness given in column 4.

Bending of Steel. Bend at least half of the bars in each beam. For intermediate support, carry the bent bars over support into adjoining span the length required. For end support, hook bent bars in column for a length of at least 9 diameters, and add one short hooked bar of largest diameter used. For an even number of bars of same diameter, bend half the bars. For an odd number of bars, bend four out of seven, three out of five, and two out of three. With reinforcement in two rows the bending should start at $0.07L'$ and $0.15\ L'$ respectively from the support, as shown in Fig. 4. With reinforcement in one row this distance should be $0.1\ L'$.

When a combination of bars of various diameters is used, see that the cross-sectional area of the bent bars is at least equal to half the total cross-section of the bars.

When more than two bars are to be bent, bends should be made in two places at each end of beam, as shown in Fig. 4. For an even number of bars, bend half of them in each place. For an odd number of bars, the number of bars bent near the support should be one greater than the number at the other bend.

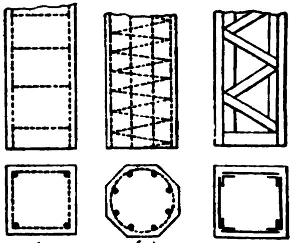
Stirrups. Beams are provided with web reinforcement of stirrups where shearing unit stress, taken as the measure of diagonal tension, exceeds 40 lb. per sq. in. Bent-up bars were not counted as web reinforcement; therefore, if desired, the spacing of stirrups may be increased where they overlap with bent portions of the horizontal bars, or altogether omitted.

Bond Stresses for Tension Bars in Beams must be calculated by formula (27), p. 445. If the bond stress is too large, the diameter of bar must be decreased or the depth of beam increased to prevent slip, Where high bond resistance is required, deformed bars, *i.e.*, bars with uneven surfaces, may be used to advantage.

Columns

Piers of short length up to 6 times the least diameter and loaded centrally may be built of plain concrete. Columns longer than this and also piers and columns subject to cross-bending must be reinforced. Formulæ for reinforced-concrete columns are given on p. 442. An outside shell of a thickness equal to 1½ in. should be considered as fireproofing. The usual mixtures for concrete columns are 1 : 2 : 4 and 1 : 1½ : 3. For columns carrying heavy loads the cross-section may be reduced by using a rich mixture of concrete. As the steel is stressed only to 15 times the allowable stress in concrete, the use of a large amount of steel is not economical; better economy is obtained by using rich mixtures. Reinforcement of columns usually consists of (1) longitudinal bars; (2) circular hoops or spirals; (3) longitudinal bars with circular hoops or spirals; (4) rigid structural shapes.

Columns with Longitudinal Reinforcement. [Fig. 5(*a*).] When the allowable unit stresses given on p. 1306 are used, the length of the column must not exceed 15 times its least diameter. The percentage of steel in longitudinal reinforcement should not be less than 1 per cent. nor more than 6 per cent. of the concrete area. Longitudinal reinforcement usually consists of bars, but small angles may also be used. The steel is placed 2 in. to 2½ in. from the surface. To prevent the steel from buckling and to keep it in place during erection, horizontal ties of small diameter are used, spaced not farther apart than the diameter of the column nor more than 15 diameters of the bar. Joints in vertical bars may be provided by lapping them for a length of about 30 diameters. For bars of large diameter, the ends should be milled and butted, with a sleeve around the joint. Steel in the basement column either must be carried 30 diameters into the footing, or dowels of sufficient length provided; or else the bars may rest on steel plates of large enough area to transfer the stress to the footing by bearing on the concrete.



(a) (b) (c)

Fig. 5.—Types of Reinforcement for Concrete Columns.

Columns with Spiral Reinforcement. When spirals are counted upon as increasing the strength of the column, the amount of such reinforcement must not be less than 1 per cent. of the volume of the concrete enclosed and the length of column not more than 10 diameters of the core. The pitch of the spiral should not be greater than one-sixth of the diameter of the column, and preferably not greater than one-tenth and in no case more than 2½ in. The ends of the spirals must be lapped or held together in such a way as to develop their full strength in tension. It is not advisable to use concrete columns with spirals only.

Columns with Longitudinal Bars and Spirals. [Fig. 5(*b*)]. When the stresses given on p. 1306 are used, the length of column must not exceed ten diameters of the core. Suggestions as to the amount of longitudinal steel and hoops and also as to their arrangement are given in the two preceding paragraphs. A column of this type is very reliable.

Concrete Columns with Rigid Structural Shapes. When small shapes are used of an amount not exceeding 4 per cent. of the concrete cross-sectional area, the column may be considered as reinforced concrete and treated as suggested under "Columns with Longitudinal Reinforcement." When a larger amount of steel is used, 10 per cent. or 15 per cent. of the concrete area, the column may be considered as a structural-steel column strengthened by the concrete. Concrete must not be relied upon as a binding material, and the shapes composing the structural-steel column must be riveted together and tied by tie plates or lattice bars, and in other respects designed in conformity with standard practice for structural steel. A satisfactory arrangement of steel shapes is shown at (*c*), Fig. 5.

Footings

Footings for separate columns are usually square or rectangular. The area of the footing is determined by the allowable unit pressure on the ground, or, if the footing is carried on piles, by the number and spacing of the piles. In figuring the moments, the projecting footing may be taken as cut along each diagonal, and each part acting as a cantilever supported at the edge of the column and loaded uniformly by the reaction of the ground, or, for pile foundations, by the reaction of the piles. The depth of the footing is determined by shear and bond stresses, formulæ (25), (26) and (27) p. 445, and is generally larger than would be required by the moment formula (4) (p. 445). The steel determined from the bending moment and the depth consists of bars, preferably of small diameter, placed at the bottom and usually in two transverse directions. Four-way reinforcement is sometimes used, but is of no special advantage. Deformed bars may be used to advantage because of their greater bond resistance. Use slab formulæ (9) to (18), p. 444, for determining depth and amount of reinforcement, and formulæ (25) to (27) to determine shear and bond. The sizes of bars to select are usually governed by the bond stresses.

Table 4. Round and Square Reinforced-concrete Columns

Table for determining cross-section of concrete and steel for required load, or safe load P for given dimensions of column.

(Based on $f_c = 450$; $n = 15$; for 1 : 2 : 4 concrete, and formula $P = Af_c[1 + (n - 1)p]$. For notation, see p. 442)

Square column, side, in.	Equivalent diam. of round column, in.	Effective area, sq. in.*	Ratio of area of steel to effective area of concrete $= p$													
			0.01		0.015		0.02		0.025		0.03		0.035		0.04	
			P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.	P/1000, lb.	As, sq. in.

* 1½ in. of concrete on each side considered as fireproofing is not included in the effective area of column.

Combined Footings for two or more columns must be considered as a slab supported at the columns and loaded uniformly by the reaction of the ground. The area of the footing is determined by the allowable pressure on the ground, and its shape must be such that its center of gravity coincides with the center of gravity of superimposed loads. This requirement is very important, as otherwise unequal settlement may result. The depth and amount of reinforcement are determined from formulæ (2) and (8) p. 443, and bond and shear from formulæ (25) to (27) p. 445. Bars placed near the top surface between columns are bent down and carried near to the bottom surface under the columns and in the projections. Transversely to this reinforcement, bars must be placed at the bottom of the footing of sufficient strength to distribute the load in transverse directions. Shear reinforcement may be required.

Spread Foundation, consisting of a slab over the entire area under the columns, or of a slab supported by beams, may be considered as loaded by a uniform upward reaction of the ground. The principle of design is exactly the same as that applied to a floor system, except that the load acts upward instead of downward.

Walls and Partitions

Reinforced concrete is well adapted to the construction of walls, especially where they have to withstand heavy pressures, such as the retaining walls of a cellar or basement, walls for coal pockets, silos, reservoirs and grain elevators. For buildings, the cost of forms may make concrete walls more expensive than brick walls, but concrete walls may be made one-half to two-thirds the thickness of brick for the same conditions. Partitions may be built of solid concrete from 4 to 6 in. thick, reinforced to prevent temperature and shrinkage cracks. The amount of steel necessary for temperature reinforcement varies from 0.3 to 0.5 per cent., the last figure to be used for thin walls in exposed locations. Bars of small diameter (1/4 to 5/8 in.) or fabric reinforcement may be used.

Forms

Forms may be built of wood or metal. Wooden forms are usually most economical unless the construction allows for the repeated use of the same forms. For wooden forms, spruce, Norway pine, and shortleaf southern pine are generally used. For slab forms and sides of beams, 1-in., 1 1/4-in. or 1 1/2-in., stock is generally used; for bottoms of beams, 2-in. stock; and for columns 1 1/2-in. stock Forms must be designed so that they can be easily erected, removed, and re-erected. The usual order of removing of forms is: (1) column sides; (2) joists; (3) girder and beam sides; (4) slab bottoms; (5) girder and beam bottoms. **Column forms** are held together by clamps made of wood or steel, the spacing of which is smallest at the bottom and increases with the decrease in pressure. **Beam forms** consist of the bottom and two sides held together by clamps or cleats and supported by posts. **Slab forms** consist of boards supported by joists spaced 2 or 3 ft. apart. The joists either rest on a horizontal joist bearer nailed to the clamps of the beam or girder, or are supported by stringers and posts or both.

Removal of Forms. The time that forms should remain in place depends upon the character of the members and upon weather conditions. The hardness of concrete must be ascertained before removing the forms. As an approximate guide for the minimum time for form removal, the following rules (from Taylor and Thompson's "Concrete Costs") may be observed:

WALLS IN MASS WORK. One to three days, or until concrete will bear pressure of the thumb without indentation.

THIN WALLS. In summer, 2 days; in cold weather, 5 days.

COLUMNS. In summer, 2 days; in cold weather, 4 days, provided girders are shored to prevent appreciable weight reaching the columns.

SLABS UP TO 7-FT. SPAN. In summer, 6 days; in cold weather, 2 weeks.

BEAMS AND GIRDER SIDES. In summer, 6 days; in cold weather, 2 weeks.

BEAMS AND GIRDERS AND LONG-SPAN SLABS. In summer, 10 days or 2 weeks; in cold weather, 3 weeks to 1 month. If shores are left without disturbing them, the sheeting in summer may be removed after one week.

CONDUITS. Two or three days, provided there is not a heavy fill upon them.

ARCHES. If of small size, 1 week; large arches with heavy dead load, 1 month.

INDUSTRIAL BUILDINGS

BY

CHARLES DAY

REFERENCES: "Principles of Industrial Engineering," Charles B. Going; "Industrial Plants," Charles Day; "The Principles of Scientific Management," F. W. Taylor; "The Principles of Industrial Management," John C. Duncan; "Factory Organization and Administration," Hugo Diemer.

THE PLANNING OF INDUSTRIAL PLANTS

The development and extension of existing manufacturing plants and the building and equipping of entirely new plants should be based upon a thorough preliminary study of the factors involved. After the influences of the product, the physical equipment, the processes employed and the methods of administration upon the proposed plant have been investigated, it is possible to determine intelligently the areas and arrangement of departments, the number and character of buildings required to house them, and the size and location of the site.

Character of Data Required. Complete data should be obtained concerning the nature and amount of the products of manufacture. In the case of the metal industries, for example, the calculations should show the **annual consumption** of gray-iron castings, forgings, bar stock steel, lumber for all purposes, molding sand, steel castings, structural material, brass or other alloys, coal and coke, core sand, etc.

The **rate of consumption** of these materials and the **supply** that trade conditions make it desirable to carry from standpoints of **price** and **delivery,** should be ascertained and recorded. Data of the foregoing character should also be secured with regard to the **finished and partially finished products.**

The following classification covers the principal items of information required: (*a*) Character and amount of raw materials that should be carried as stores; (*b*) character and amount of materials to be carried in stock after work has been done on them; (*c*) character and amount of finished product carried as stores or pending shipment.

With this information as a basis, the following data should be compiled: (*d*) The **character and extent of** the various kinds of hand, machine or process **work required to be done upon the product**; (*e*) the **weight and bulk** of the units in which the various materials are required to be **handled**; (*f*) The **cubic contents and weight of** the various **raw materials, worked materials and finished products** which will have to be **stored**; (*g*) special **notes of** any **exceptional conditions** that products may impose, such as fire, chemical and explosive hazards.

Manufacturing Equipment Needed. The types of **machinery or equipment required** should be decided upon and a list prepared comprising each specific machine that should be installed. The **probable equipment requirements for the future** should be approximated, as these govern the amount of floor space that it should be possible to secure by further extensions. All factors limiting complete freedom of choice in the selection of machinery and processes must be taken into account.

Safety Devices. Provision should be made for safety devices for machines, belting, etc., and for conditions which will increase the health and efficiency of the workers. For example, the supply of slightly heated water in the winter for tool-grinding operations has been found to increase efficiency.

Power Generation and Distribution. In the great majority of cases presented to the designer of manufacturing plants, power requirements are met most satisfactorily by the use of electric motors operating the machines either individually or in groups. The advantages of this practice as opposed to belting and line shafting connected directly with a central motive power unit are stated on p. 1467. The relative advantages of building an isolated plant or purchasing power when the latter is a possibility should be carefully ascertained, taking into account the heating and industrial requirements in connection with which exhaust or live steam may be needed.

If power from a central generating point is to be transmitted throughout the plant by means of belt, rope or gear drives and line shafting, the buildings must be designed to allow the ready installation of the apparatus in a manner that will interfere the least with the work in each department. The additional dead load and the probable effects of vibration must be taken into account. In the case of heavy machinery, such as rolling-mill equipment, the transmission apparatus may present unusual requirements necessitating special design of the building structure.

Necessary Equipment Data. The following statistics with regard to each item of machinery and equipment to be installed should be determined: Total weight; power required; supplementary handling facilities; total floor space occupied; method of applying power; head room required; special conditions. The small equipment and hand operations entering into erecting and other work performed for the most part without the aid of large machinery, should be covered with equal thoroughness.

Administration Methods. The mistake is frequently made of assuming that matters involving questions of administration can be deferred until the completion of the plant. The management of an industrial plant will never be confronted with a more opportune time to effect improvements in its methods of management than when building a new plant. The limitations imposed by the layout and character of many existing plants are often such as to prohibit the most efficient introduction of modern methods of management. Owing to the great diversity of requirements presented by industrial plants generally, it is not practicable to do more than to suggest the importance of this phase of the subject. The following specific illustrations should serve this purpose.

(*a*) The system of storekeeping requiring the use of two bins or spaces for each kind of material (to be used alternately for issuing and receiving) requires about 50 per cent. more room for the stores department than does the ordinary system in connection with which but one bin is used.

(*b*) The amount of floor space required for shop offices, as well as their location, is dependent upon the manner in which the routine of work of manufacture will be planned and directed.

(*c*) In certain cases it is desirable to group together machinery of a like character, such as lathes, boring mills, drill presses, etc., owing to the administrative advantages gained thereby, even though such a course necessitates considerable extra handling.

(*d*) Under one system of management it may be found necessary to inspect for quality and quantity in an isolated department; in another the inspection may be accomplished by "traveling inspectors," thus eliminating the necessity of moving the work for this purpose.

The ideal **arrangement of equipment** and processes is that which minimises the travel of materials of manufacture and at the same time lends itself readily to the particular plan of industrial administration that is to be used. In general, the procedure which should be followed is outlined below.

Industrial plants can be classified into two main divisions from the standpoint of **sequence of operations**, as follows:

1. Those employing **continuous operations**, as in the case of refining sugar, milling flour, manufacturing paper, etc.
2. Those employing **intermittent operations** involving the manufacture and assembly of parts in which the sequence of operations is not fixed rigidly.

The determination of the correct sequence of operations and the preparation of graphical routing diagrams as a basis for the arrangement of equipment and departments is a relatively simple matter for industries of the first class. This problem, however, becomes much more complex when dealing with industries of the second class, as it is possible frequently to attain the same final result by performing certain of the operations in different sequences. In addition, the advantage gained through arranging equipment strictly to minimize handling must be compared with that resulting from an arrangement made purely to facilitate administration and minimize investment. In one case it might be required that each department comprise the various types of equipment needed for the performance of all necessary operations on a given unit; in the other that each department contain equipment of a like character, thus requiring the movement of the product from one department to another. Then, again, in certain industries the importance of centralized inspection between operations is so great as to justify the excessive handling of all parts necessitated through such procedure.

In general, in the metal-working industries it is found best to group together equipment of a like character, such as automatic lathes, drill presses, gear cutters, etc. This permits of the smallest investment, the minimum number of operatives and satisfactory local inspection within the department. As most of this work is relatively light in weight, the handling problem is not a serious one. On the other hand, the equipment required to perform work on heavy and bulky materials, such as engine beds, flywheels, etc., is usually arranged solely with a view to minimizing the handling costs incident to a given sequence or performance. The determination of the proper sequence is governed by such considerations as the following: Planing usually precedes boring and drilling operations, the purpose being to secure finished surfaces from which subsequent operations can be laid out accurately.

Floor Space Needed. Templates should be made to a scale consistent with the magnitude of the work (¼ in. to the foot is satisfactory usually), and should indicate the overall dimensions and outlines of foundations for machinery. The floor space required by each machine and process and for the temporary storage of the materials upon which work is to be done or has been done, should be determined.

In certain instances where the work is of the continuous class, as in the case of a bleach house where the work passes continuously between certain processes in the rope form, little or no space is needed for storage. The opposite extreme is exemplified by the conditions presented in the machine shop which handles a wide diversity of work. In such a plant it is desirable usually to have several jobs laid out in advance for each machine and at a point directly accessible to it. It may also be desirable to allow the work to remain in proximity to the machine last engaged upon it until it has been inspected for quality and quantity.

Routing Diagrams. Typical forms of routing diagrams are illustrated by Figs. 1, 2 and 3.

Fig. 1 is a partial routing diagram of a sugar refinery, illustrating industries of the first class where the manufacturing **work is continuous in character.** As the diagram shows the routing in elevation only, it gives no indication of the amount of floor space required on the respective floors nor of the total amount of equipment of various classes that enter into the work. It is an example of those industries in which the material is carried to the upper floors and the processes succeed each other as it is carried down through the plant by gravity. In such a layout the handling costs are minimized. The continuous class of manufacture is exemplified in part by steel and brass rolling mills. These industries, however, require the location of the heavy equipment on a single floor and the replacement of gravity by mechanical handling, owing to the weight and bulk of the product. Cotton and paper mills, on the other hand, represent to a certain extent a combination of the principles exemplified by each of the illustrations just referred to.

Fig. 2 illustrates the use of the routing diagram as a means of **determining the correct location of machines** in each department. It exemplifies the layout of a small machine shop or machine department and shows the exact

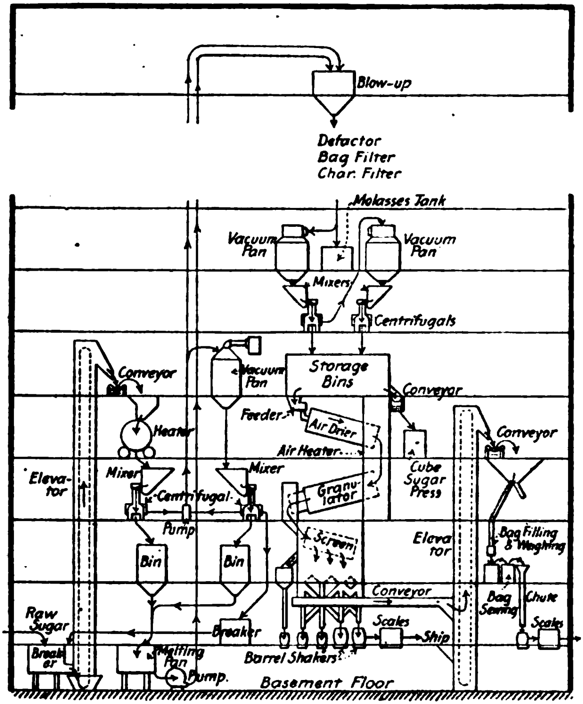

FIG. 1.—Routing Diagram of a Sugar Refinery.

paths followed by three units of the product. The diagram exemplifies the best possible condition from the standpoint of the routing of material. To avoid confusion, all of the equipment has not been shown nor the routing of the entire product indicated.

Fig. 3 illustrates the routing in a machine shop where it is necessary to inspect the work after each operation. It will be noted that equipment of like character is grouped into departments and these departments are located around the central inspection department in order to reduce travel to the minimum under the conditions imposed. The shop in question provides for the independent manufacture of small parts made from bar stock and forgings.

The **designs of the buildings** must be such that the work to be performed can go forward with practically as much freedom as though the buildings did not exist; that is, the workers, whether employed at individual machines or engaged in moving material from point to point, should be unimpeded by the housing structure. Certain of the more important factors are considered below.

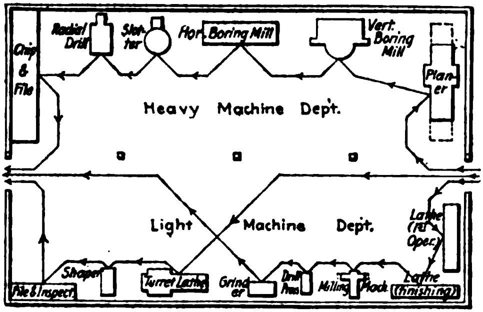

FIG. 2.—Routing Diagram of Small Machine Shop.

Certain operations and departments must be housed in single-story buildings; others may be located on the first floor of a multiple-story building, and others may be located advantageously on upper floors. If the plant is located

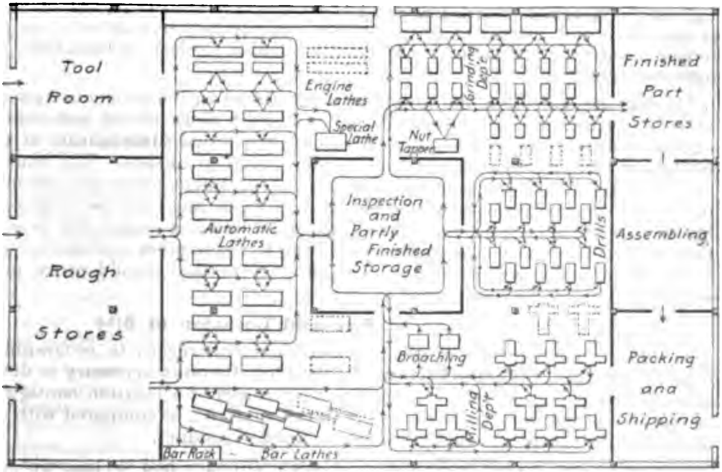

FIG. 3.—Routing Diagram of Machine Shop, Providing for Inspection of Work After Each Operation.

in a place where the cost of land is high, it may be necessary to resort to multiple-story structures wherever this is practicable; on the other hand, if the cost of land is low it may be desirable to locate the departments in single-story buildings, owing to the handling and supervising advantages that would result.

The **number of buildings** into which the requisite area should be divided, is dependent largely upon the extent of the plant and character of work to be done. The interrelationship of certain processes frequently requires that they should all be housed in the same structure; again, certain groups or processes may present certain governing requirements that are common to all the processes, as, for example, the necessity of overhead traveling cranes, or the need of exceptional conditions in regard to heating and ventilation (exemplified by certain of the textile and chemical industries), or by the exceptional fire hazard where alcohol, gasoline or other combustible materials are used extensively. Materials and parts must be made to **travel in one general direction through** the **plant,** just as through a given department, and their routing through departments where no work is done upon them should be avoided. Care should also be exercised to **prevent congestion** at any point **in the path of travel.** Departments for the receipt of raw materials and shipment of finished product and, in some instances, erecting departments, should be located adjacent to railroad sidings, docks or roads on which shipments are received or made.

In the case of a plant laid out for the manufacture of stiff derby hats, it was found that the operations entering into the work could be broadly classified into three main groups. The first group, consisting of operations performed in a dry state, was housed in a multiple-story building. The second group, consisting of operations practically all of which must be performed in the presence of water or steam, was housed in a single-story structure designed with special reference to ventilation and floor drainage. A sub-group was isolated in a fireproof structure owing to the hazard incident to the use of alcohol in large quantities. The third group, comprising operations certain of which are performed through the medium of dry heat and the balance of which are hand work, was housed in a multiple-story building.

Having decided upon the grouping of machines in departments and the grouping of departments into buildings or at least structures of well-defined character, it becomes necessary to determine the actual **dimensions of the building structures** required to meet the specified output. The routing diagram and a knowledge of the necessary department areas are the most important factors in this connection, although there must not be overlooked the requirements of good natural lighting, good building design, fire prevention, etc. With these data and those relating to the number and character of buildings required, the combination of dimensions that should prove most advantageous can be ascertained.

Determination of Size and Location of Site

In many industries the governing condition with regard to geographical location is that of **transportation.** It therefore becomes necessary to determine by actual calculation the relative advantages of a location contiguous to one or more of the sources of supply of raw material, as compared with one at or near the center of distribution for the finished product.

Where a plant is dependent upon raw materials such as clay, iron ore, limestone, etc., and particularly where the materials or product resulting from the utilisation of such materials represent but a small part of the original bulk or weight, the location of such materials determines unqualifiedly the location of a plant.

In many cases several different kinds of raw material coming from widely separated localities enter into a single product, so that it becomes necessary to decide upon the relative transportation costs. Brickyards, for example, are located at the clay deposits, as the tonnage ratio between the clay, brick and coal used is about 5:3:0.2. Blast furnaces working 33⅓ per cent. iron ore, require three tons of ore and about one ton of coke to produce one ton of pig iron. Consequently, from the standpoint of transportation, such blast furnaces should be located at the ore mines. When the quality of the ore is considerably better, and especially for puddling furnaces, Bessemer and open-hearth steel works and rolling mills, the quantity of coal is the first desideratum, for which reason the most profitable location from a transportation standpoint is at the coal mines.

In the majority of industries, however, the materials upon which work is done are purchased in a partially manufactured state, and it is frequently impossible to decide definitely in advance as to the source from which they can be secured most advantageously. In such instances, other factors should govern in the selection of the site from a geographical standpoint.

Occasionally, the **distribution of** the **finished product is the more important factor,** although this relates to those industries which depend principally upon local demand, such as bakeries, breweries, printing establishments, etc.

Labor Market. In many industries it is important to have a supply of skilled workmen in the immediate vicinity of the plant. In other cases, the necessity of being able to command employment of a large number of unskilled men is so important as to necessitate the selection of a location in or adjoining a large city. Many communities have become the centers of certain classes of manufacture, and skilled workers are attracted thereto by the prospect of more steady employment. The desirability of taking advantage of such a labor market is frequently so great as to outweigh all other considerations. The possibility of securing **cheap power** is sometimes a determining factor. The segregation of plants in the vicinity of Niagara Falls exemplifies this.

Urban vs. Suburban Sites. Having decided upon the geographical location, the next step is to determine the relative advantage of a site directly in or adjacent to a large city as compared with one at some distance from such a community. The question of labor supply also enters, as in certain industries it is possible to get skilled men in large numbers only in relatively big cities. Workmen in cities are usually more intelligent and able than those in the country; on the other hand, they are successful in demanding higher wages.

Selection of Property. Before selecting an actual site, specific information should have been compiled in regard to the following factors:

1. Amount of property required for immediate and future use.
2. Desirable shipping facilities—water, rail, highways, etc.
3. Public conveniences, such as fire-protection facilities, water supply, gas, electricity, police protection, street railways, etc.
4. Desirable topography for drainage and foundation conditions.
5. The sum of money for acquisition of property that is consistent with the estimated income of the business, and which bears a logical proportion to the total justifiable disbursement.

Other factors which must be taken into account in laying out the plant are as follows: Future growth must always be provided for. Large, unobstructed areas are generally preferable to small, enclosed areas. Large window areas should be provided and direct sunlight avoided as far as possible. Processes hazardous from the standpoints of fire or explosion, or areas too large to merit insurance at the lowest rate, should be isolated by are walls. Large plants should have separate sidings for shipping and receiving. The plant should be laid out so that an interruption in one department will not make it necessary to shut down the entire plant. That arrangement of equipment and departments which results in a minimum handling of product should not be departed from without strong justification. The pressure in the water mains must be sufficient for effective fire service. Legislation dealing with sanitary and safety equipment must not be overlooked. The requirements of underwriters in regard to fire protection must be taken into account. The minimum radius fixed by the principal steam railroads for track over which their equipment will operate should be considered, as well as the height and width of doorways through which cars are to be shifted and the platform clearances for loading and unloading. Legal requirements in these respects should also be ascertained. The possibility of purchasing electric current for light and power more cheaply than it can be generated in a private plant, should not be overlooked. The possibility of arranging with electric traction companies to transfer freight cars or to transport freight should be considered. The floors of storehouses and manufacturing departments should be designed to withstand the excessive loads imposed at times by congestion of work or the carrying of an abnormally large stock. Safety devices of all kinds should be provided, as well as adequate fire exits.

Preparation of Detail Plans. A brief statement or specification accompanied by the necessary block plans, statistical data, etc., should be prepared, defining the specific conditions imposed from a manufacturing standpoint and by the site finally selected. The information in question should include a complete survey of the property, a block plan of the proposed plant, a schedule of minimum inside dimensions, floor, crane and elevator loads, etc. All passageways, doors, and special building features should be clearly defined, and, where certain latitude is permissible, limits of possible variation should be stated.

It is of the utmost importance that data of the foregoing character should be complete in every important particular before authorizing the preparation of detail structural specifications. It is only in this way that cost can be minimized through eliminating many changes in the plans subsequent to their initial completion. This preliminary work is in no sense a function of the designing engineer or architect, but rather of the manufacturing expert.

Contracts for Building. The principal forms of contract and the onditions for which they are particularly suited, are as follows:

General Lump-sum Contract. This form of contract requires that idders shall make lump-sum bids on the entire work covered by the plans nd specifications. Until recently it has been the accepted form of contract or practically all building operations. It is now being superseded rapidly by the minor lump-sum contract.

Minor Lump-sum Contract. This form of contract relates to but a single feature of the work, the entire structure being provided for by entering into as many minor contracts as there are distinct classes of construction work. All structural steel work would be covered by one contract, brickwork by another, millwork by still another, and so on. It has the great advantage of restricting the competition to units of a like character, so permitting of a more intelligent consideration and comparison of the bids. It also results in lower prices if care is exercised in soliciting bids only from those who are thoroughly experienced in the respective functions. This form of contract therefore presents many advantages to those about to build industrial plants, unless the work involves exceptional hazards or uncertainty of construction conditions. In such cases, the percentage, or fixed-fee, contract should be adopted.

Percentage or Fixed-fee Contract. This form of contract provides that the contractor shall be reimbursed for all expenses, and, in addition, paid either a percentage on the cost or a fixed sum of money as a profit. It is adopted principally where difficulty is encountered in defining in advance certain essential conditions affecting the work, such as the character and amount of excavation that may be necessary, or the necessity of performing the work in such a manner that it will not interfere with certain other activities, as in the case of extensions to industrial plants where the manufacturing work must not be interfered with by the construction force.

DETAILS OF BUILDING CONSTRUCTION

Types of Industrial Buildings

The determination of the proper type of buildings that will house most efficiently the departments comprising a given business, involves a consideration of the following characteristics.

Single-story Buildings allow of the greatest flexibility in the arrangement of departments; provide for unlimited and uninterrupted growth in any direction to the boundary of property; allow (through the adoption of overhead skylights) of the enclosure under a single roof of an unlimited area—frequently a great industrial advantage; afford the best natural lighting, secured by sawtooth or other type of roof sash; facilitate supervision of manufacturing work through a minimum amount of isolation of departments; and in general, present less fire hazard than multiple-story structures.

Multiple-story Buildings are desirable when cost of real estate is high or a limited amount procurable; have a greater utility than single-story structures, and therefore usually bring a larger return in the event of sale or rental; are readily heated in cold weather with minimum cost of equipment; cost less per sq. ft. of floor area for most classes of occupancy, and are desirable for continuous manufacture where gravity travel can be used or for light manufacturing purposes.

Construction Materials. The decision as to whether buildings should be of reinforced concrete, mill construction, steel-frame or other construction depends upon the specific requirements dictated by the manufacturing work to be performed within them; climatic conditions; fire hazard; the type of building; the character of the locality in which the buildings are to be erected; and the limitations imposed by available capital.

For multiple-story buildings there is a decided tendency toward **reinforced concrete**, as it is the least expensive type of fully fireproof construction. It is especially adapted to plants using high-speed machinery, owing to its resistance to vibration. On the other hand, as the structure is virtually a monolith, changes are more costly than in other types of construction. Fireproof multiple-story buildings can be constructed of steel frame with tile or reinforced-concrete floors and brick or concrete walls, but in such cases all columns and exposed steel work must be thoroughly fireproofed, which, as a rule, makes the total cost greater than that of a reinforced-concrete building. Multiple-story buildings of **mill-type construction** (brick walls, wood columns, heavy timber girders and floors), if not sprinkled, generally cost from 10 to 15 per cent. less than those of reinforced concrete. If a sprinkler system is installed, such structures present a low fire hazard. Single-story structures, such as those required for heavy machine work, are usually constructed with steel frame and plank (or some form of fireproof) roof. While such structures are not combustible, intense heat may weaken them to the point of collapse, but they nevertheless meet satisfactorily the requirements of businesses that deal principally in non-combustible products. **Steel-frame construction** has been used chiefly in the past in connection with single-story buildings with sawtooth roofs, but reinforced-concrete construction is now being adopted for this purpose.

Roof Trusses

The types of roof construction which have been frequently adopted (see also pp. 1281–1284) are as follows:

The Fink truss (Fig. 4) is suitable for buildings from 40 to 80 ft. in width. It does not permit of good natural lighting nor ventilation in the greater widths.

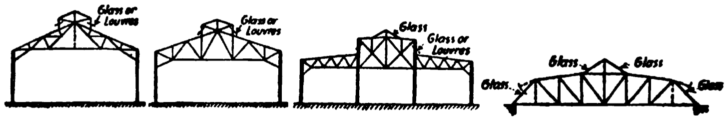

FIG. 4. FIG. 5. FIG. 6. FIG. 7.

FIGS. 4–7.—Roof Trusses for Industrial Buildings.

Fig. 5 represents a more expensive type of roof truss with the same objectionable features as the Fink truss. It gives, however, a stiffer building and overhead machinery can be hung from it readily and economically. In general, the span should not be greater than 80 ft. if effective natural lighting is to be obtained.

Fig. 6 represents an economical construction for spanning excessive widths, which provides good natural lighting and ventilation.

Fig. 7 shows a method of securing fairly satisfactory natural lighting and ventilation for buildings of large spans.

The customary **spacing** of the trusses illustrated by Figs. 4 to 7 varies from 15 to 25 ft., depending upon local conditions.

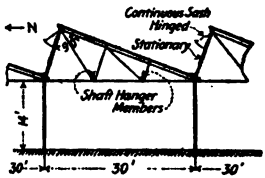

FIG. 8.—Steel Sawtooth Roof Truss.

Fig. 8 represents a steel roof truss of the **sawtooth type,** which is particularly adapted to single-story buildings covering a large area. Its use should result in relatively low cost, good natural lighting and ventilation, and ease with which line shafting can be attached. It is possible to obtain these conditions with a minimum story height and irrespective of area covered. The sawtooth should face due north to exclude the direct rays of the sun. If it were not for the inclination of the earth's axis the angle between the horizontal and the sawtooth should be 90 deg. minus the latitude in which the building is located. On account of the inclination of the earth's axis this angle must be increased by 23½ deg. In northern latitudes ranging from 35 to 45 deg. it is customary to make the inclination of the sawtooth to the horizontal about 70 deg. Where spans range from 25 to 30 ft. in width, the trusses are spaced from 15 ft. to 20 ft. center to center. **Sawtooth trusses with vertical glass faces** are not recommended, as they do not admit light as well as the type shown in Fig. 8.

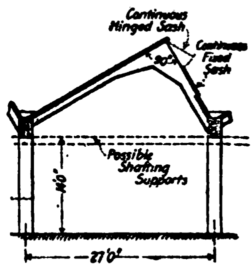

FIG. 9.—Reinforced-concrete Sawtooth Roof Truss.

Fig. 9 shows a **reinforced-concrete sawtooth truss.** It costs from 15 to 25 per cent. more than one of structural steel, but it is fully fireproof. The truss shown without a lower chord is used where overhead transmission shafting is not required and gives full sweep to the rays of light coming through the continuous sawtooth skylight. If shafting is required in the building, the truss can be designed with a lower chord of reinforced concrete, or a steel member can be inserted between the building columns made up of two channels, which makes an ideal support for shafting.

Fig. 10 illustrates a type of **building** that has been used extensively **for heavy machine and erection work**, the high bay being used for work requiring heavy crane service. In many cases the side galleries are omitted. The ratio of high-bay area to low-bay area being fixed, such a shop is capable of extension longitudinally only. Good natural lighting and ventilation can be obtained with this type of shop.

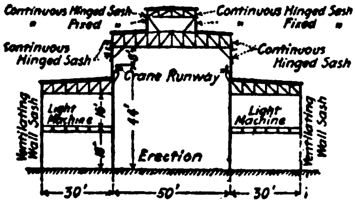

FIG. 10.

Figs. 11 and 12 illustrate types of construction that combine high center crane bays with single-story side bays of sawtooth roof construction. Such buildings permit of extension in any direction, so that any desired ratio of high-bay area to low-bay area can be secured. They are replacing to a considerable extent those illustrated by Fig. 10 on account of the ease with which they can be adapted to various manufacturing conditions.

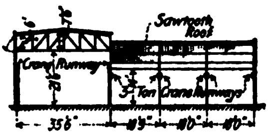

FIG. 11.

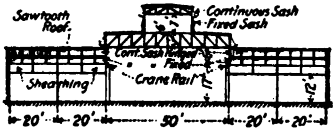

FIG. 12.

Fig. 13 represents a type of building adapted particularly to classes of industrial work which require good natural lighting combined with the best possible ventilation, such as **foundries, smith shops, drop-forge plants,** etc. Hanging gutters are dispensed with, and roof drainage is efficiently provided for, even in the coldest climates, by providing rain-water drainage inside the building where it is not subjected to outside temperatures. This design also provides excellent natural ventilation owing to the pitch of the roof toward the center and the large openings that can be provided on either side of the building directly under the eaves. As this form of truss (the Pond) is more expensive than the one illustrated in Fig. 10, its use is largely confined to those industries in which it is necessary to dispose of hot gases or fumes rapidly.

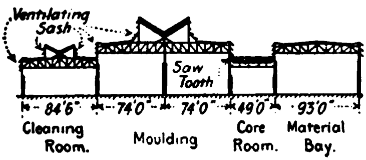

FIG. 13.

Roofs

For weights of roofing material, see p. 1280.

Wood Roofs. The wood roof is the cheapest form of substantial construction, but its life is relatively short as compared with all other types except metal, and it is combustible. If, however, the building is sprinkled and the roof covering is reasonably fireproof, the fire hazard is low. Generally, the wood roof comprises a layer of 2- or 3-in. tongued-and-grooved yellow pine fastened to wood nailing strips which are in turn bolted to purlins. Such a roof costs between 12 and 15 cents per sq. ft.

Metal Roofs. The simplest form of this construction comprises bare black or galvanized corrugated iron or steel (see p. 641) laid directly on the purlins. This is advocated only for buildings of a more-or-less temporary character. A more permanent form of metal roof is secured through the use of asbestos-covered corrugated iron, but even this material is not particularly durable if not otherwise protected. Metal roofs should have a very steep pitch in order to insure positive roof drainage. In general, they cost from 8 to 16 cents per sq. ft., depending upon the gage and grade of metal used and the type of protection afforded.

Reinforced-concrete Roofs. Various types of reinforced-concrete roofs are in general use, the principal differences being in the kind of reinforcement. Several of the commercial types of reinforcing material such as Ferro-inclave, Hy-Rib and asbestos-protected metal eliminate in large measure the use of temporary forms. In the case of steel buildings the concrete slabs may rest either directly upon the steel purlins, which procedure entails the minimum construction costs, or the concrete may be made to embrace all of the purlins for the purpose of stiffening the building and fireproofing the steel. More frequently the concrete roof is used in connection with reinforced-concrete buildings, in which case it is an integral part of the concrete construction. A concrete roof will cost from 18 to 30 cents per sq. ft.

The **Ferro-inclave type of roof** is a combination of corrugated sheet steel, concrete and cement plaster. The corrugations in the steel are dovetail in shape so as to hold the plaster coat on the under side and secure the concrete on the upper side. For spans from 5 to 6 ft. between purlins, the plaster coat on the under side is usually about 3/8 in. thick below the corrugations and the concrete on the upper side about 2½ in. thick.

The **Hy-Rib type of roof** is similar in construction to the Ferro-inclave except that the steel sheet is perforated and formed with parallel ribs an inch or two in width at regular intervals. Concrete is applied on the upper side and plaster on the under side in much the same manner as in the case of a Ferro-inclave roof.

Asbestos-protected Metal is corrugated iron coated on both sides with asbestos. When used in roof construction the concrete is applied on the upper side, usually being reinforced with steel fabric or rods depending upon the span. Plastering on the under side is usually dispensed with.

Composition Roofs. Several kinds of composition roof are in common use, some of which are built up in the field, whereas others are manufactured in units and shipped to the building site for use in much the same manner as ordinary tile. The composition in most cases consists of a mixture of gypsum and wool or straw with a steel reinforcing element. The desirable features of this type of roof are its fire-resisting qualities and its light weight (from 30 to 60 per cent. lighter than concrete). Its cost varies from 12 to 18 cents per sq. ft., depending on purlin spacing, thickness of slab, etc.

Tile Roofs. The tiles used for manufacturing buildings are usually made of reinforced cement concrete in units from 4 to 6 ft. in length by about 2 ft. in width. The mixture used in their manufacture is both fireproof and waterproof and a roof of this character does not require any additional covering for protection against the weather. The units are usually supported on purlins spaced to suit the size of tile used and are laid up somewhat like slate without cementing at the joints. Where skylights are required, tile of this character is often used with a pane of glass imbedded in the tile itself. The **cost** of such a roof varies from 15 to 35 cents per sq. ft., depending upon size of the units and the quality of material used.

Roof Coverings

For properties of roofing materials, see pp. 639 and 1280.

Slag is more commonly used than any other roof covering. First-class work requires four or preferably five layers of high-grade felt, each coated with pitch and surfaced with slag, gravel, pebbles or crushed stone. When the slope of the roof exceeds about 10 deg. a specially prepared pitch must be used to obviate the tendency to melt and run where high temperatures may prevail. A good slag covering **costs** approximately 5 cents per sq. ft. in place. It is considered practically fireproof and is guaranteed by reputable contractors to last 10 years.

Composition. Many excellent patented combinations of felt, pitch, asphalt, asbestos or other materials may be purchased in rolls. This covering is applied by nailing to the sheathing a single thickness and sealing at the seams with a waterproof compound. Practically all manufacturers guarantee their product to be fireproof and durable. Composition roof covering is ideal for roofs of steep pitch; it is also used extensively on flat roofs. The **cost** varies from 5 to 7 cents per sq. ft.

Shingles. Wood shingles (see p. 583) have been largely superseded by various patented shingles composed of asbestos and cement and furnished in units about 16 in. square. They are nailed to the roof structure like wood shingles and **cost** from 15 to 25 cents per sq. ft., depending upon the size, thickness, color and quality. Their use is restricted usually to roofs having a decided pitch.

Metal. The use of tin and copper roof covering for industrial plants is comparatively limited owing to the excessive cost, although the use of the proper materials results in the most permanent form of roof covering. The wide variation in quality of tinplate causes a range in **cost** from 8 to 18 cents per sq. ft., while copper covering costs from 30 to 40 cents per sq. ft., depending upon the gage of the metal used.

Slate. The use of slate for roof covering is limited to roofs of decided pitch and buildings where the roof forms a part of the architectural effect desired. The grades of slate in common use vary in **cost** from 8 to 15 cents per sq. ft. or even more when slate of an unusual quality, thickness or color is used.

Floors

Floors for industrial plants (see also p. 1272) may be classified broadly as (*a*) concrete, cement or asphalt, (*b*) wood plank and (*c*) wood block, the choice being governed by the nature of service to which the floor is to be subjected, the cost, and whether it is to rest upon the soil or to be supported on beams or columns.

Concrete, Cement or Asphalt Floors. A common form of construction consists of a wearing surface of ¾ in. of cement and sand laid on 4 in. of concrete over 10 in. of cinders. Such a floor is desirable where considerable moisture results from manufacturing processes or where it is necessary to flush the floor frequently. It tends, however, to create a dust where considerable trucking is done and it is difficult to make satisfactory repairs to the wearing surface. Moreover, its hardness and coldness make it uncomfortable for the operatives. A floor with a base of 1 : 3 : 4 concrete and a wearing surface composed of 1 part cement, 2 parts sand and 1 part granite screenings, will cost about $2 per sq. yd.

In another type of concrete floor the wearing surface consists of a coat of mastic asphalt compound. Such a surface is often desirable in shops where unusual traffic conditions prevail or where the floor is subjected to the action of gases or acids injurious to ordinary concrete. Cost, about $3 per sq. yd.

Wood-plank Floors. A wood-plank floor usually consists of a hardwood wearing surface supported either directly on sleepers or on an underfloor composed of plank laid in the opposite direction. Maple and birch are generally used for the wearing surface, varying from 13/16 in. to 1 3/16 in. in thickness. The underfloor is usually made of 1½- to 3-in. yellow pine or spruce planking. It is customary to use tongued-and-grooved material throughout.

For heavy machine and erecting shops tar-rock floor is frequently used. The sub-floor consists of a mixture of broken stone and tar tamped or rolled in place and covered with a 1-in. coating of sand mixed with hot pitch. A 3-in. yellow-pine underfloor is laid on this sand cushion while still hot and tamped securely in place without spiking, after which a 13/16-in. maple wearing surface is laid. The tar-rock sub-base acts as a preservative for the timber and prevents dry rot. Cost, about $3 per sq. yd.

A cheaper floor which is not recommended for heavy service and is less durable than tar-rock floor, has a wearing surface of 13/16-in. maple laid on a ⅞-in. underfloor resting on 3 × 4-in. sleepers, spaced 16 in. on centers. The sleepers are imbedded in a 4-in. thickness of cinder concrete supported on a 6-in. concrete sub-base. Cost, about $2.50 per sq. yd. A floor costing about 25 cents less per sq. yd. can be made by laying 13/16-in. yellow-pine flooring directly on the sleepers.

In another construction an underfloor of 3-in. planking is substituted for the sleepers in the floors previously described. The cost is about $2.75 per sq. yd.

Fig. 14 shows how provision may be made for the accommodation of piping or conduit work by supporting the underfloor on 3 × 6-in. sleepers resting on the concrete sub-base. Such construction has been found desirable in machine shops where the use of automatic machinery makes it necessary to install a complete system of piping for lubrication, or where any other complicated system of piping must be provided for. Cost, about $2.75 per sq. yd.

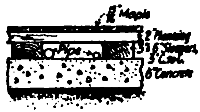

FIG. 14.

Wood-block Floors give better service than any other type where the conditions are unusually severe, such as in heavy machine and erecting shops, smith shops, drop-forge plants, warehouses, etc. They can be repaired more readily than wood-plank floors, and repairs do not have to be made so often as they will stand more abuse than any other floor. The blocks are usually rectangular, and are made from long-leaf yellow pine, maple, tamarack or other hard woods. They are generally impregnated with creosote or some other preservative, so that the liability of dry rot is practically eliminated.

Blocks for shop use vary in thickness from 2½ in. to 4 in. and generally are laid on a 1-in. cushion of sand resting on a 6-in. concrete sub-base. This floor costs about $2.25 per sq. yd. Where the loads imposed are comparatively light, and where service conditions are less severe, the concrete sub-base is sometimes omitted, the blocks merely being laid on a 1-in. cushion of sand resting directly on the soil. Such a floor costs about $1.75 per sq. yd.

Windows and Skylights

Windows. The development of metal sash has resulted in a marked improvement in the natural lighting of industrial plants. The use of metal in place of wood for the structural members of window frames and sash increases the glass area for a given window opening by over 25 per cent. Fig. 15 indicates several methods in which both steel and wood sash may be used.

Bay 1 (Fig. 15) illustrates an old type of wood window frame; the glass area amounts to only about 70 per cent. of the total window opening. With counterbalanced or double-hung sash, it is possible to secure 50 per cent. ventilation. Windows of this character can be furnished in place at from 30 to 45 cents per sq. ft.

Bay 2 shows the same size window openings as Bay 1 but with steel sash substituted for wood with a resulting increase in effective glass area from 70 per cent. to 90 per cent. of the total opening. It is possible to secure from 25 per cent. to 100 per cent. ventilation by means of ventilating panels indicated by dotted diagonal lines in the cut.

Bay 3 shows wood window frames arranged in groups of three so that the relative area of window opening to wall area is materially increased, but the net effective glass area as compared to wall opening remains the same as in the sash shown in Bay 1 (about 70 per cent.). In this case the greater size of the wood window frames increases the cost to from 40 to 60 cents per sq. ft.

Bay 4 shows the same size window openings as Bay 3 with metal sash instead of wood. This results in an increase in effective glass area from 70 per cent. to 90 per cent. with the same size opening in the wall.

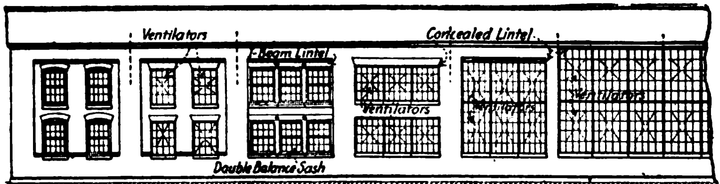

FIG. 15.—Types of Window Frames for Industrial Buildings.

Bay 5 shows a method that permits of a still greater glass area by extending the sash from pilaster to pilaster and from sill to lintel. This results in an increase of effective glass area of about 25 per cent. over that shown in Bay 4. It applies, however, only in single-story buildings of generous ceiling heights, whereas the arrangements shown for Bays 1 to 4 inclusive are equally satisfactory for single- or multiple-story buildings.

In Bay 6 no pilasters are used at the panel points, the result being that the entire side of the building is of glass. In this case, steel sash is located outside of the building columns which support the roof, giving maximum natural light through the side walls and making it possible to secure almost any degree of ventilation.

Steel sash varies in cost from 45 to 55 cents per sq. ft., depending largely on the size of units, number of ventilating panels, character of glass and quantity of sash required.

Multiple-story buildings up to 80 ft. in width can be supplied with adequate natural light by the liberal use of steel sash, whereas 60 ft. is about the limit when equipped with wood sash unless the ceiling heights are excessive.

Occasional applications of an inexpensive, white cold-water paint to walls and ceilings increase the light in all buildings.

Skylights. Formerly skylights of comparatively small area were used on buildings too wide to be sufficiently lighted through windows in the side walls. The introduction of monitors and sawtooth construction created the necessity for a continuous type of skylight with metal frames and ample provision for ventilation. Metal skylight construction must be waterproof, must permit of the automatic adjustment of the glass to unusual conditions of temperature, vibration, etc., and must provide positive drainage for moisture resulting from condensation.

Figs. 16–19 illustrate designs of skylight bars commonly used, most of which are equally suitable for flat, double-pitch, four-hip or continuous skylights.

Fig. 16 shows a common type of bar for small, non-continuous sheet-metal skylights. Cost, from 35 to 40 cents. per sq. ft., depending upon area.

In Fig. 17 the bar consists of a specially rolled section combined with a zinc or copper cap. Cost, 45–50 cents per sq. ft. Modifications of this type provided with lead liners and copper flashings, cost from 70 to 80 cents per sq. ft.

Figs. 18 and 19 illustrate bars that are easier to clean and repair than the other sections described. In these the glass rests on oakum or felt and the metal caps are held in place by large stud bolts which facilitate removal and replacement. The bar shown in Fig. 19 possesses an advantage in that the channel section or bridge connecting the bolts braces the whole construction and provides a substantial resting place for planks used in cleaning. Cost. from 50 to 65 cents per sq. ft.

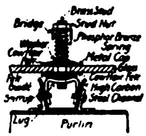

Fig. 18.

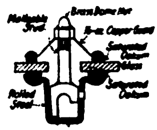

Fig. 19.

Figs. 16–19.—Types of Skylight Bars.

Heating

(See Heating and Ventilation, p. 1334)

The governing factors in the selection of a **steam-heating system** for an industrial plant are: (*a*) The degree and kind of heat required (moist or dry). (*b*) The amount of heat required for process work. (*c*) The size and type of buildings. (*d*) The amount of exhaust steam available.

The **direct system of radiation** is more desirable in multiple-story buildings and is usually more economical because of the ease with which coils or radiators can be located along side walls under the window sills. It is also more desirable in buildings of the sawtooth type because the coils located on the roof trusses will prove to be less of an obstruction to light than the large heating ducts necessary in connection with an indirect system.

The **indirect system** is usually more desirable in buildings of extreme width where large, unobstructed areas must be maintained and where the ceiling height is very much greater than in most multiple-story or sawtooth buildings. The high-bay type of erecting shop, for example, affords very little opportunity for the effective location of the heating coils necessary in a direct system, but the ducts required by the indirect system usually can be provided for satisfactorily, positive circulation of heated air being insured by fan pressure. It is particularly effective in plants where ventilation is of much importance.

Hot water is sometimes used in place of steam in direct heating systems. The greater amount of radiating surface required makes an excessive cost of installation which has been offset by combining sprinkler piping with a **hot-water heating system,** such a combination usually costing about as much as independent sprinkler and direct steam-heating systems.

Cost of Buildings

The only way to determine accurately the cost of a proposed building is to prepare detail estimates from complete plans and specifications. It is often desirable, however, to secure **preliminary estimates** before the completion of plans and specifications. For this purpose, certain **unit figures** are available, representing the results of past experience in erecting buildings of various kinds. These figures in most cases can be modified to suit conditions involved in proposed structures so that a fairly accurate estimate can be made. A number of unit figures relating to buildings of various kinds are given below, all referring to the **cost per cubic foot of space** and including all expense involved in construction work together with a reasonable contractor's profit. They do not include, however, architect's fees, cost of real estate, cost of preparing the building site or the cost of overcoming any unusual conditions such as treacherous soil, close proximity to other construction resulting in a lack of adequate working space, or unusual carriage charges owing to inaccessibility of the building site. All of these factors must be taken into consideration when using unit figures of this character and proper **allowances** made.

It should also be understood that these figures do not include anything in the nature of manufacturing, transportation or handling equipment. They represent only the **cost of a building** equipped **with the necessary service fixtures** to fit it for occupancy. The figures given cover a wide range of conditions for each type of building. Allowance must be made for all unusual conditions.

Approximate Cost of Industrial Buildings, Cents per Cu. Ft.

	Bare building, including plumbing	Complete building, including lighting and heating
Sawtooth buildings (first-class construction in structural steel and brick walls, using steel sash, a high-grade floor and slag roof)	7½ to 9	9 to 12
High monitor-type shops (foundries and heavy machine or erecting shops of structural steel, with brick walls, steel sash, first-class floor and slag roof)	5 to 6½	6 to 7½
Multiple-story buildings (slow-burning type of mill construction, with brick walls, wood sash and slag roof)	8 to 9½	10 to 12
Reinforced-concrete buildings (with maple floors, brick spandrel walls, steel sash and slag roof)	10 to 12	12 to 15
Multiple-story reinforced-concrete buildings (6 to 11 stories in height, with brick spandrel walls, steel sash and slag roof)	10½ to 13	12 to 15

REQUIREMENTS

Heating Capacity. A heating plant for a building should be capable of delivering a quantity of heat (E_t, in B.t.u. per hour) sufficient to replace that which is transmitted through the structure to the atmosphere and the surroundings under a stated extreme temperature difference, with allowances for exposure to winds, leakage and heat losses in piping and ducts. When the service is to be interrupted at night or periodically for one or more days, extra capacity must be provided for the heat that will be absorbed by the building until the normal temperature and rate of transmission are reached. The heat-storage capacity of the structure (E_r, in B.t.u.) and the time available for reaching full temperature will determine the allowance (see Reheating).

The temperatures required for various purposes and the lowest outside temperatures to be met are given in Table 1.

Table 1. Temperatures Used in Heating Determinations

INSIDE TEMPERATURES RECOMMENDED, DEG. FAHR.

Living-rooms	68°	Auditoriums	66°	Massage and operating	78°
Bed-rooms	64°	Churches	60°	Steam bath	114°

When rooms are to be **ventilated** by any method introducing air from outdoors, additional heat (E_v, in B.t.u.) must be supplied to bring it up to the room temperature. If ventilation is combined with heating, as with the indirect system, this air volume (Q, in cu. ft. per hour), must be heated through a greater range. In this case the total heat is $E_t + E_v = Q(t_f - t_o)sw$, where $E_t = Q(t_f - t_r)sw$ and $E_v = Q(t_r - t_o)sw$; t_o, t_r and t_f being the outside, room and flue temperatures respectively, w the density of the air and s its specific heat ($= 0.2375$) at constant pressure. $sw = 0.018$ for 70 deg. fahr., at which temperature the air volumes are generally based. If ventilation is independent of heating, E_v is the heat required for tempering the air supply.

In view of the increased tendency to natural ventilation in cold weather, it is proper, when calculating E_v, to figure on reduced volumes for lowest outside temperatures. A reduction to three-fourths of the volume for temperatures below 10 or 15 deg. fahr. and to one-half or two-thirds for temperatures below zero, is permissible, unless the volumes are absolutely prescribed.

Hygienic Requirements in Heating. The effect of heating apparatus on health and comfort depends on three factors, namely, the wholesomeness of the room air, the sensible temperature and the humidity. To obtain the **best results,** the following requirements should be met.

1. Even temperature within the rooms.

2. Selection of heating system. Continuous service and massive, impermeable structure are more favorable for heating by air, while the necessity for frequent airing by windows calls for direct heating. Light and permeable structure make heat reserve in apparatus (hot water) desirable.

3. Overheating of rooms depresses the vitality of occupants. The heat should always be under control, either centrally, as by variation of water temperature, individually by graduating valves on radiators, or automatically when regulation cannot be left to personal attendance.

4. The properties of fresh, cool, outdoor air should be preserved as far as possible. This means lowest room *air* temperature at which comfort can be secured and consequently the least drop in humidity. For this purpose it is best to utilize radiant heat in mild form, such as may be obtained from direct radiating surfaces at moderate temperature, spread out and spaced liberally. When air must be used to carry the heat it is better to use large volumes at low temperatures, not exceeding 125 deg. fahr. Rietschel (5th ed., p. 45) recommends a limit of 95 to 104 deg. fahr. for indirect, and 122 deg. fahr. for furnace heating.

5. Contamination of air by dust should be avoided. Clean heating surfaces of moderate temperature prevent decomposition, drying and stirring of dust. Concealed or screened heating surfaces gather dust and contaminate the air. Hot-air flues should be protected from falling dirt. Floor registers and dirt pockets generally should be avoided.

Ventilating Capacity. The **volume of fresh air** that must be introduced artificially, in order **to maintain wholesome indoor conditions,** depends on the amounts of heat, moisture, organic matter and other contamination produced in a room, less the amounts taken care of by natural absorption and leakage. The air volume varies also according to the standard of temperature, humidity and vitiation permissible in a given case. In schools, hospitals and wherever physical weakness and predisposition to disease are expected, the highest standard should prevail, and provision should be made in addition for periodical contingencies such as occur in class-rooms during breathing spells and in hospital wards at certain hours. See "Ventilation Laws," Heating & Ventilating Magazine Co., 1914.

Table 2. Heat Developed by Persons and by Various Methods of Lighting

	B.t.u. per hour		B.t.u. per c.p. per hour
Adult at hard work.....	550		
Adult at medium work.	470		
Adult at rest..........	13.2 (98.6 − t)	Incandescent alcohol light.	35 to 45
Children..............	6.6 (98.6 − t)	Petroleum................	110 to 250
	B.t.u. per c.p. per hour	Candles..................	320
		Electric, carbon filament..	10 to 16
Ordinary gas jet........	220 to 320	Electric, metal filament...	3.3 to 5.2
Incandescent gas light..	22 to 40	Electric, arc.............	4 to 6

The heat developed by persons and by various methods of lighting can be estimated from Table 2. The difference between the heat generated and the heat transmitted or absorbed represents the cooling to be effected by ventilation, E_c, in B.t.u. per hour. The volume per hour figures approximately $Q = E_c/0.018(t_m - t_s)$, t_m and t_s being the mean room and air-supply temperatures. If the volume is predetermined, the difference $t_m - t_s$ is to be figured from the same formula. Q is limited to the amount of air that may be introduced at the stated temperature without causing drafts, depending on height of room, location, style and number of inlets. From 6 to 12 renewals per hour may be permissible, depending again on the difference between t_m and t_s. If well diffused and inlets are placed away from occupants, the entering air may be kept from 5 to 10 deg. fahr. below room temperature.

The average hourly production of vapor per person, according to Pettenkofer, is 0.09 lb. for adults at rest, and 0.18 lb. for adults at work. Children will produce about one-half these amounts. The production varies with the air conditions, clothing, etc. It may be absorbed by walls or condensed by windows. The above figures therefore give no basis for calculation of the resulting relative humidity.

Air is rendered unwholesome by perspiration, by respiration, excessive heat, humidity, effluvia from the human body and other impurities directly or indirectly imparted by the occupants of a room. The percentage of carbonic acid may be regarded as a measure of the vitiation from respiration and from combustion, but not from the heat and moisture resulting from the same source. Air may be polluted with dust and other harmful matter of which CO_2 gives no indication. CO_2 tests should be used only for checking the renewal of air and its distribution within the room. The production of this gas can only be assumed as a basis for calculating the air supply where respiration and combustion (gas lights) are the preponderating factors of vitiation; in such cases the CO_2 should not exceed 8 or 10 parts in 10,000.

Table 3. Air Volume per Person in Cu. Ft. at 68 Deg. Fahr. Required if CO_2 Shall Not Exceed the Given Percentages of CO_2

(CO_2 in outside air is 0.04 per cent.)

Per cent. of CO_2	0.07	0.08	0.09	0.10	0.11	0.12	0.13	0.14	0.15
	Cu. ft. per person per hour								
Adult at work................	4650	3500	2800	2330	2000	1750	1560	1400	1270
Adult at rest................	2330	1750	1400	1170	1000	880	780	700	640
Children.....................	1500	1130	900	750	640	560	500	450	410
Gas burned, per cu. ft......	2100	1560	1250	1050	890	780	700	630	570

Table 4. Carbonic Acid Produced per Person and by Illuminants

	Cu. ft. at 68 deg. fahr.
Adult at work	1.2 to 1.6 per person per hour
Adult at rest	0.6 to 0.8 per person per hour
Children	0.3 to 0.6 per person per hour
Gas	0.5 to 0.75 per cu. ft.
Petroleum	27 per lb.
Candles	24.5 per lb.

The quantities of air based on dilution of carbonic acid may be calculated from the formula $Q = nc/(p - o)$ where Q is the number of cu. ft. per hour, p the permissible ratio of CO_2, o the original ratio in the outer air, n the number of sources producing CO_2, and c the volume produced by each source per hour. Table 3 gives the volume of air to be supplied per capita for certain limits of CO_2 under various conditions, and Table 4 the average rate of production by persons and by various illuminants.

Where the conditions affecting vitiation are uncertain factors, the air supply may be determined from general experience, according to Table 5.

Table 5. Air Supply for Ventilation

	Air supply per occupant, cu. ft. per hour	Number of renewals of air contents per hour	Remarks
Hospital wards	2700 to 3600*		*Billings
Hospital, epidemic	5000*		*Carpenter
Schools	1800* to 2400		*Legal requirements
Prison cells	500 to 750		Carpenter 1700
Prison wards	350		
Barracks	3000*		*Billings
Water closets	2400*	10 to 20**	*Per fixture, Billings **Wolff's practice
Living rooms	700 to 1200	1 to 2	
Kitchens		8 to 12*	*Wolff's practice
Auditoriums	1000 to 2000*		*Carpenter
Theaters	1500 to 1800*		*Snow-Nolan
Restaurants		5 to 6*	*Allen

The volumes given above may be reduced for rooms with very high ceilings when occupied for short periods only, and in general when leaky or not easily overheated. They should be increased where these conditions are unfavorable. Greater volumes or provision for increased air movement are required for summer.

Quality of the Air Supply. The **temperature** of the entering air should be that of the room, or lower when required for cooling. It is not advisable to combine the air supply with heating, which tends to raise the room air temperature. The latter can be kept lower by applying mild radiation independently. The air supply should help to maintain equable room temperature. The **relative humidity** may range between 30 and 70 per cent. of saturation, when the air is relatively cool and pure. Extremes are felt and become harmful when the air is overheated and dusty. The **purity** of the air supply is of prime importance. Where metallic, mineral and organic dust is present, it should be removed by washing or filtering and the air ways designed to be self-cleaning. **Movement** of air in a room is desirable, but it must not cause a sensible draft. Natural, gentle movement is favored by low air temperature. Drafts are felt quicker in hot air. For the velocity of the incoming air, see p. 1359.

SYSTEMS OF HEATING AND VENTILATING

Heating Systems

Open Fireplaces and grates are adapted only to mild climates or to rooms well protected from the weather. As auxiliaries to other apparatus or for ventilating they are desirable, but uneconomical as to fuel. Franklin stoves, which retain the advantages of the open fire, are somewhat better in this respect.

Closed Stoves, for wood or coal, can be fairly economical when of ample size, and are satisfactory for single-room heating. Iron stoves are too hot for wholesome effect. Tile ovens are better in this respect, especially for intermittent wood firing.

Individual Gas Stoves are cheap in first cost, but not economical in operation if connected to a flue, unless the heating surfaces are ample. Their surface temperature is generally too high for wholesome heating. When the products of combustion are allowed to escape into the room, the air is rapidly vitiated. This practice ought not to be tolerated for permanent installation.

Gas-fired Boilers for water and steam differ from coal-fired steam or hot-water systems only in that grates are replaced by burners. A greater number of small heaters may be used, by which long mains are avoided and the apparatus made more adaptable to control. This last feature reduces the gas consumption to a minimum and may often bring the cost of operation down to a reasonable figure. Whether it will prove advantageous depends on the price of gas, the saving in attendance and the value of the convenience.

Electric Heating is limited to where current is very cheap, where the cost or inconvenience of any other form of heat outweighs the operating expense, as for railways and where heat must be conveyed quickly to distant or inaccessible points, as in emergencies. When resistance coils are used as heating surface, their temperature is likely to be higher than desirable for hygienic reasons. This sanitary objection is avoided by heaters in which the surface temperature is reduced by some intermediate substance.

Hot-water Heating can be used to advantage wherever several rooms or buildings are to be heated from one service point. Water is best adapted to absorb heat from fuels, waste gases and exhaust steam. It can carry it economically for short or long distances. Through variation of water temperature it offers considerable range for general regulation, which is an important factor in reducing losses from pipe lines. The absence of rust and sediment resulting from the continuous use of the same water insures durability and reliability of apparatus. The danger of freezing is negligible with proper design and installation. High water pressure in tall buildings can be overcome by division of the system.

The **open system** should be used for gravity and forced circulation, with an expansion tank connected to the flow and return mains, so that air and steam may escape freely. The **cost of hot-water heating** depends upon the limit set to the water temperature. It is not necessarily higher than with steam heat and generally offers a better investment.

The choice between **gravity circulation and pumping** is decided in the main by the yearly expenses for carrying the heat. The **method of distribution** is determined generally by structural conditions. A small ratio of height to length of mains favors the overhead system. Tall risers generally make underfeed more desirable. Where the bulky lines are not objected to, single mains may prove the cheapest. Good circulation can be obtained by any of these methods where sufficient head is available. **Artificial acceleration** is recommended only to overcome special conditions.

Steam Heat is indicated where exhaust can be utilized with the least complication of apparatus, where general heat control and moderate temperature of surface are of secondary importance, and where heat is to be carried to distant points under a considerable pressure drop. In its simplest form, steam heat is generally cheaper in first cost than hot water, but less economical in operation and less desirable from the hygienic point of view. Steam heat is applied in **closed systems** under 1 to 10 lb. pressure, with two- or one-pipe distribution, the latter being the cheapest form. **Vapor systems** carry steam at practically atmospheric pressure. They are generally open through the returns. The flow of steam is restricted to the condensing capacity of the radiators, which permits graduated hand control through special valves. **Vacuum** is applied in different ways, through air lines or returns, according to the problem of drainage or removal of air. This auxiliary is used extensively in connection with exhaust-steam heating with the idea of reducing back pressure. When considering it with this in view, the additional apparatus involved will not always justify itself, since good circulation can be effected without suction in a correctly designed pipe system at not more than 0.2 lb. per sq. in. pressure drop, and the vacuum, being in practice maintained on return and air lines only, cannot increase the power output of the engine to any extent. Such apparatus is indicated mainly for special cases and for correcting difficulties of circulation on old plants.

The choice of the **method of distribution,** which may be overhead or from below or both, with wet or dry returns, is partly dictated by structural conditions, but it may also be influenced by the problem of equalization.

Warm-air Heating by furnace depends entirely on air as the heat carrier. This system should be used only where the first cost must be kept down and where the conditions are favorable. Sometimes it may be indicated for churches and halls to be heated only at intervals during which a steam or hot-water apparatus might freeze up and where it will not pay to keep the fires going in cold weather for better service and for the preservation of the building. When applied and designed with judgment, warm-air heating can give fair service, but its efficiency in utilizing the fuel is lower than that obtained with other heat carriers.

Indirect Steam and Hot-water Heating with the air circulating under gravity, is likely to be inefficient. This system is expensive in first cost as well as in operation and not desirable from the sanitary point of view, because the heating surfaces are never kept clean.

The **hot-blast system,** which is also a form of air heating, reduces the bulk of the ducts, the uncertainties of delivery and also the sanitary objections, in so far as the heating surfaces and air passages can be made self-cleaning. The heat is absorbed more readily under forced circulation, which greatly reduces the surface and often pays for the necessary machinery. Hot blast will pay generally for delivery of warm air at considerable distance, and is indicated where direct radiation is not practicable or not desirable, as in certain types of factory buildings, see p. 1332. **Hot blast with double ducts** for tempered and heated air is often used for schools. Unless distribution is made by a plenum chamber and well-proportioned individual ducts to each room, distribution is uncertain, because of the changing pressures in the ducts. The varying temperatures of the air supply are also liable to be felt in the rooms. From the heating point of view the system shares the uncertainties of hot air.

Ventilating Systems

Natural Ventilation by leakage through walls and around windows gives about one renewal of the air contents of a room per hour for average conditions during the winter season. This amount may vary considerably according to building structure and exposure. When supplemented by occasional airing, this natural exchange may suffice for rooms with light occupancy. Windows and transoms are also natural (and in some ways the best) means for ventilation, but they should be relied upon only where an occasional quick airing will suffice during the winter season. For crowded rooms or to meet some particular source of vitiation calling for a steady renewal of air, window ventilation is too uncertain, and if attempted to any extent, makes proper heating almost impossible.

Sash Ventilators depending on wind pressure or temperature difference will inevitably be closed during cold and windy weather and give little effect in still, mild weather when active renewal is most needed. Even where vent flues are provided to draw in the air, their action is most uncertain and liable to be reversed by outside influences. These devices should be used only for light duty, with the idea of increasing natural leakage when desired. **Air inlets**, behind or in connection with radiators (the **direct-indirect system**), are unsanitary when designed with box bases and screens that are bound to fill with dirt from the street. With large inlets the effect is even more uncertain than that of the sash ventilators. Considerable extra heating surface is required to cover the losses, which adds to the difficulty of the heat control.

Gravity Vents in the form of flues leading above the roof with ventilating or protecting hoods depend on temperature difference and wind. They should be considered as an aid to natural or window ventilation. When used in connection with a forced air-supply system, they should be calculated liberally, for a small temperature difference, so as to reduce the back pressure. Vents can be made to create a positive movement under all conditions when accelerated by heat. Since the greater part of this heat is lost, this method will not pay unless waste heat can be utilized for such purpose.

Mechanical Exhaust by fans is indicated for the removal of any special sources of vitiation and excess heat. It is most effective when applied locally, so as to prevent the spreading of heat or impure matter. Exhaust is also indicated when it is desired to put rooms under vacuum, to confine odors. Provision should be made in such cases for free access of air to these rooms from a locality not affected by wind.

Mechanical Air Supply by fan without any positive means for the removal, is sometimes called the **plenum system**, the object being to keep a room under pressure to avoid indraft. The results of this system depend largely upon the natural leakage of the rooms or the capacity of any vent flues, which are both influenced by the weather. The plenum is also used in distribution as a means for equalizing pressure by a large duct or a plenum space.

Mechanical Air Supply Combined with Exhaust, both by fans, is the proper equipment where positive, continuous ventilation is desired and prescribed volumes of air, tempered or otherwise conditioned, are to be introduced, and must be under complete control and independent of the heating apparatus. The needs of heating and ventilation do not coincide. The best results are obtained if each equipment is designed for itself and to best advantage for its own duties.

Open Disk Fans for circulation within a room do good service when air movement is desirable to relieve heat stagnation which cannot always be taken care of by apparatus designed principally for use in winter.

THE TRANSFER OF HEAT

Transmission of Heat in Buildings. The safe way to determine the hourly heat loss of rooms, etc., is by calculation on the basis of the surfaces exposed to cooling, and to estimate the effects of exposure and leakage under wind action. This loss is given by the formula, $E_t = [ak(t_i - t_o) + lQ(t_i - t_o)c](1 + e)$, where a is the wall, window or other area in sq. ft. exposed to cooling, k the heat transmission per deg. fahr. per hour per sq. ft., $(t_i - t_o)$ the temperature difference between inside and outside, l the number of hourly renewals of air, Q the cubical contents of the room, c the specific heat of the air per cu. ft. (0.018) and e the allowance for exposure and wind action according to the points of compass, as a fraction of the heat transmission and leakage. Table 6 gives the rate of heat transmission k, and is based on German and American practice. The values for corrugated iron are from a test by A. H. Blackburn. They apply to quiet air only. Extra large allowance must be made for wind action and height of walls. The figures for frame walls are those used by the Supervising Architect of the U. S. Treasury Department, Washington, D. C. Only one coefficient is given for single glass, to be used for windows and skylights with allowances for height, which induces air currents and increases the transmission. The factor l, giving the number of hourly renewals of air by leakage, is estimated from the exposure and material. With one outside wall, l varies from 0.5 to 0.8; for corners, from 0.8 to 1.2, and for rooms with through or updraft, 1 to 1.4.

Table 6. Coefficients of Heat Transmission in Buildings

(k = B.t.u. per hour per sq. ft. per 1 deg. fahr. difference in temperature)

WINDOWS AND DOORS

	k		k
Single windows	1.03	1-in. wood doors	0.50
Double windows	0.48	2-in. wood doors	0.46
Double glass on single sash	0.72

Plaster, air space, concrete arch and cement	0.24
Plaster, air space, single wood floor above	0.18
Plaster, air space, double wood floor above	0.16
Plaster, brick arch, wood floor on sleepers	0.14

For exposure and wind action add the following percentages, e, to outside transmission and natural ventilation: North, 20 per cent.; Northwest, 25 per cent.; West, 20 per cent.; Southwest, 10 per cent.; South, 0 per cent.; Southeast, 5 per cent.; East, 10 per cent.; Northeast, 15 per cent. These percentages are to be modified according to situation. They are to be increased where glass areas are large and decreased for small windows, solid construction and a preponderance of cooler inside surfaces not exposed to wind. The area a should be measured from c. to c. of intersecting walls, floors and ceilings. Window areas are understood to be the clear openings in walls.

For very tall buildings it is necessary to take into account the pressure created by the column of warm air within, as the several connecting stories act in the manner of chimneys, drawing air from below and discharging it above the "neutral zone." Where halls, elevator shafts and rooms interconnect freely, also in tall rooms, the resulting tendency for indraft of cold air through windows and doors at the lower levels must be taken care of by additional heat. Such allowances may run up to 50 per cent. of all other losses. It is not safe to deduct correspondingly from the heat for upper floors, since the warm air from below will not always and should not travel through the rooms above.

This method of estimating the heat requirements may be applied to all classes of buildings, excepting only very massive structures (see p. 1343), but in general it should be borne in mind that the figures given are necessarily approximate, since the heat transfer varies with quality of materials, dryness of surface and interior, finish and other minor factors. Considerable judgment should be used in estimating coefficients.

Carpenter's Rule for Ordinary Buildings, which should be used for approximation only or for estimating, is as follows: B.t.u. per hour $= (Cn/55 + W/4 + G)d$, where C = volume of room in cu. ft., W = sq. ft. of exposed wall surface, G = sq. ft. of windows, d = difference between inside and outside temperatures in deg. fahr., and n = the number of times per hour that the air is changed in the room ($n = 1$ for ordinary rooms = 2 to 3 for halls and vestibules).

Reheating Buildings. Allowances for reheating are not necessary where heat will be needed for the greater part of every day. In such cases the service should be continuous in coldest weather in order to maintain a desired temperature. This applies in general to residences, to most business buildings and to greenhouses. When heat is needed only for the smaller part of the day, as in many schools, some allowance should be made for reheating. Substantial buildings with considerable heat reserve will cool off more slowly, but will also take much time for reheating. Leaky, exposed buildings cool off quickly and are slower to heat up under extreme conditions, as the rapid transmission leaves little margin for raising the temperature. The allowance should be increased according to the ratio of the heat transmission to the heat reserve E_t/E_r, and according to the time stipulated for reheating. From 10 to 25 per cent. should be added to the boiler capacity and radiating surface for daily reheating. The same principle applies to buildings heated periodically and allowed to cool to any extent, such as churches. The maximum heat required per hour will then figure approximately $E = (E_r/H) + E_l + E_t[½(t_l + t) - t_o]/(t - t_o)$, where H = number of hours allowed for reheating, t_l and t = lowest and normal inside temperatures, t_o = outside temperature, E_l = heat losses in transit from generator to heating surfaces, and E_r = thermal absorption of building and apparatus during the period of reheating.

Assuming the mean temperature of the structure to be halfway between the indoor and outdoor temperatures, the total heat absorbed is $E_r = 0.5\,(t - t_l) \times cW + (t_m - t_l)cW$, where cW represents the sum of products of specific heat and weight of the materials warmed in building and apparatus, as calculated from Tables 7 and 8, and t_m the maximum temperature of the water to be reheated. Where a banked fire is kept up, t_l (the lowest temperature of the apparatus) can be assumed higher than the lowest room temperature.

Table 8. Approximate Weights and Thermal Capacities of Heating Apparatus

	Approx. wt. per sq. ft. rating, lb.	B.t.u. per 1° F. (sp. ht.) per sq. ft. rating	Water contents per sq. ft. in lb. at 60° F. or B.t.u per 1° F.
Cast-iron sectional boilers	(S) 2 to 4; (W) 1.2 to 2.4	(S) 0.26 to 0.52 (W) 0.16 to 0.32	(S) 0.35* (W) 0.25*
Cast-iron sectional radiators	(S) 6.5; (W) 7	(S)0.85;(W)0.9	(W) 1 to 1.5

(S) for steam, (W) for water. * Obtained for "Mills" boilers only.

For weight and capacities of piping, see p. 797.

Rietschel gives two formulæ for reheating. For rooms which are heated daily, but with interruptions during the night, the heat per hour A to be added to the other heat losses is $A = 0.0625(n - 1)W_1/z$ and for rooms which are not heated daily, $A = 0.1(8 + z)W/z$, where W_1 = the heat lost per hour in normal operation through the outside wall and windows and other exposed surfaces which have to be rewarmed, W = the total heat loss of the room per hour, from all causes when normally heated, n = the number of hours from the ending of the daily heating in the evening to the beginning in the morning, z = the number of hours from the beginning of the heating of the morning to the time when the building is thoroughly heated. A should never be taken greater than $\frac{1}{2}W$.

In exceptional cases, when a very **massive structure** is used occasionally for a few hours, the heat transmission will not be normal and the walls keep on absorbing heat until some time after the room temperature is reached. Rietschel gives the following approximations for these problems:

For direct heating $E = \frac{A_g k(t - t_o)}{2} + A_w\left[8.5 + \frac{(t - t_i)}{H}\right]$;

For indirect, or hot-air heating $E = \frac{A_g k(t - t_o)}{2} + A_w\left[14.8 + \frac{2(t - t_i)}{H}\right]$

where A_g and A_w are the glass and total inside and outside wall areas, and k the coefficient of transmission for glass (1.02). For rooms over 40 ft. high, add 15 per cent. for every 10 ft. of additional height.

It will be found in some cases that the capacity of apparatus figured from these formulæ will be several times greater than that based on continuous heating. The question will then arise, whether in mid-winter a steady service, reduced between periods of occupancy, will not pay better. As a general rule, little or no fuel is saved by interruption of service. Continuous heating reduces the capacity of apparatus required, the time of reheating, gives a steadier load on boilers, and results in warmer walls and more equable, agreeable conditions in rooms.

Calculation of Heating Surface for Rooms. The heating surface required to make up the losses by transmission and for reheating $E_t + E_r = E$ is figured by the formula $S = E/(t_r - t_a)k$, where E is the total heat to be emitted in B.t.u. per hour, t_r and t_a the mean temperatures of the heat carrier in the radiator and of the surrounding air, and k the coefficient of transmission in B.t.u. per hour per deg. fahr. difference.

For **direct surfaces** the average values of $(t_r - t_a)k$ used in **steam and hot-water heating practice** are given in Table 9. They apply closely to the typical sectional radiators and pipe coils standing not more than 3 in. and not less than 2 in. from a wall.

Corrections.—For lower room temperature than 70 deg. fahr., increase the heat emission by 1 per cent. for every degree lower; for a higher room temperature, reduce by 1 per cent. for every degree higher.

For surfaces under windows add 5 per cent. to the emission.
For surfaces on inside walls subtract 5 per cent. from the emission.
For radiators of less than 6 sections add 5 per cent.
For radiators of less than 4 sections add 10 per cent.
For 1-in. pipe add 5 per cent.; for 2-in. pipe subtract 5 per cent.

When sections are widely spaced apart the coefficient is likely to be somewhat higher. When spaced close together k is generally lower, except when the design favors air currents. Corrections should be made for higher or lower room temperatures, for location, length of radiators and pipe diameter of coil surfaces, as stated. The heat emission is further affected by the finish of the surfaces, which bears on radiating qualities. This applies particularly to styles of radiators giving a greater proportion of radiant heat. According to Prof. J. R. Allen (see *Trans. A. S. H. & V. E.*, 1909) the customary bronzing materially reduces efficiency, while lead paints and enamel finish are as good or better than bare surfaces.

Percentage of moisture saturation	20	30	40	50	60	80	100
Coefficient of transmission	1.79	1.77	1.75	1.72	1.69	1.63	1.59

Table 12. Heat Transmission through Cast-iron Radiators at Varying Temperature Differences

(John R. Allen, Nat. Dist. Htg. Assn., June, 1911)

Temperature difference, deg. fahr	80	100	120	150	170	190
Coefficient of transmission	1.56	1.58	1.62	1.65	1.69	1.72

Marble or iron tops, shelves or any feature that will obstruct circulation or radiant heat will also keep down the heat emission. For screened heating surfaces, according to the experiments by Brabbée (*Gesundheits-Ingenieur*, No. 44, 1911), the efficiency is reduced most for low radiators and where the air circulation is through the front only. The reduction may reach 40 per cent. for metal screens. For insulated wood boxing with low solid top the emission is reduced by at least one-half, and still more when surfaces are dusty. Screens practically stop the radiant heat and turn the apparatus into an unsanitary, inefficient and expensive hot-air heater. Direct heating surface should not be concealed.

For **indirect heating surface** in stacks the calculation should cover the losses by transmission and ventilation $E_t + E_v$, including the losses in flues. The rate of heat emission depends upon the obtainable velocity of the air, the character of surface, which is usually extended by ribs or pins, and upon the depth. For steam heat, with air at about 3.5 ft. velocity per sec., $k = 3.0$ for plain, and 2.4 for extended, surface. For hot-water heat with air at about 3 ft. vel. per sec. $k = 2.75$ for plain, and 2.2 for extended, surface. For deep sections (20 sq. ft.) the coefficients should be taken about 10 per cent. smaller. For higher and lower velocities the efficiency, according to Carpenter (5th ed., p. 103), varies as the square root of the velocity. The velocity obtainable in the stack should be verified (see p. 1358).

For **direct indirect radiators**, where fresh air enters a room through a direct radiator, the heat emission is extremely variable and uncertain, depending on the arrangement of the air inlets. It is not safe to assume the efficiency of the surface higher than that of ordinary direct radiation. The calculation should be based on $E_t + E_v$, according to the renewal of air assumed.

Hoffman ("Handbook for Heating and Ventilating Engineers'" p. 116), gives the following rules for indirect heating, which may be used for approximation: Duct area in sq. in. = sq. ft. of radiation installed $\times\ C$; and cu. ft. of air supplied = sq. ft. of radiation $\times\ K$, values of C and K being as follows:

	C		K	
	Steam	Hot water	Steam	Hot water
First floor	1.5 to 2	1.00 to 1.33	200	150
Second floor	1.0 to 1.25	0.66 to 0.83	170	130
Other floors	0.9 to 1.0	0.6 to 0.66	150	115

Allen gives the data of Table 13 on the heat emission from the standard types of indirect radiators.

For **hot-blast surface**, box coils or cast-iron sectional radiation may be used. For cast-iron surface specially designed for blast, the manufacturers give figures for various depths, velocities and temperatures of steam and air. The efficiency of the type of coils in general use, with 1-in. pipes, 2⅛ in. on centers in staggered rows, giving about 40 per cent. free area, the rate of emission for different speeds and depths of heater, may be obtained from Fig. 1, which represents the average results of several series of tests by differ-

Table 13. Heat Emission from Indirect Radiators

Cu. ft. of air per sq. ft. of radiation	Increase in temperature of the air passing the radiator, deg.		Steam condensed per sq. ft. of radiation, lb.		B.t.u. transmitted per sq. ft. of radiation per deg. diff. in temp. of the steam and the air

300	119	112	0.700	0.61	4.22	3.60

ent experimenters. For other air and steam temperatures the efficiencies will be roughly proportional to the mean differences, but increasing for colder and decreasing for warmer air. The rate of emission is not affected to any extent by the condition or finish of the surfaces, but is liable to be influenced by interior circulation, or lack of it.

EFFICIENCIES OF HOT-BLAST COILS

40% FREE AREA

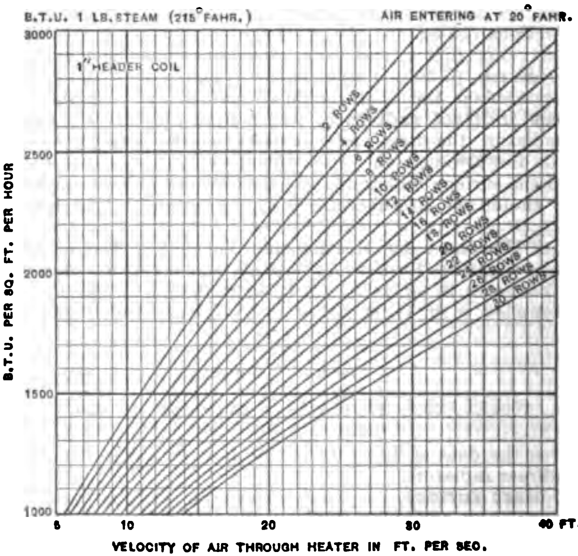

FIG. 1.

Laws of Convection, Steam to Air (From tests of 1-in. wrought-iron pipe, by Carrier and Busey, *Htg. and Vent. Mag.*, Jan., 1912):

$$\log [(T_s - T_1)/(T_s - T_2)] = f/(0.1119V + 127); \text{ also,}$$
$$\log [(T_s - T_2)/(T_s - T_1)] = 0.3994\, fK/V,$$

where T_s is the steam temperature, T_1 the entering air temperature, T_2 the final air temperature, $f = S/A$ = ratio of total surface to clear area, V = velocity of air through clear area (at 70 deg.) in ft. per min., and K = B.t.u. per sq. ft. per hour per deg. temperature difference between steam and air.

For ordinary calculations where it is desired to solve for the initial and final temperatures when f and V are known, first determine approximate values of T_1 and T_2 from the first-given equation. Then solve for the mean temperature difference between steam and air, using the above-determined values of T_1 and T_2 in the formula $(T_s - T)_m = 0.434\ (T_2 - T_1)/\log [(T_s - T_1)/(T_s - T_2)]$ where $(T_s - T)_m$ represents the mean effective temperature difference between the steam and air.

Boilers. See also pp. 866 to 937. For low-pressure ($\leq$ 20 lb.) steam heating, **cast-iron sectional boilers** are usually best adapted, especially for the smaller units. They are rated by the makers in terms of the radiation surface, S, in sq. ft., which they will supply; in B.t.u. per hour the capacities are $250S$ for steam and $160S$ for hot water. Ratings are given for anthracite; for bituminous coal boilers should be from 10 to 30 per cent. larger. In small boilers allow 1 sq. ft. of **grate surface** to every 15 to 30 sq. ft. of heating surface. Over half the heating surface should be exposed to direct radiation from the fire. With average draft they burn from 2 to 6 lb. of anthracite per sq. ft. of grate surface per hour, and with bituminous coal from 3 to 8 lb. Efficiencies run from 50 to 70 per cent.

Hot-air furnaces burn from 2½ to 6 lb. of coal per sq. ft. of grate surface per hour. Their efficiencies vary from 50 to 70 per cent. **Grate surface** in sq. ft. = $H/20{,}000$ to $H/45{,}000$, where H = B.t.u. required per hour. The **furnace capacity** should be increased 25 per cent. for bituminous coal and 33⅓ per cent. for Rocky Mountain bituminous or lignite.

The heat transmission from hot gases to air under the conditions of a hot-air furnace is from 550 to 750 B.t.u. per sq. ft. per hour for smooth surfaces and from 450 to 550 B.t.u. for extended or ribbed surfaces. Recknagel gives 1.0 to 1.4 B.t.u. per 1 deg. fahr. difference of temperature per sq. ft. for air velocities of about 3 ft. per sec. Allen allows 50 to 70 sq. ft. of heating surface per sq. ft. of grate surface.

MECHANICS OF HEATING

The movement of the heat carrier is effected either under its own power, as in gravity circulation and by the pressure of steam, or the necessary power is applied by machinery, as in forced circulation. The principles of distribution remain the same. The energy is used in part to overcome pipe friction and local resistances, the balance being expended in the desired movement. The problem of distribution is the adjustment of the resistances to the pressure available for each point of delivery. Tables based on total pressure alone can only give average sizes and may serve for estimates. The correct **sizes** of pipes and ducts to assure good distribution should be obtained by calculating and equalizing the resistances of the individual circuits.

Gravity Hot-water Circulation. The distribution of heat to a number of radiating units is calculated for a uniform temperature difference between all the rising and falling columns of water, making the difference in weight of the two columns proportional to the height available. The actual height h of the columns required to produce the flow, or the difference in mean level between the heat-emitting and receiving surfaces, usually represented by the radiator and boiler, is given by the equation $(w_1 - w)h = H(w + w_1)/2$, or $h = 0.5H(w + w_1)/(w_1 - w)$, where w and w_1 are the densities of flow and return water, H the sum of resistance heads for the circuit in question. The weight (W) in lb. per hour and the velocity (v) in ft. per sec. of the water quantity for which H must be figured, are $W =$ B.t.u. per hour$/(t - t_1)$ and $v = W/[3600a(w + w_1)/2]$, where t and t_1 are the temperatures, w and w_1 the densities of flow and return water in lb. per cu. ft. and a the pipe area in sq. ft.

A distributing pipe system is to be proportioned so that the sum of friction and local resistances, as read from Fig. 2, expressed in differential heads for the chosen temperature drop, in this case 30 deg. fahr., equals the actual height available between the radiator and boiler for each of the circuits in question. As the water expands 1 ft. in 100.3 ft., the true head is multiplied on this chart by 100.3. The slope of the lines is based on Tutton's general formula, as used by Schoder (see *Eng. Rec.*, Sept. 3, 1904, and *Trans. A. S. C. E.*, vol. 51, p. 308) and applied by Meier to heating with allowances for conditions in practice. The friction and resistance heads for runs of even diameter and velocity between junctions will figure $h_f = 0.0257 \times (v^{1.86}/2g)(l/d^{1.25})$ and $h_r = 1.38rv^{1.86}/2g$. In the above equations v is the velocity of flow in ft. per sec., r is a resistance factor whose values for different types of obstruction are given in Fig. 2, l and d are respectively the length and diameter of the pipe in ft. For a circuit of several runs the total resistance H equals the sum of h_f and h_r, which is $H_f + H_r = H$.

The readings from the chart in Fig. 2 agree substantially with the results of formulæ with variable coefficients of friction in so far as they apply to conditions in actual heating practice. The local resistances are read along the same velocity line, where it intersects with that for the features to be calculated. The resistance heads h_r are not strictly proportional to the velocity head, but taken to vary in this respect as the friction, the results being close enough to established facts for all practical purposes.

In using Fig. 2, start with the amount of heat to be given up by the water (as shown on the lower horizontal scale) and follow vertically till the assumed pipe size (lines inclining down to the left) is reached. The velocity in the pipe is given by the lines inclining down to the right. The vertical scale gives the height required to overcome the frictional head in 10-ft. length of the pipe, or the resistance offered by various obstructions. These heights must be read at the level of the intersection of the inclined velocity line with the pipe size and the obstruction lines. For example, for a transmission of heat of 240,000 B.t.u. per hour, with 4-in. water main, the velocity is seen to be 0.4 ft. per sec. The height required to overcome frictional resistance is 0.29 ft. per 10-ft. length of pipe; to overcome the resistance of a gate valve on the same run it is 0.1 ft.; of an angle valve 0.35 ft.; of a globe valve 0.77 ft.

The **calculation** is the same in principle for single or multiple circuits and for any method of distribution and means of acceleration. The choice between single-main distribution with secondary circulation, the underfeed or the overhead distributing system, is sometimes decided by the structural and service conditions. The feasibility of increasing or decreasing the effective head by the heat losses in transit, as may be needed to equalize, will decide in favor of one or the other method. In any event, it is necessary to follow the individual circuits and to calculate the mains so that the radiating surfaces in least favorable locations will have sufficient head available with connections of reasonable size.

For **rational calculation** it is necessary to establish all factors systematically by the use of a pipe schedule in the shape of an isometric drawing, showing all lengths and elevations to scale, also all the features causing local resistances. The B.t.u. carried may then be entered for all runs of even

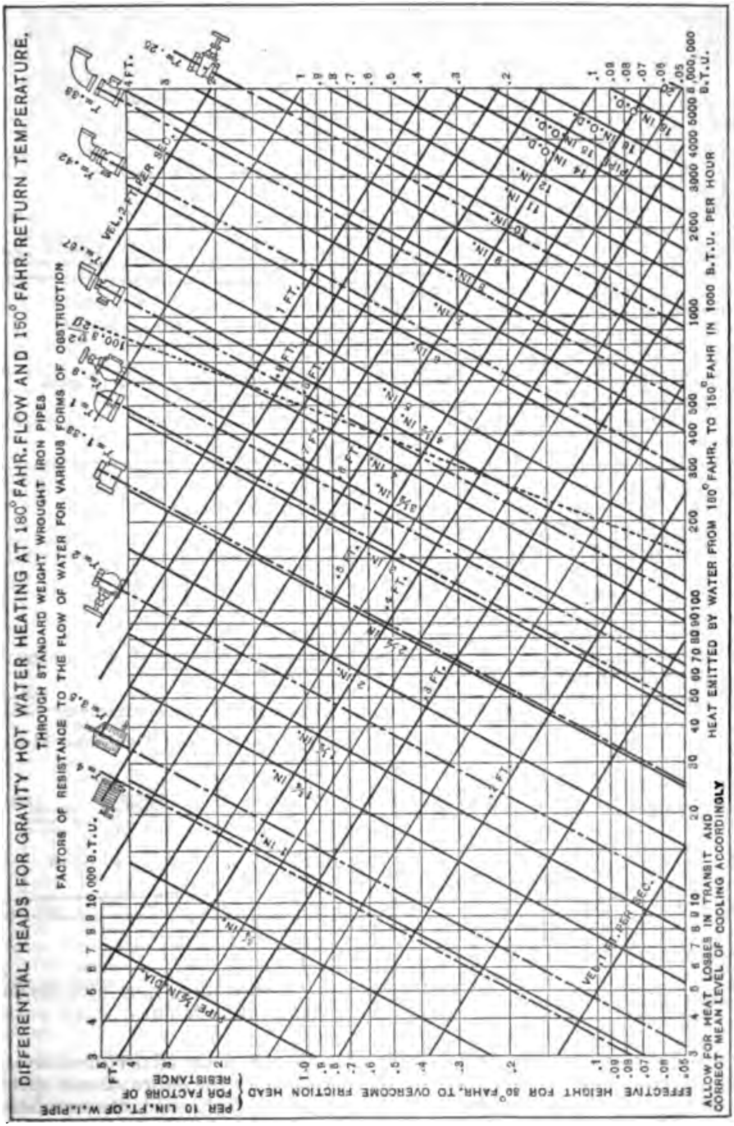

Fig. 2.—Chart for Gravity Hot-water Circulation.
(Condensed from Meier's "Mechanics of Heating and Ventilation.")

diameter on branches and added up for the mains. The piping is then to be sized tentatively by means of the table of approximation. On the basis of these preliminary sizes the resistances can be figured and modified where necessary to balance the effective available heights. This calculation is facilitated by the chart in Fig. 2, which permits direct readings of the losses of head by friction and local resistances for any quantity of water, or heat carried under the same range of temperatures. For smaller or larger range the volumes as well as the difference in density will vary. The B.t.u. and friction head in Fig. 2 should be multiplied by 1.15 for 26 deg. fahr. drop, 1.07 for 28 deg., 0.94 for 32 deg., and 0.88 for 34 deg.

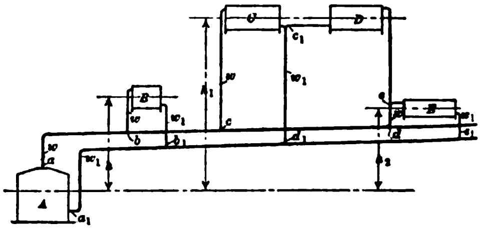

FIG. 3.—Hot-water Heating System with Underfeed Mains.

Greater drop of temperature is preferable for long mains. Smaller drop may be indicated for great heights; in other cases it results in excessive water bulk, slow heating and high cost.

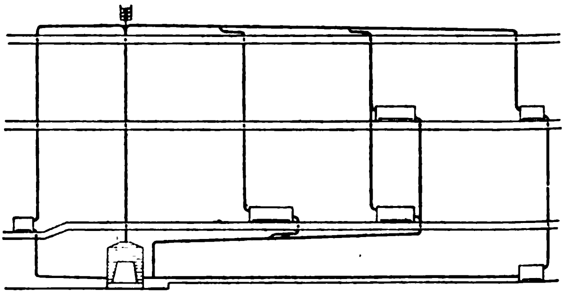

FIG. 4.—Hot-water Heating System with Overhead Mains.

The **heat losses along** the **uncovered flow mains** and bare risers should be estimated in B.t.u. and added to the tax on the lines. If these losses occur mainly at higher or lower levels, the mean height of cooling should be established and taken as the effective head.

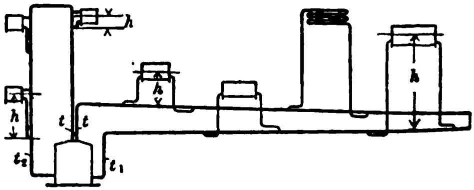

FIG. 5.—Hot-water Heating System with Single Distributing Main.

When using Fig. 2 the resistances are obtained for runs of even diameter, from junction to junction, usually together for flow and return. Starting at the boiler the items h_f and h_r are added successively, up to the radiator closing the circuit. The sum for the entire circuit should then approximate the head available. Where properly sized, the circulating system will need no adjustments.

For an **underfeed system** (Fig. 3), the resistances are figured first for the runs $a - b - c - d - e$ plus $e_1 - d_1 - b_1 - a_1$ plus $e - E - e_1$, for which the sum of differential heads, as read from the chart, should approximate the actual height h_2 in ft. The circuits nearer to the boiler are figured in the same way, the connections being modified to make up the desired totals h_1 and h.

With an **overhead system,** the circuits are followed in the same manner, but flow and returns must be figured separately from the first to the last junction. It pays in such cases to take advantage of the increased effective head due to the cooling of the mains at a higher level. Fig. 4 will suggest the method for calculating the mean effective head available for a branch carrying a stated total heat, also for radiators placed in sequence.

For **single-main distribution,** as shown by Fig. 5, the main should be calculated as a circuit by itself for a temperature drop $t - t_1$ or $t - t_2$ that will assure sufficient heating effect for the branches farthest from the boiler. The branch circuits are to be calculated independently for any range and height h above main, and need not be balanced against each other.

Table 14 gives sizes of mains and risers for various lengths of circuit and height h for gravity hot-water systems. It may be used for approximation and estimating.

Table 14. Gravity Hot-water Heating. Approximate Capacities of Mains and Risers for Range from 180 to 160 Deg. Fahr.

Capacities (including losses in transit) are in 1000 B.t.u. per hour and allow for average resistance of boilers, radiators and piping. For sq. ft. of radiating surface supplied (160 B.t.u. per sq. ft.), multiply the tabular figures by 6.25.

* The length and mean height above boiler are those of the circuit for the most distant radiator in lowest location.

† The mean height above boiler is that of the circuit in question. This table is for a circuit 200 ft. long. For other lengths allow about in proportion as given above for mains.

Accelerated Gravity Circulation. Where difficult conditions are to be overcome, the circulation may be accelerated by the injection of steam into the flow main. The increased differential weight gained thereby is the motive power for most of the artificial systems of quick circulation on the market.

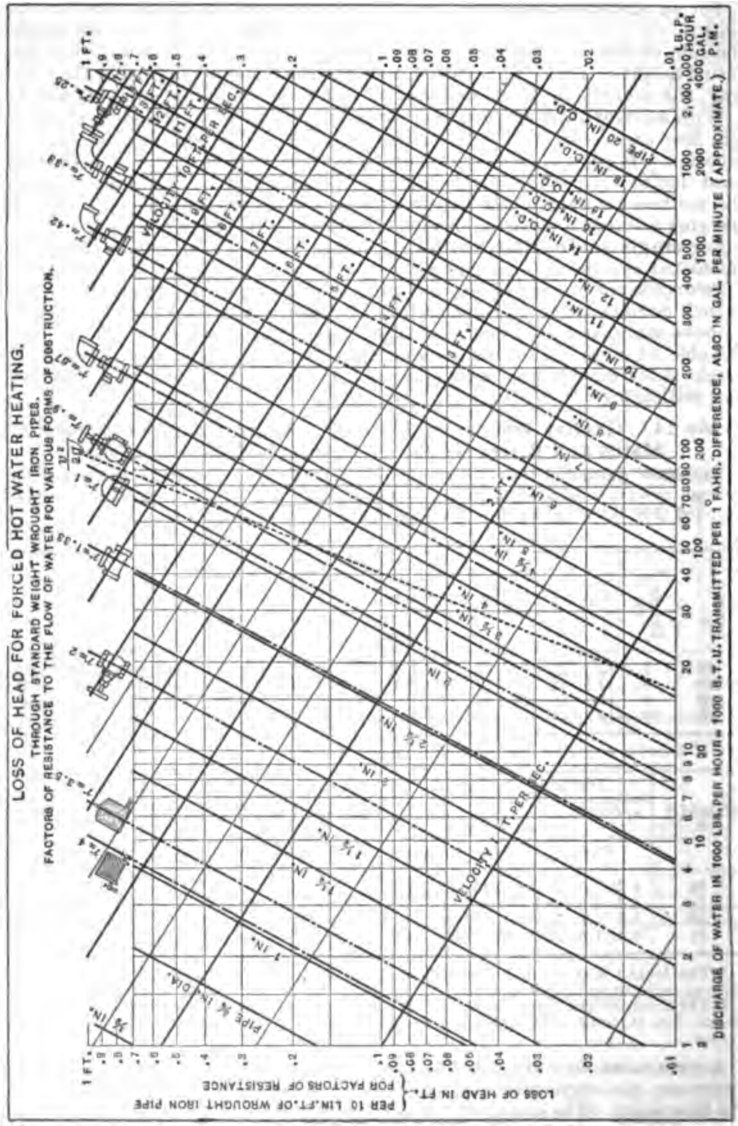

Fig. 6.—Chart for Forced Hot-water Circulation.
(Condensed from Meier's "Mechanics of Heating and Ventilation.")

With closed systems, permitting water temperatures above the boiling point, the circulation can be forced by greater ranges between flow and return. Either method depends on high flow temperatures and should not be recommended, except to meet special conditions.

Forced Hot-water Circulation is used where the saving due to the use of smaller pipe sizes will pay for the cost of pumping, which is often the case in connection with power plants. Centrifugal or rotary pumps are preferred for this work.

The **range of temperature between flow and return** with forced circulation, or the volume and speed of the water, are determined by the temperature available in the generator and that desired at the radiators. Ranges of 10 to 20 deg. fahr. difference are within the limits of good practice.

To approximate, the system is first sized on the basis of an even rate of pressure losses, along one horizontal line of the chart in Fig. 6, selected according to power and length, or the initial velocity desired. The losses of head throughout the system and the resulting differential pressures are then obtained conveniently, and the sizes of branches can be modified to make up the same total. The losses of head in this case are expressed in actual ft. of water column. It is advisable to eliminate any gravity head by using sufficient pump head.

In using Fig. 6 proceed as in Fig. 2, noting however that the abscissæ are weights of water circulated and that the ordinates are losses of head. For 240,000 B.t.u. per hour, and a temperature range of 12 deg. fahr., the weight of water circulated is 20,000 lb. per hour. With 2½-in. pipe the velocity is seen by the chart to be 2.75 ft. per sec. The losses in head due to this velocity are 0.19 ft. per 10-ft. length of pipe; 0.037 ft. per gate valve; 0.13 ft. per angle valve and 0.27 ft. per globe valve. The pressure loss for instance from a to a_1 on Fig. 7 must be made to equal that for $a - b - b_1 - a_1$ and $a - b - c - c_1 - b_1 - a_1$.

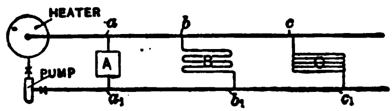

Fig. 7.

The **sizes** may be **varied** for flow and return or for portions of runs **to effect close equalization,** which will obviate the need of adjustments. The lines to and from the expansion tank should also be equalized to prevent short circuit, as well as the possibility of freezing. The suction at the pump inlet should be overbalanced by the static head of water to prevent boiling at the highest return temperature. The calculation of pressure losses will give the proper head, speed and motive power for centrifugal pumps.

For **central-station heating** the distribution to several buildings can be figured on the same principle, the service connections being the points of delivery. Allowance should be made in arrangement and sizing for future additions and flexibility in general.

Steam Heating. Although a part of the sensible heat is utilized, it is safer to count only on the latent heat of condensation as the energy delivered. The volumes carried by any run of pipe should be understood to include the losses beyond that run as well as half of its own losses. In **high-pressure distribution,** the friction, local resistances and head of discharge can be calculated from the following formulæ, which give substantially the same results as those of Babcock and Darcy having variable coefficients: $p_f = 0.0257wv^{1.95}l/(144 \times 2g \times d^{1.2})$; $p_r = 1.12wv^{1.95}r/(144 \times 2g)$; $p_v = wv^2/(144 \times 2g)$, where p_f, p_r and p_v are the pressure losses in lb. per sq. in. due to friction, obstructions and velocity respectively, d and l the length and diam. in ft., v the mean velocity in ft. per sec., and w the weight in lb. per cu. ft. of the steam at mean pressure. $v = W$ per hour$/3600wa =$ B.t.u. per hour$/3600waC$, C being the latent heat per lb. of steam, W the weight in lb. and a the area of the pipe in sq. ft. The pressure drop should be

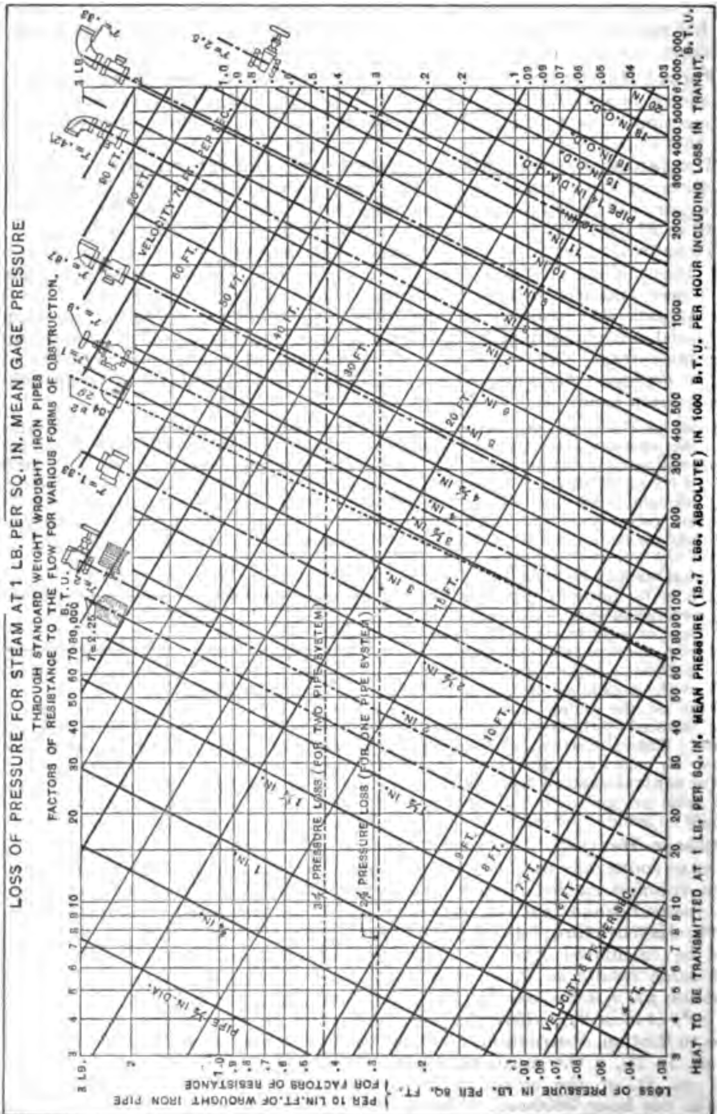

Fig. 8.—Chart for Steam Heating.
(Condensed from Meier's "Mechanics of Heating and Ventilation.")

equalized for all points of delivery by the resistance of piping. The returns may be sized for one-half the diameter of the steam pipes. When carrying steam, they should be made larger up to the trap.

Low-pressure Steam Distribution. The flow of steam in low-pressure systems is expressed by the same general formulæ given above for high pressure, except that different values are taken for the coefficients of friction and local resistances, or for the exponents of v and d, owing to the lesser density of the fluid. For pressures near the atmospheric, the friction and resistance losses in lb. per sq. ft. are $p_f = 0.0257\ wv^{1.97}l/(2g \times d^{1.16})$ and $p_r = 1.07\ wv^{1.97}r/2g$, where v = B.t.u. per hour/$3600waC$ and should represent the mean velocity of the steam.

The chart in Fig. 8 gives the **pressure losses for 1 lb. steam pressure.** For other pressures the velocities as well as the friction and resistance heads must be corrected according to the latent heat and the density. The resistances decrease about as the volume and velocity, and the heat carried for the same pressure drop increases as the square root of the density. For approximation the pipe sizes may be read from the lines of equal pressure loss, taking 0.288 lb. per sq. ft. per 10 lin. ft. for a rate of 2 per cent. and 0.432 lb. for a rate of 3 per cent. loss in 10 lin. ft. The former will serve for one-pipe, the latter for two-pipe systems.

In using Fig. 8 note that the ordinates are pressure losses measured in *lb. per sq. ft.* For a heat transmission of 240,000 B.t.u. per hour, follow vertically from the corresponding abscissa to the selected pipe size, which in this case may be assumed to be 4 in. The intersection is at a velocity of 19.5 ft. per sec. Corresponding to this velocity the pressure loss for a 10-ft. length of pipe is 0.2 lb. per sq. ft.; for a gate valve 0.06 lb. per sq. ft.; for an angle valve 0.21 lb. per sq. ft.; and for a globe valve 0.47 lb. per sq. ft.

In any system, equalize roughly the pressure losses from the boiler up to all points of delivery. In a **closed or sealed system** with wet returns, when the working pressure is generally higher than that needed for distribution, the equalization need not be close, but in dry-return systems the pressure losses should be equalized more closely in order to avoid short circuits and the flow of steam against condensation, which causes water hammer.

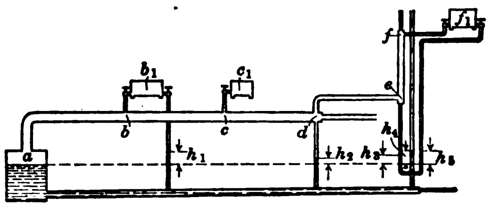

Fig. 9.—Steam Distribution with Wet Returns; with or without Vacuum on Air Lines; with Single or Double Piping to Individual Radiators.

With the **open-return system** the pressure drop in distribution must equal the working pressure, and the delivery is to be limited to the condensing capacity of the radiation so that no steam escapes to the atmosphere. The main advantage of an open system is the graduated control, and if that is to be realized, the equalization must be accurate. For this purpose liberal sizes of mains and relatively small branches closely calculated are desirable, even when final adjustment is made by valves.

For **rational calculation** all factors should be established by the use of a pipe schedule. The principle of equalization of pressure loss to the point of delivery remains the same for all systems, but the procedure varies. For a wet-return apparatus, as represented by Fig. 9, the pressure loss for the run $a - b - b_1$ should be made equal to that of $a - b - c - c_1$ and $a - b - c$

$- d - e - f - f_1$. The heights of the water columns correspond to the losses of head between the boiler and the various radiators and junctions. Those for radiators, h_1 and h_2, should be equal. The total pressure drop should be assumed no larger than necessary to equalize with reasonable pipe sizes for nearest and farthest radiator. It will range from 6 to 20 lb. per sq. ft., according to situation, for two-pipe systems, and from 4 to 12 lb. for one-pipe systems. For the latter, which generally do not require close equalization, allowance should be made for extra resistance on the lines carrying the whole condensation against the steam, by doubling the values of p_f and p_r as obtained from the charts.

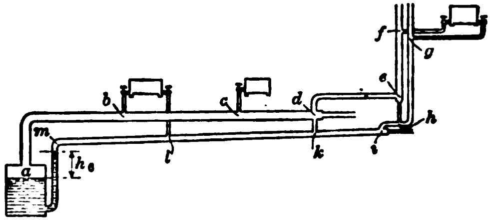

FIG. 10.—Steam Distribution with Dry Returns; with or without Vacuum on Returns or Air Lines; with Single or Double Piping to Risers and Radiators.

The resulting difference in the water line is $H = 0.192P$ in in. of water column. Thus, for a total pressure drop of 20 lb. per sq. ft. it would figure 3.84 in. To allow for increased steam volumes while reheating, the radiators or mains should be kept about four times higher above the water line in the boiler.

The losses of steam in transit are often a considerable factor. For a dry-turn apparatus the volumes carried are further increased by the condensation in the returns. The points of delivery for which to equalize, for instance, Fig. 10, would be l, k, i and h. If the pressure loss for $a - b - l - m$ is made to approximate $a - b - c - k - l - m$, no backing of steam against water, and no disturbance, will take place. Dry-return systems may be sized for the same total pressure drop as wet-return systems. The mains will figure somewhat larger when all factors are considered.

With the open-return system (Fig. 11), the working pressure or total loss is expressed by the water column H. It may be assumed to be from 5 to 10 lb. per sq. ft. The pressure drop of run $a - b - b_1 - b_2 - i - k$ should be made to equal that for $a - b - c - d - e - e_1 - e_2 - f - g - h - i - k$. In practice, the losses beyond radiators are negligible.

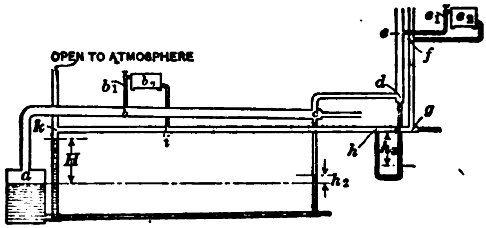

FIG. 11.—Steam Distribution with Open Returns, with Adjustable Valves Only.

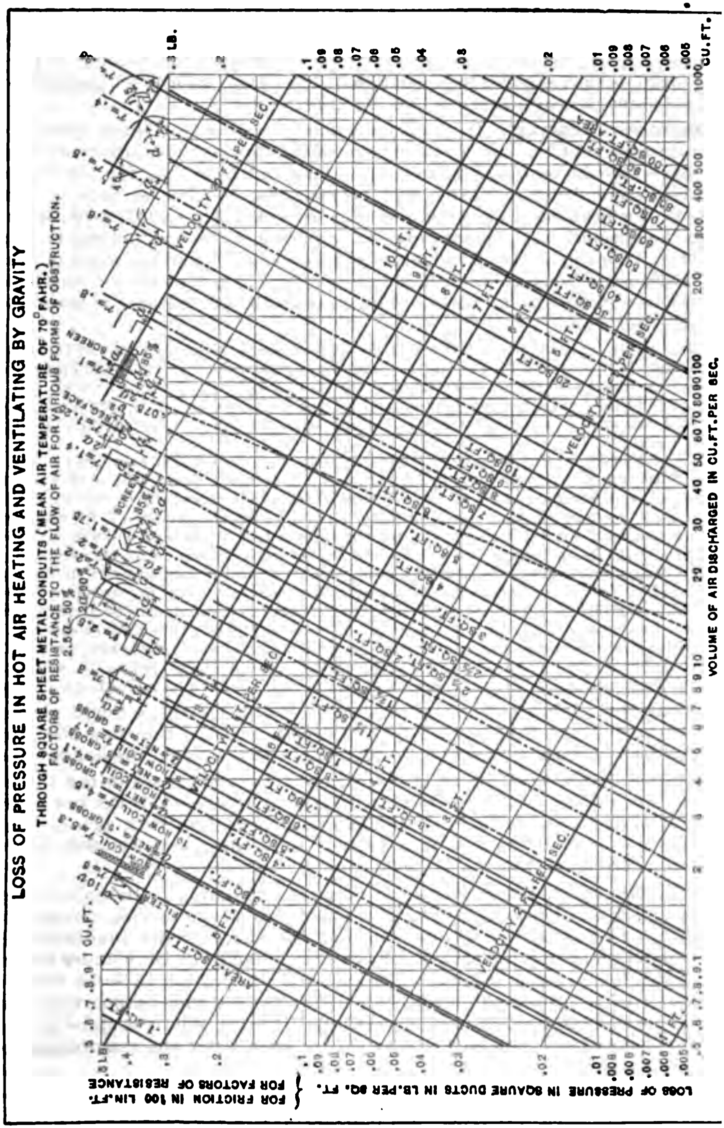
The return pipes should be taken about one-half the diameter of the steam pipe, rounded up for smaller sizes and dry returns and rounded down for larger sizes and wet returns. Air lines are taken about one-fourth of the diameter of the steam pipe.

The application of **vacuum** to air lines through automatic valves will



LOSS OF PRESSURE IN HOT AIR HEATING AND VENTILATING BY GRAVITY

FOR FACTORS OF RESISTANCE

accelerate the removal of air during reheating, but will not affect distribution when the valves close under the action of steam. The pipe size should be determined, irrespective of vacuum devices, for greatest volume and at pressure drop permitting fair equalization. The same applies to vacuum on returns through thermostatic valves or traps.

Warm-air Heating. In gravity systems the ducts and flues should be calculated so that the sum $P_f + P_r + p_v = P$, the total pressure created by the difference in temperature between room and heat flue, for the height between mean level of heater and transmitting surfaces in rooms. The pressure for heat flues above 70 deg. fahr. $P = 0.075[1 - (530/T_f)]h$, where T_f is the absolute flue temperature. The friction heads for uniform runs of ducts and flues $p_f = 0.075 \times 0.00624(v^{1.9}/2g)l(c/a)^{1.18}$, and the losses of heat by local obstructions $p_r = 0.075 \times 1.25(v^{1.9}/2g)r$, as well as the velocity head p_v may be obtained from Fig. 12. The sums for the whole length of main and branch are P_f and P_r.

The pressure for a flue temperature of 135 deg. fahr. and a room of 70 deg., 20 ft. above the heater, is $P = 0.165$ lb. per sq. ft. The theoretical velocity corresponding to this pressure is $V = 12$ ft. per sec.; the approximate actual velocity resulting $= 0.4V = 4.8$ ft. per sec. This velocity may be assumed for the estimates and as a preliminary for the final calculation, rounding it off for systems with considerable obstruction, as with indirect stacks.

To find the size of ducts that will approximately use up the total pressure available while delivering the desired volume, Fig. 12 is used as follows: For a volume of 5 cu. ft. per sec. at, say, a velocity of 4 ft. per sec., the intersection shows an area of 1.25 sq. ft. The nearest commercial flue size is 12 × 16 in., or 1.33 sq. ft., giving 3.7 ft. velocity. The friction head for this size is given by the intersecting abscissa as 0.038 lb. per 100 ι. ft., or 0.019 lb. for 50 ft. The resistance p_r for the two registers, for the same velocity that of the flue, happens to be read at the same point and makes up 0.038 lb. per sq. for each. The elbow, at the intersection of the diagonal for $r = 0.4$, on the same veloc- r line, uses 0.007 lb. The resistance of a typical stack is estimated to be about equal that of an 8-row coil, in this case for 2 sq. ft. area = 0.03 lb. The casings should be .ken separately, entrance and exit being figured like flanged flue ends: $r = 1$, for which $p_r = 0.017$ lb. each. The above items make up the sum of 0.166 lb. per sq. ft., which is the total head available, the velocity head p_v being included in the losses for the registers.

Chimneys. For steam plants the gases should leave the boiler at not more than 400 deg. fahr., and for water boilers at not more than 350 deg. On this basis, which assumes ample fire surface in the boiler, the flue area in sq. in. $= A = E/C\sqrt{H}$, where H is the height from the grate to the top of the flue, ft., E is the total heat to be generated by the boiler, B.t.u. per hour, and C a coefficient varying from 400 for retarding factors, such as long connections, exposure to cooling, flat shape of flue, offsets, etc., to 600 where conditions are favorable.

Conduits. Split-tile conduits laid on good foundation, with underdrains below and pipe rollers inside, filled with mineral wool, or asbestos sponge, are durable and generally the best investment. Wooden sectional conduits with sheet-metal lining and pipe insulation are cheaper and will serve under favorable conditions, in dry ground, when installed with care. In some cases a concrete trench, properly drained, with slanting cover, pipes supported clear of the floor and insulated, is used successfully. A layer of broken stone should be provided under all conduits to take care of snow water and assist drainage in general.

Heating Guarantees. In heating installations the customary guarantee is for the maintenance of stated inside temperatures at stated lowest outside temperature when all rooms are heated continuously.

MECHANICS OF VENTILATING

The static pressure in rooms may differ from the atmospheric on account of wind pressure or suction from the outside, temperature conditions, and the ventilating equipment itself. Temperature differences between inside and outside create a suction and indraft at bottom and pressure causing outward leakage near the top, with a zone of atmospheric pressure, called the **neutral zone,** between. This zone is maintained at its natural height, the mean level of leakage, when air supply and exhaust are of equal capacity. An excess of supply will depress the neutral zone, increase the area of outward leakage and put the room under a pressure, which reduces the head available for supply. An excess of exhaust will raise the zone and increase the head for the air supply.

When it is desired to maintain a plenum or excess pressure in a room, for the purpose of checking indraft through doors, allowance must be made for delivery against back pressure. This can be calculated approximately from the height of the room and the temperature difference, as for gravity vents. (See p. 1361.) Taking for example a hall of 30 ft. in clear height, in which the zone of inward leakage should be depressed below the doors, at floor level, the natural height of the zone, being at half height, must be brought down by 15 ft. For a temperature difference of $t_r - t_o = 70$ deg. fahr. this will equal a pressure of 0.17 lb. per sq. ft., which the supply fan is to meet. The capacity of the exhaust system is to be reduced correspondingly by the assumption of greater height of draft or greater pressure difference available.

An air-supply system depending on outward leakage and exhaust depending on inward leakage cannot be relied upon to give the desired volumes unless the excess pressure is made sufficient to overcome the resistance of the structure to leakage, which is most variable and beyond calculation.

When a room is to be kept under suction to localize odors, free ingress must be assured from a neutral source not affected by weather.

In tall buildings, to assure proper action of ventilating equipment, whether gravity or mechanical, it is essential to stop intercommunication between different stories, since the pressure disturbances affecting the delivery may be considerable and change constantly with atmospheric conditions.

Forced Ventilation. A system of conduits is calculated for even pressure loss for all individual outlets while delivering the desired volumes. The run and sizes of certain parts of conduits being determined by various considerations, the pressure losses of a system can be equalized by calculating friction and local resistances in these fixed portions, such as main ducts, flues and outlets, and proportioning the variable sections, usually the connections between ducts and vertical flues, to make up the differences of pressure to the individual outlets.

For air-supply registers, when air is being delivered at about room temperature, the velocity should not exceed 2 ft. per sec. when the outlet is below or near the headline and sensible drafts must be avoided. When the registers are at least 8 ft. above the floor, velocities from 4 to 10 ft. may be allowed, according to the distance from the opposite wall or the space to be covered. The velocities through ceiling registers should be from 2 to 4 ft., according to height. These velocities are based on the gross area as determining the current of air in front of the register. As a general rule, colder air should be introduced more slowly, while warmer air may be brought in at higher speed. For exhaust, the velocities given above for bottom and top registers may be doubled, if resistances allow, without causing objectionable draft.

The velocities in vertical flues should average about twice the velocity given for the registers, except for extremes. The ducts and other parts of the system, such as intakes, discharge flues and air passages in heaters, are determined largely to suit the total pressure or power, while the branch ducts and connections between ducts and flues are graded to effect equalization of resistances.

For **calculation of friction** and local resistances in the customary square **sheet-metal conduits,** the chart in Fig. 13 may be used. This chart is

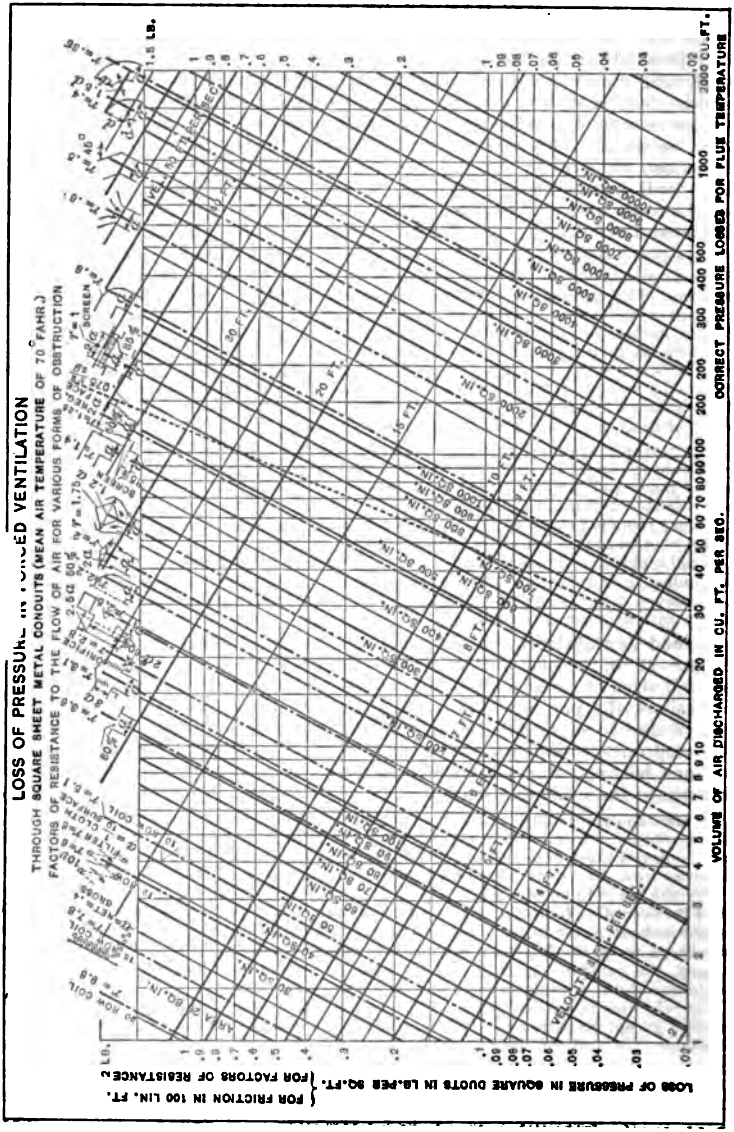

Fig. 13.—Chart for Forced Ventilation.
(Condensed from Meier's "Mechanics of Heating and Ventilation.")

based on the formula for friction loss $p_f = wfv^{1.9}l(c/a)^{1.18}/2g$, and that for local resistances $p_r = 1.25\ wrv^{1.9}/2g$ (approximation), where $w = 0.075$ for air at 70 deg. fahr., coefficient of friction $f = 0.00624$, c, a and l the circumference, area and length in ft., and r the factor of resistance, expressed in velocity heads, v = velocity in ft. per sec. and p_f and p_r are expressed in lb. per sq. ft.

The true velocity head of discharge $p_v = 0.075\ v^2/2g$, as an item in the sum for the whole length of main and branch, $P_f + P_r + p_v = P$, is included in the factors for typical outlets given, but may be read separately for any velocity by means of the dotted line. For round pipes of equal area, multiply values of p_f by 0.87. For flat ducts of equal area, multiply p_f by 1.07, 1.18, 1.30 or 1.43, respectively, according as the duct sectional dimensions are in the proportions 1:2, 1:3, 1:4 or 1:5.

The total resistance of the distributing system, heating coils, intakes, filters and other apparatus gives the total **pressure to be produced by the fan,** which determines its speed and blast area. The theoretical velocity $V = \sqrt{2gP/0.075}$, the blast area $A = Q/V$, Q being the cu. ft. per sec., and the theoretical power $= QP/550$. The actual power depends on the efficiency of the fan. It averages twice the theoretical power.

As an example in the use of the chart, Fig. 13, if 100 cu.ft. of air are to be discharged per sec. through a square duct of 1000 sq. in. area, the velocity will be 14.4 ft. per sec., the loss of pressure 0.2 lb. per sq. ft. per 100 linear feet of duct, and the resistance of an elbow $1.5d$ = 0.085 lb. The velocity head (given by the diagonal dotted line) p_v = 0.25 lb.

To calculate systematically, it is advisable to work out a duct schedule from the scale plans, showing all runs, volumes to be carried with allowances for leakage and flue sizes as predetermined by brick dimensions, speed at outlet desired and space. The main ducts may then be sized for an even rate of pressure loss of say, 0.4 lb. per sq. ft. per 100 linear ft. of duct, or 0.5 lb. for higher speeds and shorter runs, as experience will show. The resistances by friction and obstructions may then be figured from the outlets or registers backward to the first junction and from there with increasing volumes toward the fan. If the total for two branches is made equal for the proper volume by variation of sizes on connections, the equalized total at junctions will give the actual pressures that will obtain at these points. The resistances along the mains are then figured likewise, from junction to junction, up to the fan, giving the pressure for which to equalize other branches. When equalization becomes difficult, owing to excessive speeds in certain parts, it is advisable to ease the total losses by enlargement of mains, using a lower rate of resistance.

For **exhaust systems** the procedure is the same, except that the suction is to be equalized for all branches, and the resistance of discharge represents the back pressure to be added to the suction in order to obtain the total to be created.

Gravity Vents. The total pressure available for a gravity vent is $P = 0.075[(530/T_o) - 1]h$, for the density of the air at 70 deg. fahr. in the room and the flue, T_o being the absolute outside temperature and h the height of the flue, measured from the neutral zone in the room to the top of the flue. When the flue temperature is higher than 70 deg., the pressures should be corrected by multiplying P by $T_f/530$.

When several flues are joined into a main vent duct, the pressure losses in the several branches should be equalized for the desired volumes. If the heights of draft vary, the resistances must be made to conform to the respective heads, but any such differences in head must be made up in the branches, so that the least pressure given by any flue still leaves a margin for the resistances in the main duct. In other respects the calculation is carried through on the same principles as for mechanical ventilation and gravity warm-air heating, using the chart, Fig. 12, for the latter.

AIR CONDITIONING

BY

W. H. CARRIER

REFERENCES: Carrier, "Rational Psychrometric Formulæ" and "Air Conditioning Apparatus," *Trans. A. S. M. E.*, vol. 33. Lyle, "Atmospheric Cooling and Dehumidifying," *Trans. Am. Soc. Refrig. Engrs.*, 1912.

(For properties of moist air, dewpoint, wet-bulb readings, etc., see pp. 338–341.)

Air conditioning may be divided into three different operations, air washing, humidifying and dehumidifying.

Air Washing. Air washers contain sprays and eliminators. The air is drawn through the mist in the spray chamber, and then through the eliminator where an additional washing effect is obtained. The latter may or may not be independently flooded. The efficiency of an air washer will vary from 60 to 70 per cent. with fine dirt up to 98 per cent. with coarse dirt. Some **cooling** may be obtained with an air washer, even when the spray water is recirculated. In a well-designed apparatus this will vary from 70 to 80 per cent. of the wet-bulb depression. **Air velocities** of from 450 to 550 ft. per min. through the washer are used. The resistance will vary from 0.20 to 0.50 in. water gage, according to the velocity of the air and the type of washer. The water pressure on the sprays should be from 15 to 25 lb. per sq. in., depending on the nature of the impurities to be removed and on the design of the nozzles. From 3 to 3.5 gal. of water per 1000 cu. ft. of air will ordinarily be required.

Humidifying. Humidifiers may be divided into the following general types according to their method of operation: Direct (spraying into the room); indirect (introduction of moistened air); and combined (direct and indirect). **Indirect humidifiers** are similar in operation to the spray-type air washer, except that the water is sprayed directly against the incoming air. During cool weather the dewpoint or saturation temperature at the apparatus is secured and controlled artificially. During warm weather, it is often impossible to obtain as low a dewpoint as desired without refrigeration, which in the majority of cases is impracticable. The lowest saturation temperature that can be obtained is the same as the outside wet-bulb temperature. Therefore, the dewpoint in the room will always be the same as the outside wet-bulb temperature. The room temperatures corresponding to certain percentages of relative humidity are given in Table 1.

Table 1. Room Temperatures (Deg. Fahr.) at Various Outside Wet-bulb Temperatures and Various Percentages of Humidity in the Room

In the majority of industrial applications the problem during warm weather is as much a question of cooling as of humidifying, and in the moist-air system one is dependent on the other. The air required per B.t.u. of cooling effect is given in Table 3. The **degree of saturation of the air** leaving the humidifier depends upon the intimacy of contact of the air and water, upon the relation of the water temperature to the wet-bulb temperature of the entering

Table 3. Cooling Capacity of Carrier Humidifying System

air and upon the length of the spray chamber and the air velocity. The smaller the nozzle orifice the greater will be the air and water contact, and the greater the degree of saturation attained. It is customary to use smaller nozzles more closely spaced than in an air washer, with a water pressure of about 35 lb. Higher air velocities are also used than through the air washer, 600 to 700 ft. per min. being the ordinary range. The resistance at these velocities will vary from 0.35 to 0.45 in. water gage.

Methods of Humidity Control. The various methods of controlling the humidity in a room or building may be classed as follows: (1) **Humidistat**—operated by some hygroscopic material. (2) **Wet-and-dry-bulb hygrostat,** either of the **differential or vapor pressure type,** consisting of two members, one exposed to the wet-bulb and one to the dry-bulb temperature of the air, and maintaining a constant relative humidity in the room. (3) **Dewpoint or Differential Thermostat.** The dewpoint thermostat gives a constant dewpoint at the apparatus, and consequently a constant moisture content in the air of the room. A second thermostat may be arranged to maintain a constant temperature in the room. The differential thermostat is used when it is impracticable to maintain either a constant dewpoint or a constant room temperature, controlling either one with respect to the other. Table 4 gives the heat required for tempering and humidifying air at various wet-bulb and dewpoint temperatures.

Dehumidifying. In many industrial establishments a comparatively low moisture content is required in the room, or at least lower than exists in the outdoor air. This reduction in moisture content may be obtained by reducing the dewpoint of the incoming air and condensing the excess moisture in either one of three ways: (1) By means of some chemical process, by bringing the air into contact with calcium chloride or with concentrated sulphuric acid —only practical where small quantities of air are to be treated. (2) By

employing surface condensation, the air being passed over brine or direct-expansion ammonia pipe coils or other means of refrigeration. (3) By condensation with a cold spray and the elimination of any free or entrained moisture. Either artificially cooled water or brine or cold well water is used.

Surface Required for Surface Condensation. The rate of heat transfer in cooling air where condensation occurs is variable and depends upon the proportion of latent to sensible heat removed from the air. Providing the mean temperature of the water in the cooling coils is maintained constant, the ratio of initial to final temperature difference between the cooling water and the air is substantially the same whether there is moisture condensed from the air or not, so that the following approximate formula (for transverse flow of air) may be used:

$$\log_{10}[(t_w - t_1)/(t_w - t_2)] = S/(0.1119Q + 127A)$$

where t_1 = temperature of the entering air; t_2 = temperature of the leaving air; t_w = mean temperature of the water (all in deg. fahr.); S = sq. ft. of condensing surface; A = clear area in sq. ft. through coils; Q = cu. ft. of air per min. The amount of heat removed is equal to the difference between the total latent and sensible heat in the air at temperatures t_1 and t_2, respectively. It should be noted that the air leaving a surface dehumidifier is not necessarily saturated. The weight of water per lb. of air leaving the dehumidifier may be determined approximately from the equation

$$W_2 = W_1 - [(W_1 - W_m)(t_1 - t_2)/(t_1 - t_w)]$$

where W_1 = weight of water per lb. of air entering dehumidifier; W_2 = weight of water per lb. of air leaving dehumidifier; W_m = weight of water per lb. of air contained in air saturated at a temperature corresponding to the mean water temperature in the cooling coils.

The **spray-type dehumidifier** is similar in design to the spray-type humidifier, except that two banks of nozzles are ordinarily used to each stage, spraying against the incoming air, with a water pressure of from 25 to 30 lb. In a properly designed apparatus of this type the temperature of the leaving air will be not more than 1 deg. above the final water temperature. The air will always become saturated, and thorough elimination is required to remove entrained moisture. The **water required** for a one-stage-type dehumidifier may be determined by means of the formula

$$W = N[(H_1 - H_2)/(t_w - t_2)] = N[(t'_1 - t_2)/(t_w - t_2)]h,$$

where W = weight of water, lb.; N = weight of air, lb.; t_w = initial water temperature; t'_1 = initial wet-bulb temperature of air; t_2 = final dewpoint temperature of air (all in deg. fahr.); H_1 = initial total heat in 1 lb. of air at wet-bulb temperature, t'; H_2 = total heat in 1 lb. of air at final dewpoint t_2; h = approximately the average total change in latent and sensible heat per degree change in temperature in saturated air as determined from psychrometric charts or tables. The **refrigeration required** for spray-type dehumidifiers is given in Table 5.

Table 5. . B.T.U. Refrigeration Required to Cool 1000 Cu. Ft. of Air (Measured at 70 Deg. Fahr.) from a Given Wet-bulb Temperature to a Given Dewpoint

Intensity of Light

The Physical Basis of Light. The sensation of light is a function of the quantity of luminous energy which produces it, and of the coefficient of sensibility of the eye for the particular kind or kinds of luminous energy concerned. The limits of the electromagnetic wave lengths sensible to the eye lie practically between 800 $\mu\mu$ and 400 $\mu\mu$,* differing slightly for different eyes and different conditions of the same eye.

The common sources of light are hot bodies, whether minutely divided as in particles which glow in a flame, or continuous solids as in filaments of incandescent lamps or the mantle of a gas burner. Certain established laws define, to a close approximation at least, the relation between the temperature of a hot body and the radiant energy sent out by it. The first is Stefan's law (see p. 309). This law, however, does not tell anything about the relation of the luminous energy to the total energy.

A second relation connects the temperature of a hot body with the amount of radiant energy of each particular wave length delivered by it. This relation, known as Planck's law, is: $E_l = Cl^{-5}/(e^{k/lT} - 1)$, where E_l is the intensity of radiation at the wave length l, e is the Napierian logarithmic base, and C and k are experimental constants. It is also found that the product of a given temperature by the wave length of maximum energy is a constant; and that this constant is approximately 2940 when the wave length is taken in thousandths of a millimeter. The practical significance of this fact is that a hot body must attain a temperature of at least 5000 deg. cent. absolute before the maximum energy radiated falls in the middle of the region of luminous energy already referred to. For gaseous substances in which luminous radiation may be excited by electric discharges, Planck's law does not in general hold.

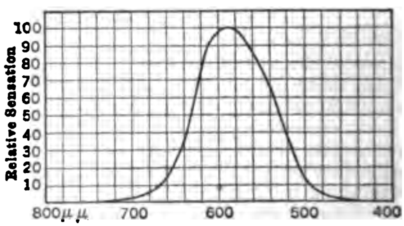

FIG. 1.—Typical Luminosity Curve of the Human Eye.

Physiological Relations of Luminous Energy. The sensibility of the eye for stimuli of various wave lengths varies with the intensity of the luminous radiations. In daylight or brilliant artificial light the eye is most sensitive to the wave lengths near 560 $\mu\mu$, that is, to those which correspond to a yellowish-green in color; in twilight or in faint artificial light the maximum sensibility of the eye lies in the full green near

* 1 $\mu\mu$ = 1 micromillimeter = 1/1 000 000 000 of a meter.

wave length 510$\mu\mu$, and with varying intensities of light shifts between these limits. Fig. 1 shows the typical "luminosity curve" of the human eye. The ordinates show the relative amount of luminous sensation derived in daylight from a given amount of luminous energy at each of the wave lengths concerned. The curve indicates that in the full red (650 $\mu\mu$) and in the blue (490 $\mu\mu$) a given amount of energy produces less than one-fifth the sensation that it would produce if it were in the yellowish-green. This shows how difficult it is to get bright lights of strong color. The eye sees best by nearly monochromatic light of a wave length corresponding approximately to the maximum of the sensibility curve.

Two characteristics of the eye are important in considering illumination. The first of these is its power of shade perception. Objects are perceived chiefly by their difference in luminosity, although nearby help is obtained from binocular vision, and, to a less extent than is generally supposed, from color differences; but the main thing in vision is difference of luminosity. The visual picture, according to Helmholtz, is about equally distinct, whatever the absolute brightness may be, provided the relative brightness of the parts remains the same. The eye sees almost equally well in the bright sunshine of noon and at sunset, although the absolute intensity of the light observed is changed in the ratio of more than 100 to 1. For ordinary eyes, and illumination as bright as diffused daylight or bright artificial light, the proportional difference for shade perception is about 0.01; that is, two adjacent surfaces can be distinguished as separate if one reflects to the eye about 1 per cent. more light than the other. In very dull light this fraction, generally known as Fechner's, increases, and may be several tenths, as, for example, in moonlight. One of the determining facts in artificial illumination is the quantity necessary to bring the shade perception of the eye to its normal value.

The second matter regarding vision that is important in practical illumination, is visual acuity; that is, the power of perceiving as distinct, closely placed objects which present no difficulty from mere lack of contrast. Acuity varies very widely in different eyes, but, like shade perception, it remains nearly uniform over a very wide range of illumination, beginning to fail only in the same dim light that causes shade perception to fail. Fig. 2 gives practically the relation between visual acuity, shade perception, and illumination for the human eye, as determined for the former factor by Dr. Uhthoff, and for the latter by Drs. Koenig and Brodhun. The lower shade-perception curve, *a*, is for white light; *b* is for crimson light. The abscissæ are expressed in meter-candles, the meter-candle being merely the light given by a standard candle at a distance of 1 meter. Both the shade-perception curves and the acuity curves reach practically steady values at a light intensity of from 20 to 30 meter-candles.

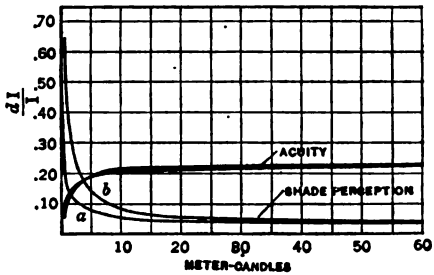

FIG. 2.—Relations Between Visual Acuity, Shade Perception and Illumination.

These curves show the approximate amount of light which must be supplied and need not be greatly exceeded. These values of the illumination, however, refer to the observation of white or very light colored surfaces. If the surfaces are dark so that they reflect comparatively little light to the eye, the illumination required for good seeing must be proportionately increased.

Photometric Units

Primary Standards of Light. Some of the more important standards which have been used in the past are as follows: The **British candle**, which loses in burning 120 grains per hour; the **French Carcel lamp**, an Argand burner of specified dimensions which gives the standard brightness when consuming 42 grams of colza oil per hour; the **amyl-acetate lamp**

designed by **von Hefner-Alteneck,** giving the standard brightness when burned at its normal flame height of 40 mm.; the **Vernon-Harcourt pentane lamp,** an Argand gas burner fed by air saturated with pentane vapor and used extensively in England; and the **bougie decimale,** or 1/20 of the light given off normally by 1 sq. cm. of surface of platinum at its point of solidification. In 1909 the national laboratories of the United States, England and France agreed upon a common unit called the **international candle,** which has since been adopted by several other countries. This unit has the value of the bougie decimale. The relations between these primary standards are shown in Table 1.

Table 1. Relations Between the Primary Standards of Light

Standard	International candle	Carcel	Hefner	British candle
International candle....	1.0	0.104	1.11	0.98
Carcel..................	9.6	1.0	10.7	9.4
Hefner..................	0.9	0.0935	1.0	0.88
British candle..........	1.02	0.106	1.14	1.0

In actual practice incandescent electric lamps properly seasoned and compared are the usual custodians of this standard for laboratory use. In gas lighting, however, a flame standard is often desirable as tending to eliminate the variations due to moisture, CO_2 and barometric pressure, and for this purpose both gas lamps and kerosene lamps—of which a definite area of flame is exposed—are in common and successful use.

Photometric Units. Table 2 gives the practical photometric units in fairly well-established use. The unit of luminous flux, or the **lumen,** is the flux from a source of unit intensity through one unit solid angle. In the sphere there are 4 π such angles, so that 1 mean spherical international candle is a source of 4 π lumens. Any surface subtending one unit solid angle from such a source receives a total flux of one lumen. The practical unit of illumination is the **lux,** which is that illumination received from unit source at 1 meter distance. Hence the total luminous flux in lumens received over a given area, divided by that area in square meters, gives the illumination in lux.

Table 2. Practical Photometric Units

Magnitude	Unit	Symbol*
Intensity....................................	Int. candle.........	I (J)
Luminous flux................................	Lumen..............	F (Φ)
Illumination.................................	Lux (foot-candle)..	E (E)
Intrinsic brightness.........................	Candles/sq. cm. (candles/sq. in.)	b (e)

* Symbols in parentheses are those used in connection with the Hefner unit by German writers.

The defining equation for illumination is $E = F/S = I/R^2$, where S is surface in square meters and R is distance in meters. In English-speaking countries many measurements of illumination are expressed in the **foot-candle** unit, this being the illumination received from an international candle at 1 ft. distance. The flux in lumens is reduced to illumination in foot-candles by taking the area concerned in square feet. The intensity of a source is known as intrinsic brightness, and is measured in candles per square centimeter, or per square inch. The **intrinsic brightness** customarily denotes the total intensity of a source in any direction divided by its apparent area when viewed from that direction. The lux and the foot-candle are connected by the following equations: 1 lux = 0.0929 foot-candle; 1 foot-candle = 10.76 lux

COMPUTATION OF ILLUMINATION

In computing illumination, two procedures are open: first, the determination by the flux-of-light method; second, the determination of the illumination at a point or points from the intensity of the source and from the distance. The first is extremely convenient in dealing with conditions by general average, and also in determining the effect of secondary sources of light, like brilliantly lighted surfaces. The **flux-of-light method**, for example, gives very readily the average illumination over any enclosing surface about the source considered. It does not, however, readily yield directly the illumination on a particular working plane. To facilitate the computation of this case, it is necessary either to determine the solid angle or angles involved, or to proceed by a process of averaging. The latter plan is usually adopted in dealing with ordinary illumination problems, the former being reserved for the illumination produced by secondary sources. In working out the illumination by the flux-of-light method, dependence is usually placed on experimental coefficients determined for different kinds of lighting installations. For example, with a working plane 10 m. square and light sources giving 1000 lumens, it is expedient in determining the illumination to fall back on the **coefficient of utilization** of the particular sort of installation adopted. This coefficient is the proportion of the total lumens falling on the plane in question. For example, it is found that the coefficient of utilization in using incandescent lamps with certain diffusing glass reflectors is 0.5. This means that of 1000 lumens delivered by the sources assumed, 500 reach the working plane. This being 10 m. square, the mean illumination on it is therefore $1000 \times 0.5/10^2 = 5$ lux. The formal equation is $E = FK/S$, wherein K is the coefficient of utilization of the installation and S the surface of the plane with reference to which K is assumed. The method is a very quick and easy one for approximate average results. Transformed to the form $F = ES/K$, it serves to give the necessary flux for a required illumination at the given working plane. Table 6 gives values of K found in practice.

The second method, of **computing illumination from the distance and intensity of the source**, is readily applied to points or small areas, but is less easy to use for quick approximations over considerable areas than is the flux-of-light method. The simple radiation from a luminous point follows the law of inverse squares, $E = I/l^2$, the element of surface at which E is reckoned being normal to the ray. The criteria for the applicability of the law of inverse squares are (1) that the angle subtended by the dimensions of the luminous area as seen from the point under consideration shall be small, and (2) that the luminous radiation shall be free and not complicated by reflections or refractions, as, for example, by mirror surfaces or lenses. When the light is received on a surface inclined to the ray, the illumination is proportional to the cosine of the angle of incidence. (**Lambert's Law.**)

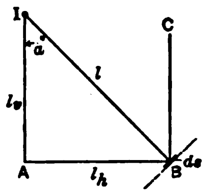

FIG. 3.

In Fig. 3 let a source of light I be located at a distance l_v above the plane of reference AB, and consider, at a distance l_h along this plane, an element of surface ds normal to a ray received from I over a distance l. On ds, $E = I/l^2$, but if ds lies in the plane AB, the illumination is reduced by the obliquity to $E = (I/l^2) \cos a$. If ds is projected on a vertical plane BC, the illumination becomes $E = (I/l^2) \sin a$. Sometimes it is convenient to compute the illumination by starting with the height of the source l_v and obtaining the illumination for various values of a. Noting that $l = l_v/\cos a$, the formula for the normal illumination E_n becomes

$$E_n = (I/l_v^2) \cos^2 a$$

For illumination on the horizontal plane AB,

$$E_h = (I/l_v^2) \cos^3 a$$

and for the vertical projection on the plane BC the expression becomes

$$E_v = (I/l_v^2) \sin a \cos^2 a$$

When artificial light is derived from a number of sources at varying distances and at the same height, the general summation for the normal illumination received at a point is

$$E_n = I_1(1/l_1^2) + I_2(1/l_2^2) + \ldots\ldots I_n(1/l_n^2)$$

or, for equal sources,

$$E_n = I[(1/l_1^2) + (1/l_2^2) + \ldots\ldots (1/l_n^2)]$$

and for equal lights carried at a uniform height,

$$E_n = (I/l_v^2)(\cos^2 a_1 + \cos^2 a_2 + \ldots\ldots \cos^2 a_n)$$

where a_1, a_2, etc., are measured from the various sources.

Inasmuch as an element of surface cannot be illuminated normally by a number of light sources, Lambert's law must be taken into consideration in a general case, which, for lights of uniform height and intensity, becomes

$$E = (I/l_v^2)(\cos^3 a_1 + \cos^3 a_2 + \ldots\ldots \cos^3 a_n)$$

Usually $\cos^3 a$ is negligible for a part of the sources or several nearly equally distant sources can be lumped together; or some sources are cut off by obstacles so that the summation need seldom include more than three or four terms. The average value of I in any of these formulæ must be taken from the polar distribution curve of the light as installed.

In lighting indoor spaces, the light received at any given point will be a certain amount, E_0, derived directly from the radiant object according to the formulæ already given, plus a certain other amount, E_r, reaching it after one or more reflections from the walls. The effect of these reflections cannot be calculated, since they come from useless as well as useful directions, and the law of inverse squares does not hold for large and near surfaces like those of walls. It is necessary to evaluate E_r by an indirect method.

Every surface has a **coefficient of reflection**, k, giving the proportion of the incident light reflected. This reflection may be specular, as from a mirror, diffuse, as from a piece of white blotting paper, or mixed, as from a glossy painted surface, in which the reflected image of a light source can be plainly seen, while yet there is a considerable amount of diffuse reflection. For the purposes of computation one need not discriminate between these kinds of reflections, and the first approximation to the effective illumination as reinforced by reflection, is $E = E_0 [1/(1 - k)]$, where k is the average coefficient of reflection of the surfaces concerned. Large values of k indicate considerable assistance from reflection. Table 3 gives the reflection coefficients from a number of typical surfaces.

The variation in k is very great, dark-colored papers and paints reflecting very little light, and very few wall surfaces of any kind giving k above 0.4 to 0.5. The majority of light painted or papered walls have k within these limits. Light creams, buffs and greens give the highest coefficients. A very slight admixture of black or red in a painted surface, resulting in an apparently light and warm tone, will reduce the reflecting power very materially.

Table 3. Reflection Coefficients

Material	k	Material	k
Polished silver	0.92–0.95	Yellow cardboard	0.30
Mirror silvered on back	0.82–0.88	Light blue cardboard	0.25
White blotting paper	0.82	Brown cardboard	0.20
White cartridge paper	0.80	Yellow painted wall (dirty)	0.20
Polished brass	0.70–0.75	Emerald green paper	0.18
Mirror backed with amalgam.	0.70	Dark brown paper	0.13
Ordinary foolscap paper	0.70	Vermilion paper	0.12
Chrome yellow paper	0.62	Bluish-green paper	0.12
Orange paper	0.50	Cobalt blue paper	0.12
Yellow wall paper	0.40	Black paper	0.05
Yellow painted wall	0.40	Ultramarine blue paper	0.035
Light pink paper	0.36	Black velvet	0.004

The floors and window spaces in rooms are practically negligible as aids to illumination. Unless special effort has been made to get light surfaces, the quantity $1/(1 - k)$ rarely exceeds 1.5. With dark walls, the aid received is negligible, so that the amount of light required to illuminate a room with dark walls may easily exceed that required for the same room with light walls by 50 per cent. or more.

PRACTICAL SOURCES OF LIGHT

Flames. The flame sources commonly used are candles, kerosene, and gas flames from ordinary illuminating gas, air-gas and acetylene. Ordinary commercial **candles** are made of stearin, paraffin or wax, or mixtures of these substances, give a little more than 1 international candle power (c.p.), and usually burn from 110 to 130 gr. per hour. The cost per candle-hour is from ¼ to ½ of a cent; specific consumption of energy, about 90 watts per c.p.

Ordinary **kerosene lamps** give from 10 to 30 c.p., according to size, on a consumption of from 50 to 60 gr. per hour per c.p., or about 800 candle-hours per gal.; cost per candle-hour, ordinarily not over 0.02 cent. The light given by a well-designed kerosene lamp properly shaded is very steady and soft, and not surpassed in quality by any light ordinarily used.

Gas lamps burning illuminating gas are inefficient, often unsteady and rather rapidly passing out of use. Ordinary slit **gas burners** consume about 5 cu. ft. of gas per hour at the usual pressure and give 14 to 17 c.p., or about 3 c.p. per cu. ft. Argand burners with proper chimneys give a somewhat higher efficiency—up to 3.5 c.p. per cu. ft.—and a light admirable in quality and steadiness.

Air-gas, commonly known as gasoline gas, has been widely used for isolated plants in villages and country houses, and consists of air charged with gasoline vapor to a point in excess of the maximum percentage which can form an explosive mixture. More rarely a mixture too lean to explode is used with fair results in Welsbach burners. The mixture commonly used in this country is about 6 gal. of gasoline per 1000 cu. ft. of air. The illuminating power of such **air-gas** is not widely different from that of ordinary commercial gas.

A flame illuminant occasionally very useful is **acetylene**, see p. 615. Acetylene is so rich in carbon that it must be burned with a very liberal supply of air, but when so burned gives a very brilliant whitish flame and produces something like 40 c.p. per cu. ft. It is very easily generated, and furnishes a most useful local source of light. The ordinary burners are of about 20 c.p., consuming about 0.5 cu. ft. per hour. Commercially it is frequently supplied dissolved in acetone and under pressure in metallic cylinders containing about 100 times their volume of free acetylene at atmospheric pressure. In this form it may be very safely and easily transported. Acetylene is exceedingly valuable for the temporary lighting of interior or exterior spaces and is a reasonably cheap illuminant. One ton of carbide, costing $60 to $80, will produce between 9000 and 10,000 cu. ft. of acetylene.

It should be noted that, despite appearances, flames are very nearly transparent and give about the same illumination in all directions in which the light is not obstructed by some part of the burner.

Mantle Burners. The standard types of mantle, consisting of about 99 per cent. thoria and 1 per cent. ceria, give, when the burner which heats the mantle is suitably regulated, from 15 to 18 spherical c.p. per cu. ft. of gas as the initial efficiency. The inverted mantles perform in this respect slightly better than the older erect mantles. They are therefore 5 or 6 times as efficient as light producers as the gas flame. The efficiency of the mantle gradually falls off with use, the older mantles dropping fully half their c.p. in the first 500 to 800 hr. The later mantles, made on a basis of ramie fiber or of artificial silk, *i.e.*, collodion cotton dissolved and squirted into fibers, hold up much better than the cotton basis formerly used. The illuminating value just given is based on ordinary pressures of 2.5 in. of water. By using gas at high pressure, which takes in a correspondingly larger portion of air, the combustion of the burner can be forced as in a blast lamp so as to carry the mantle to a very high temperature, with a corresponding increase in efficiency. Pressures of from 40 to 90 in. of water are in use in these intensive burners. So burned the gas gives 30 to 50 c.p. per cu. ft. according to the quality of the gas and pressure. The mantles used with this "press gas" are several inches in length and give from 1000 to 2000 c.p. each at the higher pressures. So great is the luminous efficiency of the Welsbach mantle that its use has practically wiped out the objections to gas on the score of pollution of the air. Mantle burners are frequently used with gasoline gas and more rarely with acetylene.

Electric Illuminants

Open Arc Lamps. The earliest electric illuminant was the arc struck between two carbons burned in the open air. The passage of the current carries the two carbon electrodes to a very high incandescence, and in the upper and positive one is formed a crater in which the carbon is heated practically to its boiling point. This point of highest temperature gives the major part of the light, which is therefore turned somewhat downward, with a maximum at about 40 deg. below the horizontal. The light from an open arc in good order and supplied with high-grade carbons, is steady, powerful, and gives a low specific consumption, somewhat better than 1 watt per mean spherical candle power (m.s.c.p.). The difficulty of getting proper carbons and the considerable cost of the frequent renewal of the carbons necessary in view of the rather rapid consumption per hour (at least ½ in.) in ordinary lamps, caused the open arc to come into disfavor, and it was rapidly displaced about 1900 by the **enclosed arc lamp.** In this type the consumption of the carbon electrodes is reduced by keeping the arc in an enclosure of hard glass, closed by caps with holes for snugly fitting carbons. In this arrangement the air in the enclosure is rapidly burned to CO and nitrogen, and the wasting away of the carbon is reduced to ⅙ in. or so an hour in ordinary lamps. No crater is formed with the enclosed arc, although the carbon points are highly heated. A considerable proportion of the light comes from the arc itself, which gives a strongly bluish cast to the illumination. The efficiency is much less than that of the open arc, the specific consumption ranging between 2 and 3 watts per m.s.c.p.

Flame Arc Lamps. Carbon is the ideal substance for the electrodes of an arc lamp, inasmuch as it burns to a gaseous, odorless, and non-corrosive oxide, but its light-giving power is strictly due to the high temperature to which it can be forced by the electric current. Hope of higher efficiency than that thus attained has rested in the choice of electrodes capable of giving selective radiation in the visible spectrum. From work along this line has originated the whole group of flame and luminous arcs. The first-named of these burn carbon electrodes like ordinary arcs, but the electrodes carry an admixture of from 10 to 20 per cent. of metallic salts, the vaporisation of which gives a powerful arc stream radiating selectively according to the character of the material with which the carbon is mineralised. The commonest substance thus used is calcium fluoride, which gives a band spectrum as fluoride, intensively brilliant in the orange and green and giving light of a strong yellow cast. The specific consumption of such lamps, which usually operate at 10 or 12 amperes and a voltage at the arc of 40 to 45, ranges from 0.35 to 0.45 watt per m.s.c.p. Such lamps are made in two forms, one with converging carbons meeting at an acute angle from above, and another with carbons vertical, as in the ordinary lamp, the negative carbon being uppermost. Such lamps are made both for alternating current and direct current. Of late, mineralized carbons have been introduced, giving a white light at a slightly reduced efficiency. These carbons are mineralised chiefly with the by-products of the Welsbach gas-mantle industry, and occasionally with some admixture of other substances. Fig. 4 gives the polar distribution curve of an ordinary converging-carbon yellow-flame lamp.

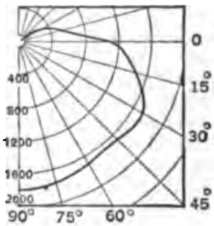

FIG. 4.—Candle Power of Yellow-flame Arc Lamps.

Lamps of the flaming class give a white fume of oxide, which somewhat militates against their use in contracted spaces. The flame arcs can be enclosed to prolong the life of the carbons, which ordinarily burn away at the rate of something like ¾ in. per hour. The arc is maintained in a tight-fitting globe of refractory glass, and provided with merely enough circulation to help carry the fumes into a cooler part of the lamp structure where they may condense and settle so as not to obstruct the light. Such long-burning flame arcs are rather less efficient than the flame arcs burned more intensively, but show a life of the carbons of 75 to 100 hr. Fig. 5 shows the distribution curve from one of the well-known types of long-burning flame arc which gives a specific consumption at the lamp terminals of 0.58 watt per m.s.c.p. Enclosed flame arc lamps are made both for direct and alternating currents.

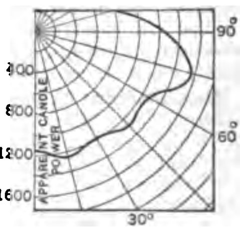

FIG. 5.—Candle Power of Long-burning Flame Arc Lamp.

Luminous Arc Lamps. Still more important in American practice is the so-called luminous arc, of which the well-known **magnetite arc** is the chief type. In this lamp the arc is struck between a positive electrode of thick copper and a negative lower electrode consisting of an iron tube packed with a mixture of metallic oxides consisting chiefly of magnetite with an addition of 20 to 25 per cent. of titanium oxide and occasionally small quantities of other substances. The arc stream is chiefly from the negative electrode, and is itself the chief source of light, giving highly selective radiation of a good, whitish color. The life of the electrodes is, according to size and current, from 75 to 150 or more hours. The positive copper electrode contributes very little vapor and has to be renewed only at intervals of months. As in case of all arcs, the efficiency of such lamps rises with the current. Two forms are commonly used, one taking 4 amp., and the other 6.6 amp. The former gives with a clear globe about 240 m.s.c.p. at a specific consumption of about 1.25 watts. The latter gives a little over 800 m.s.c.p., and its specific consumption is a little over 0.6 watt per candle. Fig. 6 shows the distribution curve of the 6.6-amp. lamp in the clear globe, and Fig. 7 the same lamp with a light opal globe, highly desirable with so powerful an illuminant to reduce the intense brilliancy of the arc. The m.s.c.p. is reduced by such a globe by a little over 0 per cent. Magnetite cs in burning give fumes of brown oxides, which have to be disposed of to ep them from settling on the globe and clogging the mechanism. This is rried out in practice by a flue through which the fumes are carried away, n the whole, pretty thoroughly. This lamp cannot be used on alternating currents. A similar lamp with a carbon upper electrode and a lower tube packed with a mixture chiefly titanium carbide has been found applicable to alternating currents, but has not yet come into considerable use, although highly efficient, on account chiefly of the difficulty of getting rid of the fumes.

Candle Power of Magnetite Arc Lamps.

Incandescent Lamps. The **carbon incandescent lamp** has a specific consumption of from 3.5 to 4 watts per m.s.c.p. and survives only in lamps of 16 c.p. and less, and in miniature lamps. For most practical illumination with units of 16 c.p. and above, the only form of carbon filament in extensive use is the so-called "metallized filament," produced by firing the carbonized filament material in the electric furnace at so high a temperature as to alter its structure. Lamps of ordinary or metallized carbon filaments are available in all ordinary voltages from 2 c.p. up to about 50. Their efficiency is very low but they are suitable, on account of their low cost, for use in places where the lamps are infrequently used, and where a smaller light is desired than is now available with **metallic filament lamps,** as in some decorative work, and occasionally in domestic use.

The **tantalum lamp,** on account of the comparatively low resistance of the metal, requires a very long and slender filament that in the usual commercial size, giving 20 to 25 m.h.c.p. (mean horizontal candle power), is about 0.002 in. in diameter and about 2 ft. long. The specific consumption of the tantalum lamp is slightly below 2 watts per m.h.c.p., and the effective life down to 80 per cent. of the initial c.p. is 750 to 1000 hr. It has been nearly driven out in the last few years by the tungsten lamp, which is the chief reliance of efficient illumination at the present time. The life of the tantalum lamp on a.c. circuits is scarcely two-thirds of that on d.c. circuits.

The use of **tungsten** for **filaments** marked a great advance in efficiency, tungsten being the metal with the highest known melting point, about 3200 deg. cent. Tungsten is found in liberal amounts in the minerals wolframite and scheelite. The metal was at first obtained only as a black powder, and filaments were made by mixing the finely divided metal with a binder, squirting into filaments and then sintering. Such filaments were extremely fragile except when hot. Tungsten is now obtained as a pure, solid metal, bright steel-gray in color (very hard), yet sufficiently ductile to enable it to be drawn into wire having the extraordinary tensile strength of nearly 500,000 lb. per sq. in., although when in service in filaments it tends to decrease in tensile strength. The drawn-wire filaments are very much stronger than those previously used and it has been possible by their use to increase the efficiency of the lamp materially, in the larger sizes up to a specific consumption of not more than 1 watt per candle and very commonly less, without undue sacrifice of life. The working temperature of the filament at 1 watt per candle is approximately 2300 deg. cent. The **tungsten lamp** has its drawn-wire filament carried on a spider because the specific resistance of the material is so low as to require a very thin and long filament. Tungsten lamps are known under a wide variety of trade names (that best known in this country being "Mazda") and are now available in sizes taking 10, 15, 20, 25, 40, 60, 100, 150, 250, 400 and 500 watts at voltages between 100 and 130, and with a specific consumption varying from about 1.3 watts per candle in the smallest sizes to 0.95 watt per candle in the largest. Lamps are made for series circuits at the ordinary amperages in most of the sizes mentioned except the two smallest. Some odd and intermediate sizes not mentioned here are occasionally found. All these sizes except the smallest ones are now to be had for the higher voltages of 200–260. The general average life of the lamps in all these sizes runs above 1000 hr. The specific consumption quoted above is in watts per m.h.c.p. For spherical c.p. the reduction factor is 0.78 to 0.80.

Gas-filled Lamps are lamps with tungsten filaments enclosed in bulbs filled with nitrogen at nearly atmospheric pressure. The effect of the nitrogen is two-fold: (1) It diminishes surface evaporation from the filament; (2) the products of evaporation are carried to the upper part of the bulb. By this use of nitrogen it becomes possible to push the filament to a temperature of 2600 to 2700 deg. cent. and to reduce the specific consumption to from 0.5 to 0.7 watt per m.h.c.p. The loss of heat by convection is nevertheless severe, and this convection loss falls most heavily upon the slender filaments. Therefore high efficiency can be best reached by lamps carrying large current. With currents of 2 amp. or less the gain in efficiency by the use of the nitrogen-filled bulb becomes small, but for multiple distribution this type of lamp works well in sizes taking from 200 watts upward at 110 volts.

Lamps for series circuits, in which the filament is short and thick, work well and are made for currents of 5 or 6 amp. and upward in sizes from about 50 watts up to 500 or more. The larger sizes are preferably made for currents of 10 or even 20 amp. derived locally from series transformers. Such lamps give specific consumption down to 0.5 watt. Within proper limits of current the nitrogen lamp at its high efficiency bids fair to give about the same useful life as other tungsten lamps and to be of large use in replacing the inefficient enclosed arcs. The high filament temperature gives a much whiter light than ordinary tungsten lamps, although distinctly less white than the intensified or the white flame arcs. The nitrogen lamp has not been fully standardized. Series lamps of the ordinary candle powers up to 1000 are available, and multiple 110-volt lamps from 600 c.p. to above 2000. Some very recent lamps are filled with argon instead of nitrogen, which gives a still higher working efficiency.

Nernst Lamps. The Nernst lamp employs a thin pencil of material which conducts tolerably well when hot, although a non-conductor when cold. The pencil forms the glower and is about 1 in. in length and about 0.02 in. in diameter. For starting, a heating resistance close above the glower heats the latter until it begins to conduct, when the heater is automatically cut out of circuit. A certain amount of resistance has to be placed in series with the glower to steady its action. Including the ballast resistance, the specific consumption of these lamps is between 1.5 and 2 watts per candle and the light is of good color and steady. They are manufactured in sizes of from 50 to 500 m.s.c.p., the larger sizes having several glowers in multiple. They are rapidly being driven out of use by tungsten lamps.

Vapor Lamps. In these lamps the source of light is a gaseous mass rendered luminous by the passage of electric current. The efficiency of such sources is not a mere matter of temperature as with incandescent illuminants. The spectra given are discontinuous and the efficiency depends on the relation of the intensities of the various spectral lines. The most important source of this kind is the **Cooper Hewitt mercury vapor lamp,** in which a column of mercury vapor is rendered luminous by the passage of the current. The ordinary type of lamp consists of a glass tube about 1 in. in diameter and 2 ft. in length, terminated by bulbs containing the negative) mercury and (positive) iron electrodes. The hood above the tube ontains inductance coils, a steadying resistance, an automatic tilting magnet nd the necessary contacts. When the current is hrown on the lamp is tilted, and as it drops back he current follows the mercury back through the tube and establishes a luminous body of vapor. The light is of a strong greenish cast, but steady, of relatively low intrinsic brilliancy, 10 to 11 c.p. per sq. in., and of high efficiency. The ordinary lamp gives about 300 m.l.h.c.p. (mean lower hemispherical c.p.) when worked at 3.5 amp. with about 192 watts at the terminals; in other words, it works at a specific consumption of about 0.67 watt per candle.

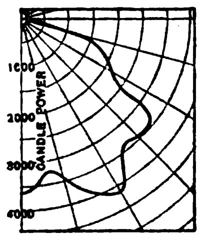

FIG. 8.—Candle Power of Quartz Mercury Vapor Lamp.

An important development from this principle is the **quartz mercury lamp,** in which the same plan is used, but the containing tube is of fused quartz which is so refractory as to allow the lamp to be worked intensively with a great concentration of energy in the vapor column. In the quartz lamp the tube is less than 0.5 in. in diameter and but 4 or 5 in. long in the usual lamp, taking 3.5 amp. at something over 200 volts. Lamps of the same amperage are available as well, for use on 110-volt circuits. The life of the tubes is 2000–4000 hours. This intensive working results in a very great increase of efficiency. Fig. 8 shows the distribution from such a quartz lamp which gave a little over 2300 m.l.h.c.p. at a specific consumption of 0.3 watt per candle. The quartz lamp is one of the steadiest and one of the most powerful known illuminants and has come into considerable use. Both the ordinary form of Cooper Hewitt lamp and the quartz lamp are essentially d.c. lamps, and when only alternating sources are available, it is necessary to employ a current rectifier.

The only other gaseous illuminant is the **Moore tube,** which is practically a gigantic Geissler tube excited by high-tension alternating currents delivered directly to the tube by an attached step-up transformer. The tube is generally about 1.5 in. in diameter and may be of any length up to several hundred feet. It is installed in the form of an enclosed loop or loops around the area to be illuminated, and serves itself as the secondary of the transformer system. The tube is commonly filled with nitrogen at a pressure of about 0.1 mm. of mercury, and under normal conditions gives a specific consumption of about 2.4 watts per m.s.c.p. The light is pleasant, steady, and of very low intrinsic brilliancy, not exceeding 0.5 c.p. per sq. in. Similar tubes coiled up into a small space and filled with CO_2 have been introduced for color-matching purposes, the light giving a close approximation to daylight; the efficiency, however, is very greatly reduced by the use of CO_2 instead of nitrogen.

Table 4, due to Dr. Lux, summarizes some of the essential properties of sources of light.

Table 4. Efficiency, Specific Power Consumption and Specific Output of Various Illuminants

Illuminant	Watts consumed	Per cent. power radiated as light	Mean spherical candle power	Watts per m.s.c.p.	Lumens per watt
Hefner lamp	86.3	0.103	0.726	128.8	0.106
Kerosene lamp	508.0	0.25	10.56	48.2	0.261

Quartz tube mercury arc	691.0	6.0	2640.0	0.261	48.0

METHODS OF LIGHTING

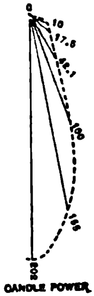
Shades and Reflectors. The intrinsic brilliancy of a light source, as the eye sees it, should not exceed 2 or 3 c.p. per sq. in. Most sources run to hundreds of c.p. per sq. in., and consequently require shading. The surface of a properly designed shade will act as the apparent source of light, and will keep down the intrinsic brilliancy. The effect of the shade on the source is (1) to cut off some of the light and (2) to redirect the light. Usually it rounds out the distribution curve, but if this is very irregular in shape it may produce a noticeable redistribution of the light.

Table 5. Loss of Light in Passing through Closed Shades

	Loss, per cent.		Loss, per cent.
Alabaster glass	15 to 20	Opal glass	25 to 60
Opaline glass	20 to 40	Milk glass	30 to 70
Alba glass	20 to 30	Paper	40 to 80
Ground glass	25 to 30	Textiles	40 to 80

The loss of light in closed shades of medium density through which the whole light flux has to pass, is approximately as given in Table 5.

Reflectors are made of polished or enameled metal, of porcelain, opal glass, of silvered metal or mirror glass, or of prismatic glass which sends back the light from its prismatic elements by total reflection. Prismatic glass shades may act both by transmission (the light being directed by annular prisms) and total reflection. In any case, the purpose is to reflect such portion of the light as may be radiated in useless directions so that it will fall upon the working plane.



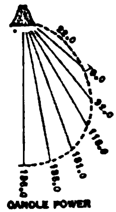


FIG. 9. FIG. 10.

FIG. 9.—10-in. Cone Reflector Lined with Mirror.

FIG. 10.—Reflector Lined with Corrugated Mirror Surface.

If the reflector covers, as is common, something like half of the total solid angle about the source, the total light below the lamp will be that directly radiated in the lower hemisphere plus that radiated above in the upper hemisphere multiplied by the coefficient of reflection of the surface used. This coefficient may vary from 30 to 40 per cent. in the case of some forms of glass and enamel, up to 80 or 85 per cent. in the case of silvered surfaces. The light delivered in the lower hemisphere is consequently reinforced by about 50 per cent. of its own value in the form of light turned down by the reflector. Reflectors may be divided into three classes according as the effect of the reflector is designed (1) to concentrate the light in a narrow area, (2) to spread it over a moderate area, or (3) to scatter it widely. Reflectors of the first class are usually deep, so that comparatively little light escapes from them unreflected and undirected, and find their most perfect development in the parabolic reflectors such as are used in automobile headlights. **Commercial reflectors** of this type are usually made of polished metal or mirror surfaces, or of prismatic glass. Fig. 9 shows the distribution of light from a 16-c.p. electric lamp placed in a 10-in. cone reflector lined with mirror. The intensity in the axis is very high, but the cone of rays is narrow and covers only a small space.

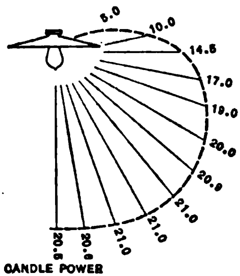

FIG. 11.—Flat Reflector.

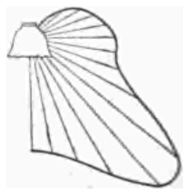

FIG. 12.—Prismatic Glass Shade.

The second type of reflector is the one most commonly used for general illumination, inasmuch as the light is considerably intensified in a large space underneath the lamp. Fig. 10 shows the distribution from a reflector of this character lined with corrugated mirror surface.

The third type of reflector is useful when for any reason a large area has to be lighted from a single source. It takes two general forms, one (Fig. 11) being a comparatively flat reflector, used slightly above the source of light.

This turns down much useful light while allowing lateral rays to escape unreflected. This arrangement is objectionable in that it allows the light of the source itself to be really visible, but is occasionally useful when the lights are not of very high intensity, or are located where they are somewhat out of the field of view. The typical distribution is a rounded one, as shown. Fig. 12 shows a more exaggerated type of wide distribution obtained from a prismatic glass shade which more completely shields the lamp itself, the light in this case being reflected backward from the wall of the shade and out of the shade in the other direction.

Indirect Lighting. In indirect lighting the reflectors are inverted so as to throw the light against the ceiling, from which it is diffused and reaches the working plane. This tends toward uniformity of illumination and completely conceals the source of light, but causes loss of light flux from the secondary diffusion by the ceiling. This loss, commonly 40 to 50 per cent., may be somewhat reduced by giving the ceiling an exceptionally good diffusing surface and keeping it clean. For a given intensity of illumination the indirect lighting usually requires in the neighborhood of 1.75 times the intensity of source necessary in case of direct lighting from open reflectors.

Semi-indirect Lighting. In semi-indirect lighting, which is frequently used to good advantage, the reflecting screen is placed as in indirect lighting, but is of translucent material so as to let through considerable light besides turning a large fraction backward to the ceiling. It lies in efficiency and general characteristics about midway between the systems already described.

The Planning of Illumination

Table 6 shows about the range of efficiencies of utilization which may be expected in practice, using modern shades and reflectors. It will be seen that the most efficient reflectors are the mirror or prismatic glass ones of a fairly concentrating character. Next in order come the usual types of open diffusing reflectors of prismatic or opal glass or metal, and after these follow diffusing shades which completely enclose the lamp, semi-indirect, and completely indirect lighting.

Table 6. Efficiencies of Utilization

	Coeff. K		Coeff. K
Concentrating reflectors	0.7 to 0.8	Half-globes, prismatic	0.45 to 0.50
Concentrating prismatic reflectors	0.7 to 0.8	Coves, indirect	0.15 to 0.36
Concentrating mirror reflectors	0.8 to 0.85	Indirect lighting	0.25 to 0.35
Diffusing reflectors	0.44 to 0.63	Semi-indirect lighting	0.35 to 0.45
Diffusing balls	0.34 to 0.36	Semi-indirect (enclosed arcs and diffusers)	0.45 to 0.50
		Arc with opal globe	0.45 to 0.50

To utilize Table 6, see p. 1369. At any required intensity in lumens per sq. ft. the total flux which must be obtained is this intensity multiplied by the sq. ft. of area, and this flux is that derived from a total flux in lumens, F, multiplied by the coefficient of utilization, K. The illuminants may be subdivided as convenience dictates, bearing in mind that good utilization of the reflectors generally requires the lights to be spaced apart from 1½ to 2 times their height above the working plane. As the space becomes bigger in area and height, it becomes permissible to use larger and larger units for obtaining the same effective illumination.

To pass from the rating of illuminants in the customary horizontal c.p. to the spherical c.p., it is necessary to know the **spherical reduction factor** of the lamp, or the quantity which multiplied by the horizontal c.p. gives the mean spherical c.p. This is usually about 0.8, but in case of an unusual type of illuminant it should be ascertained and not taken by average. For example, with tungsten lamps the illumination is about 0.8 horizontal c.p. per watt, or about 0.64 m.s.c.p. per watt, or, multiplying by 4π, practically 8 lumens per watt. With suitable reflectors it is easy to reach a utilization factor of 50 per cent., which means that about 4 lumens per watt can be obtained on the working plane. An allowance of 1 watt per sq. ft. should give approximately an illumination of 4 foot-candles. Lamps should preferably be rated in lumens.

Sometimes it is necessary to compute **special illumination** at certain points in addition to a general illumination, and in this case the flux method as here indicated may be used in combination with a point-by-point computation for the special places to be considered.

Table 7. Illumination Requirements

Locality	Illumination

Amount of Light Required for Various Kinds of Work. The estimates made of the light required for various classes of work differ very much, being based mostly on specific examinations of practical examples which vary widely in the actual requirements represented. Table 7, published in the *Illuminating Engineer* (London), gives a consensus of opinion on the subject, and the average values indicated are probably as near the requirements of sound practice as the data allow.

PREVENTION OF ACCIDENTS

BY

D. S. BEYER

REFERENCES: "Unfallverhütung und Betriebssicherheit," by Schlesinger (Carl Heymanns, Berlin), which includes several hundred illustrations of safety devices used in different industries; "Prevention of Railroad Accidents," Bradshaw (Norman Henley, New York); "Work-accidents and the Law," Charities Pub. Comm., No. 105 East 22nd St., New York City; "Accident Prevention and Relief," Schwedtman and Emery, Nat. Assn. of Mfrs., No. 30 Church St., New York City; "Industrial Accident Prevention," D. S. Beyer (Houghton Mifflin Co.).

Legislation, Etc. The following States have recently passed workmen's compensation laws: Arizona, California, Connecticut, Colorado, Illinois, Indiana, Iowa, Kansas, Louisiana, Maine, Maryland, Massachusetts, Michigan, Minnesota, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New York, Ohio, Oklahoma, Oregon, Pennsylvania, Rhode Island, Texas, Vermont, Washington, West Virginia, Wisconsin and Wyoming. Several of the other states now have commissions at work drafting additional legislation of the same nature (Nov., 1915).

The common tendency of this legislation is to eliminate the defenses which were formerly open to the employer (notably the "assumption of risk," "fault of fellow servant" and "contributory negligence" rules), and in most cases a fixed schedule of payments for injuries has been established, to apply in ll cases except those where the "serious and wilful misconduct" of the injured an is directly responsible for the accident. In addition to these compensa- ›n laws, more stringent factory inspection legislation is being adopted by ırious states and municipalities.

The increased responsibility of industry for its accidents has multiplied :eatly the cost of insurance against industrial accidents. This increased cost, and the certainty with which it is applied, has put a premium on accident prevention work; this cost can be materially reduced by the installation of safety devices. Experience has shown that approximately 50 per cent. of all industrial accidents are preventable.

The logical time to install safety devices is while general construction work is being done, or when alterations or repairs are being made; results can be accomplished with a minimum of expense and delay at the time plans and specifications are being prepared.

Checking for Safety. In order to make sure that the question of safety will not be overlooked, it is well to have all plans, specifications and drawings "checked for safety," making special provision for this in each set of specifications, and in the title plate of each drawing.

Buildings

Accidents involving the greatest loss of life in relation to the construction and arrangement of buildings are chiefly attributable to explosions, fires or conflagrations; and collapse or failure of building structures.

Less important from the standpoint of individual catastrophes, but involving a wider range of minor injuries, are insufficient lighting, inadequate ventilation, general features such as defective stairways, platforms, etc.

Explosions. The most serious accidents in this class are caused by (*a*) boilers and other high-pressure steam apparatus; (*b*) flywheels (principally those on engines); (*c*) miscellaneous explosives such as dynamite, benzine, naphtha, etc.; (*d*) hot metals.

Classes (*a*), (*b*) and (*c*) should be considered with reference to their location relative to buildings commonly occupied. Engines, boilers and explosives of any sort should be located in separate rooms or buildings sufficiently isolated from other parts of the establishment where workers are employed, to reduce to the lowest point danger of personal injuries in case of an explosion. The planes of rotation of engine flywheels should not be in line with workrooms. High-pressure steam piping should not pass through rooms or buildings in locations which would endanger human life if the piping or fittings should burst. (*d*) This class of accidents is due principally to molten metal being caught in a confined space where moisture is present, causing instantaneous generation of steam. All furnaces and receptacles of molten metal should be so located in respect to sewers, water piping, etc., as to minimize this danger.

Fires or Conflagrations. Means for preventing accidents from this source are (*a*) adequate exits and escapes; (*b*) non-combustible construction; (*c*) apparatus and facilities for detecting and controlling fires. See also section on Fire Protection, p. 1390.

(*a*) **Exits and Escapes.** So far as practicable, all **doors** should open outward, or *with* the natural direction of egress; they must not block passageways from other floors or parts of the building. This rule should be observed particularly in all cases where a sufficient number of persons are involved to make hasty exit important.

For buildings of two stories or higher, two or more "fireproof" **stairways** or exits should be provided for each of the upper floors (including the roof); these exits should be separated in such a manner that they are not liable to be cut off by a single local fire. (The location of stairways around or adjacent to passenger elevators is undesirable, unless they are adequately isolated by fire walls, or unless other means of egress are provided.)

Where stairs are used they should be at least 22 in. in width, and any increase in this width should be in increments of 22 in.; the bottom of each flight should be in the immediate vicinity of and in line of travel with the top of the next lower flight. All stairways should have handrails on both sides; those 8 ft. or more in width should have an intermediate handrail, centrally located. Every story below the street grade should have at least two means of egress to the ground level. Stairways and fire exits should be of such capacity and arrangement that persons coming from upper floors will not find their passage blocked by those escaping from the floors below. Outside fire escapes are inferior to stairways as means of egress; where used they should be located on dead walls, or arranged so that persons on them will be protected from flames issuing from windows or openings underneath by the use of wired glass in standard metal frames, fire doors, etc. The best arrangement is that known as the **"Philadelphia" fire escape, or "smoke-proof tower."** This consists of a stairway contained in an outside tower entirely isolated by fire walls from, and without any direct openings to, the building proper; communication with this tower is by means of vestibules or outside balconies on each floor, with doors opening to the balconies from both building and tower.

MUNICIPAL REQUIREMENTS REGARDING STAIRWAYS, EXITS, FIRE ESCAPES, ETC. are extremely varied, and notably lacking in definition and standardization at the present time. The following paragraphs from the "Specifications for Construction of a Standard Building" prepared by the committee on Fire-resistive Construction of the National Fire Protection Association, are recommended as indicating good practice from the standpoint of safety to human life. See also N. F. P. A. reports of "Committee on Safety to Life."

Height from Grade to Roof Line, irrespective of its occupancy, not to exceed 70 ft., unless the building be fully equipped with automatic sprinklers, in which case the height shall not exceed 125 ft.; nor shall any standard building exceed a height of two and one-half times the width of the widest street upon which it is located.

Area Within Inclosing or Fire Walls not to exceed 7,500 sq. ft., with no dimension greater than 125 ft. for a building without automatic sprinklers; or 20,000 sq. ft., unrestricted as to linear dimensions, for a building fully equipped with automatic sprinklers.

Exits to be one of the two following forms: (1) Stair exit, consisting of the direct connection of any floor area to an approved stairway built either as (*a*) an enclosed interior staircase, or (*b*) a smoke-proof tower. (2) Horizontal exit, or the connection of any floor area through a fire-exit partition, fire wall, or an open-air balcony or vestibule to another floor area in the same or an adjoining building having its own independent stair exits; the other area to be of sufficient size to contain temporarily the joint occupancy of the two areas thus joined, allowing not less than 5 sq. ft. of unobstructed floor space per person, and providing at least ¼ normal exit capacity for joint occupancy.

Number of Exits Required. Every floor area to have at least two separate exits, and whenever any floor area exceeds 10,000 sq. ft. at least one additional exit to be provided.

The occupants of every floor above the first to be provided with exits computed on the basis of at least 22 in. in width for every 14 persons for stair exits, or 22 in. in width for every 50 persons for horizontal exits. At least one of the exits provided for every such floor area to be a stair exit.

No width of exit stairway or passageway required by these rules to be reduced at any subsequent point in the direction of exit travel.

Exits to be remote from each other, and no point of any floor area to be more than 100 ft. distant from an exit. Whenever any building is more than four stories high, and has an occupancy greater than twenty-five people above the fourth floor, then each floor area of such building to be connected either directly or indirectly through horizontal exit to a smoke-proof tower.

Automatic sprinklers (see p. 1390) are one of the best safeguards for human life in high buildings; the record of some 13,000 fires in sprinkled buildings, covering a period of 16 years, shows an efficiency of 95.1 per cent. in fires extinguished or held in check.

(*b*) **Non-combustible Construction.** See p. 1390.

(*c*) **Fire Apparatus.** See pp. 276, 1393.

Lighting. Adequate light has an important bearing on the prevention of accidents. Walls, ceilings, columns, etc. should be light in color in order to ›flect and diffuse the light. Widely separated light units of high intensity ıould be avoided, since they give a dazzling effect in their immediate vicinity, ith heavy shadows and outlying zones of intense darkness. From the andpoint of safety, small lighting units of frequent spacing are preferable.

Ventilation. The lack of adequate ventilation helps to bring on fatigue and reduces the alertness of the workmen.

Accessibility, Stairways, Platforms, Openings, Etc. All **valves, operating mechanism, etc.**, which require attention at intervals, should be so located as **to be readily accessible.** Where they cannot be reached from the floor, suitable platforms should be erected, with convenient means of access. For this purpose stairways are preferable to ladders, see p. 1389. Falls from, or with, ladders constitute a material percentage of all industrial accidents.

All **stairways** should be provided with hand rails at both sides. Stair treads should be of such material and construction as will prevent their wearing smooth and becoming slippery with use. Iron or steel plates with "checkered" or roughened surfaces may be used; a good non-slipping tread with large capacity for wear consists of plates surfaced with an abrasive material such as alundum or carborundum. Crystals of these materials, about the size of buckwheat, may be imbedded in the surface of concrete while it is still soft, giving a similar but somewhat less efficient form of "safety tread."

All **overhead platforms** should be equipped with railings or barriers of a construction suited to the materials handled on them.. Such railings should not be less than 42 in. in height, and unless they are solidly enclosed, should have an intermediate member. Coamings or "toeboards" not less than 6 in. high should be placed along the edges of the platform at foot of railing, to prevent loose objects from falling off. **Railings** should preferably be of riveted structural steel shapes; if pipe is used it should be "extra heavy," with special hand-rail fittings.

As far as possible, **openings through floors or platforms** should be avoided; where they necessarily occur, they should be protected with railings, as described above, or with **covers**. Such covers should be hinged or permanently attached so as to prevent their being entirely removed. It is often possible to equip covers or trap doors with rest rods which support the door at such an angle as will permit easy egress from the open end, but still form a natural barrier at the other three sides.

Power Equipment

Power Generation and Distribution. **Electric power is to be preferred** to steam from the standpoint of safety, on account of its flexibility and ready adaptability to various methods of control. Individual or group motor drives naturally bring the controlling switch near the point where power is used, and can readily be controlled from a distance. With motor drives the momentum of moving parts is relatively small, so the machinery comes to a standstill quickly after power is shut off.

There are certain features common to all forms of power transmission, namely, power-disconnecting devices; shafting, pulleys and couplings; belting; and gearing.

Power-disconnecting Devices. There should be provided means for quickly disconnecting the power in each room or floor where machinery is used. This may take the form of an "automatic engine stop" operated with electric push buttons, or a quick-closing valve with mechanical tripping device where steam power is employed, or clutches (preferably of friction or magnetic type) may be applied to the various lines of shafting. Push buttons located near the machinery driven may also be used for controlling water wheels, gas engines, etc.

Shafting, Pulleys, and Couplings. The **elimination** from revolving shafting, couplings and pulleys of all **projecting parts** which might catch in the clothing, such as set screws, bolt heads, keys, etc., is of primary importance; these can generally be countersunk or covered so as to render them safe. Where transmission **shafting** is near the floor or ordinary working positions of operators, it should be enclosed or **protected by** suitable **barriers.** Pulleys should be spaced far enough from hangers to allow adequate clearance if a belt should drop off on the hanger side. Where lines of shafting are placed high above the floor, it is desirable to provide suitable means for oiling them from the floor, such as long-spout oil cans.

Belting. Guards should be placed under main transmission belts, to protect workmen underneath in case the belt should break. Such **guards** should be substantially constructed and should be continuous to the ceiling or adjacent supports so that they will not leave an end over which a breaking belt might catch. Belts on individual machines should be guarded as specified later.

Gearing. All gearing should be **completely enclosed**, the covers being made preferably of cast iron or sheet steel, of substantial construction, and shaped to conform to the gear outlines. It is often possible to design these guards so that the gears can be run in an oil bath, thus increasing their life and efficiency.

Boiler Plant. The nature of this equipment and the danger of explosions or other accidents which may fill the room with hot steam, make it particularly important to provide adequate means for quickly and safely reaching all working positions. A system of walks or **runways** should be erected to give convenient access to overhead valves, water columns, etc., also passages from boiler to boiler and suitable platforms at individual valves from which they can be safely operated or repaired. Walks and platforms should be well lighted and free from breaks or obstructions which might interfere with their use; they should be equipped with standard rails and coamings (see "Buildings," *ante*) and wherever possible stairways should be used in preference to ladders for giving access to these walks. Means of egress should be provided for **overhead walks** or **underground tunnels** at both ends of each line of boilers, and at one or two intermediate points in large plants. From the standpoint of **safety**, water-tube **boilers** are preferable to those of return tubular type. The use of "**non-return valves**" of the triple-acting type is recommended in plants where two or more boilers are connected in one battery. Gage glasses should be equipped with suitable guards to prevent eye injury when the glass bursts. Where these **gage glasses** are located near the floor, or close to ordinary operating positions, so that constant protection is desired, a guard of wired glass, or other suitable construction, which can be in place between the eyes of the operator and the gage glass at all times, is desirable; where the glass is high above the floor, a swiveling guard consisting of a semicircular shield of sheet metal gives adequate protection.

Escape pipes from safety valves should be arranged so as to discharge steam outside the building when a valve blows off; wherever practicable these pipes should extend vertically through the roof, and open drain connections should be provided for each pipe, close to the valve.

Distributing Piping. Systems of steam piping should be laid out with great care to avoid danger from expansion and contraction. It is particularly necessary to see that the **expansion** does not throw undue strain on any part of the piping system, or on the steam chests of engine cylinders, etc. to which the pipes are connected. Where main lines branch, or a distributing pipe leads off from the main line, a valve should be placed close to the connection so that the branch line can be shut off independently. Care should be taken to avoid "**water pockets,**" and where these necessarily occur suitable drain pipes should be provided for the removal of condensed steam. Separators should be placed in the pipe connections to individual engines, with traps for discharging water from same located where their operation may be constantly under observation.

Engines. Governors, if not of the shaft type, should be driven with ropes (not less than three in number). Corliss **valve gear** should be equipped with safety cams which unhook the valves when the governor weight drops to low position; a bracket should be provided for supporting this weight when shutting down the engine, so arranged that it will drop out automatically after the engine is started up. Where a fly-ball governor is used, the revolving parts should be adequately guarded or enclosed. Where **main bearings** cannot readily be reached from the floor, they should be equipped with steps having standard handrails. Some type of safety tread, with non-slipping surface of lead or abrasive material, is particularly desirable for engine-room steps on account of their liability to become slippery with oil. Cross heads, connecting rods and cranks, and tail rods should be guarded or enclosed. A **relief valve** should be placed in each end of each cylinder; these valves should have hand levers or other means for lifting the valve from seat for testing.

Care should be taken in the design of valve mechanism and other moving parts to avoid places where a hand or foot might be caught and crushed; where such places necessarily occur, they should be properly safeguarded. **Flywheels** should be suitably railed or guarded; standard coamings should be placed around the edges of flywheel pits, engine platforms, etc. Railings around rope sheaves should be sheeted solidly from top to floor to prevent breaking ropes from catching in the railing.

Electricity. In considering electrical equipment for industrial establishments, it should be borne in mind that the **hazard** to human life **increases with** increase in **voltage**, and economy in transmission wiring and copper parts which is achieved through the use of high-tension motors, may be offset by increased danger of accident. For small motors, lights, and general service inside industrial plants, installations of 110 or 220 volts are recommended.

All **switches, fuse boxes,** terminals, starting **rheostats, motors, etc.,** should be **enclosed** or guarded in such a manner as will prevent accidental contact with live parts, irrespective of voltage. **Switches** should be arranged so that they can be **locked** in the open position, to guard against a switch being thrown in accidentally while men are at work on the lines or equipment which the switch controls. High-tension **equipment of over 550 volts** should be isolated from other operating equipment, in separate rooms or enclosures, with provision for locking up these enclosures. All **metallic cases, frames,** and **supports** of such equipment should be permanently grounded. Foundation bolts should not be depended upon for this purpose, but substantial ground conductors should be used. It is preferable to have these ground wires accessible for inspection. All **low-tension secondary circuits** of 550 volts or less (such as light circuits, motor circuits, and meter circuits) should be permanently grounded whenever a neutral point is available for the purpose. Secondary circuits of 250 volts or less should be permanently grounded, even though a neutral point is not available. Whenever grounding has to be omitted, the frame or casing of the apparatus should be permanently grounded, and all live parts of the secondary circuit should be shielded to prevent accidental contact therewith. It is also desirable to have floors or platforms adjacent to switchboards built of non-conducting material, or suitably insulated. In the absence of such construction, rubber mats may be used.

General Machinery

Machine Design. All gearing should be completely enclosed with substantial cast-iron or sheet-steel covers, so designed as to be readily detachable; all set screws, keys, bolts, etc. in moving parts should be countersunk or covered in such a way as to eliminate danger of accident; unused portions of keyways should be filled so as to present a smooth surface.

Where machines are belt-driven, shifters should be provided. All shifters should be so arranged that they will lock automatically in both positions; this may be accomplished by notching the sliding parts or by locking crank motion.

Belts to individual machines should be guarded so as to prevent danger of anyone being caught between the belt and pulley. A height of 5 ft. above the floor line is recommended for such guards, if within 6 in. of the belt.

Care could be taken to avoid shearing or crushing motions between the moving parts of machines, or between such parts and the adjacent framework. Counterweights should be placed in such positions as will minimize danger of injury in case the support gives way and allows the weight to drop; where they cannot be guarded by natural location, they should be suitably enclosed.

Construction Details

Beds of **metal-working planers** should be covered or sheeted over, to avoid shearing action with the reciprocating table. **Emery wheels** should have safety hoods (preferably of steel, not less than $\frac{3}{16}$ in. in thickness), and all dry grinders should be provided with suitable exhaust connections; emery-wheel flanges should be not less than half the diameter of a new wheel. **Wood jointers** or **planers** should have standard safety cylinder or circular heads, and should preferably be equipped with exhaust connections; an additional guard which automatically covers the unused portion of the revolving knives is desirable in addition to the safety head. **Band saws** should have upper and lower wheels enclosed, and all portions of the saw except that over the table subject to immediate use should be guarded against accidental contact. **Circular saws** should be guarded and where possible should be equipped with a "splitter," except in the case of self-feed saws.

Elevator Specifications and Installation Rules. The following requirements are prepared with freight elevators particularly in mind, although similar requirements also apply to passenger elevators.

There should be at least two lifting and two counterweight cables each, and both lifting and counterweight cables of a drum-machine elevator should have not less than two full turns of cable on the drum when the car is at the lowest and the highest points of travel. Sheaves of operating ropes should be thoroughly guarded, so that the ropes cannot be misplaced. An approved device should be provided for locking or securing the starting rope in the cage so that the elevator cannot be started from any other point. Unused sides in the car should be enclosed to a height of at least 6 ft. from the floor; oven steel fabric of about No. 9 wire, 1-in. mesh, makes a good material for is enclosure. Unless otherwise specified, the elevator car should be provided ith a substantial cover to prevent danger of tools or material falling from erhead and striking persons in the car; this cover should preferably be ranged in two or more sections, hinged to the supports so they will swing pward if they strike any obstruction as the car descends. Where an elevator serves two stories or more it should be equipped with an approved speed governor.

All elevators except those of the hydraulic plunger type should have an approved type of safety clamp which will engage the guides and stop the car in case the hoisting cables should break or become detached. This clamp should be thrown into engagement by a spring or mechanical device, and not by gravity; it should be arranged, however, so that the gripping power of the clamp is not obtained from a spring. The elevator well should be completely enclosed on the unused sides and from the head clearance (7 ft.) up to the ceiling, where entrances occur. Doors or gates should be placed at all entrances, and, wherever practicable, should be arranged so that they can be opened only from within. If gates are used they should be preferably of the semi-automatic type; but they may be manipulated entirely by the operator, if necessary, and full automatic gates may be used at upper and lower floors. Wherever possible gates should be at least 6 ft. in height, to prevent any one looking over the top of them; if this height is impracticable, suitable means should be provided to prevent accidents from the descending cage (such as tell-tale chains, suspended from bottom of cage). Where the elevator car passes close by beams, floors, etc., the latter should be beveled off and sheeted over to prevent possibility of a foot being crushed between them and the floor of the cage.

Platforms with railing and toeboards should be placed at the top sheaves, for use of oilers, repairmen, etc., with permanent ladders to these platforms where necessary. A pit at least 3 ft. 6 in. in depth should be provided at the lower floor, and an equal clearance allowed between overhead platform, or beams, and the top of cage when it is at the upper floor level. Bumpers should be placed in the bottom pit, arranged so as to secure a minimum clearance of at least 30 in. between bottom of cage and pit floor. For further details see Massachusetts "Elevator and Escalator Regulations."

Ladders. The following precautions should be taken:

Fixed ladders are safer than portable ones; they should be made of steel to secure the highest degree of permanence and stability. At least 8 in. clearance should be allowed back of each ladder, and care should be taken to avoid any obstruction which would decrease this clearance and interfere with a proper foothold on the rungs of the ladder.

Where a high ladder is necessary (say 30 ft. or over), it is desirable to provide it with a "safety cage" consisting of a series of parallel bars arranged so as to enclose any one using the ladder in a cage or tube. A good form of construction is to make this cage approximately 27 in. inside diam., with seven parallel bars (about $\frac{3}{8} \times 1\frac{1}{2}$) supported at intervals of 6 to 8 ft. by a circular band rigidly attached to the ladder proper. It is also well to divide such ladders into sections of 15 or 20 ft., offsetting each section and constructing a railed landing between sections.

Where portable ladders are used for oiling shafting, suitable hooks should be placed at the top of the ladder for engaging with the shaft or hanger.

"Safety feet" should be attached to the bottom of each ladder; for wood floors a radial steel plate having a series of sharp spurs is desirable; for concrete floors it is well to use a foot which is pivoted, so as to give a large bearing surface on the floor; this foot may be advantageously made of metal surfaced with an abrasive material such as carborundum or alundum.

Safety Organizations, Societies, Etc.

The National Safety Council serves as a general clearing house of safety information. It sends out weekly distributions of safety literature, including bulletins, statistical information, descriptions of safety practices, rules, etc. It has branch Councils in many of the principal cities of the United States and holds an annual safety congress. It has a Standardization Committee at work on the standardization of safety devices and practices for various industries. It is a co-operative organization conducted without profit. Secretary, Mr. W. H. Cameron, Continental and Commercial Bank Bldg., Chicago.

The National Affiliated Safety Organizations represent the National Association of Manufacturers (30 Church Street, N. Y. City), the National Founders Association (29 South La Salle Street, Chicago, Ill.), the National Metal Trades Association (Peoples Gas Building, Chicago, Ill.) and the National Electric Light Association (29 West 39th Street, N. Y. City). A joint "Conference Board on Safety and Sanitation" representing these associations is working on the development of safety devices and practices, and the dissemination of information on them through various publications, bulletins and magazine articles. Such devices at present (1915) include first-aid jars (see p. 1747), stretchers, respirators, chip guards, ladder feet, foundrymen's shoes and leggings, knuckle guards for trucks, etc. Mr. M. W. Alexander, West Lynn, Mass., is secretary of the Conference Board.

The American Museum of Safety is a museum of industrial safety and hygiene. It issues publications, assists in public safety campaigns and other lines of safety work and holds an annual exposition of safety and sanitation in New York. The museum is located at 14–18 West 24th St. New York City. Dr. W. H. Tolman is the director.

The Underwriters' Laboratories (207 E. Ohio Street, Chicago, Illinois) which, for a number of years, has examined fire and electrical appliances for approval, under the direction of the National Board of Fire Underwriters, has arranged to test and approve safety devices also. It maintains a card service on approved devices.

FIRE PROTECTION

BY

H. O. LACOUNT

Construction

Types of Construction. The use of reinforced concrete affords a **non-combustible construction** that greatly reduces the conflagration hazard. **Slow-burning mill construction** (see p. 1325) can be easily protected by automatic sprinklers, and fires can generally be extinguished before the building is seriously damaged. In any case, roofs or roof coverings should be of non-combustible construction in order to prevent ignition through sparks brought from a distant fire.

Areas. (See also p. 1383.) Small areas tend toward limiting the damage from any given fire. Usually, they should not exceed 20,000 to 30,000 sq. ft., but with safe occupancies, such as weaving, machine shops, etc., larger areas would not be unreasonable. The more hazardous processes should be placed in separate buildings or separate rooms. Processes of widely different hazards should not occupy the same room. Processes in which fires are liable to start should not be located on floors above valuable occupancies specially susceptible to water damage.

Cut-offs. Subdivision should be obtained by substantial fire walls parapeted through the roof, and necessary openings protected by self-closing fire doors. Fire curtains should be provided in very large areas. Good cut-offs floors are especially important to prevent fire, heat, and smoke in a lower floor from quickly spreading throughout the upper floors. Stairs, elevators and main belts should be enclosed, preferably with non-combustible construction, though for many of the smaller stairways a good plank or double matched sheathing partition would be satisfactory. All openings in these enclosures, except those of plank, should have fire doors, and good wood doors should be provided at either top or bottom of stairs enclosed with plank. Belts, except the smaller ones, especially need enclosing, for they create drafts which readily carry fire from one floor to another. Brick or concrete towers are usually provided for main drives, but expanded metal and cement plaster on iron framework is satisfactory for belts in general.

For **Fire Hose** and **Fire-extinguishing Streams** see p. 276.

Automatic Sprinklers

Where Needed. Sprinklers should be installed throughout the premises, including basements and lofts, under stairs, platforms, and large shelves, in towers, elevator wells, dry boxes, etc.; in small enclosures such as belt boxes, chutes, conveyor trunks, etc.; also in cupboards and closets unless they have tops entirely open or are covered with light, inflammable material, and are so located that sprinklers can effectively spray therein. Sprinklers should not be omitted in any room merely because it is wet or of non-combustible construction.

Sprinklers **may** generally **be omitted** under non-combustible construction when the occupancy does not involve the introduction of combustible material.

Sprinklers **should not be omitted** over electrical apparatus except in dynamo or transformer rooms where voltages exceed 600. With these higher voltages the apparatus is liable to be damaged from a wet-down, and it is important to guard against possible loss in case of accidental opening of a head. If the sprinklers are omitted, the room or building should be of non-combustible construction or all exposed woodwork should be adequately fireproofed. In some cases suitable non-combustible shields can be erected over the machines and thus permit the use of sprinklers without danger of wetting the electrical apparatus.

In **power houses** having non-combustible walls the need of sprinklers may be avoided by making the roof also non-combustible, or, if the roof is of wood, by fireproofing the underside with metal laths and cement plaster.

Table 1. Spacing of Automatic Sprinklers

Water pressure at highest sprinkler	Kind of hazard*	Spacing of sprinklers, ft.						
		Standard mill construction					Open-joisted ceilings	
		Width of bay, ft.					Sprinklers at right angles to joists	Sprinklers parallel with joists
		12	11	10	9	8 and under		
Exceeding 20 lb. per sq. in.	Medium..	8	9	10	11	12	8	10
	Special....	7	8	9	10	11	7½	9
Less than 20 lb. per sq. in., or supplied by tank.	Medium..	7	8	9	10	11	7½	9
	Special...	6	7	8	9	10	6½	8

* The terms "medium hazard" and "special hazard" relate to the contents or occupancy of each room. Specially hazardous places are such as picker rooms, planing or sawing departments of wood-working establishments, painting or varnishing rooms, etc.

Arrangement. In general, at least one sprinkler should be allowed for every 100 sq. ft. of floor area, the sprinklers never to be more than 12 ft. apart in either direction and preferably not more than 10 or 11 ft. No branch line should contain more than 7 sprinklers.

Spacing. For standard mill construction (6- to 12-ft. bays), one row of automatic sprinklers is placed midway between beams in each bay, and the sprinklers should be spaced according to Table 1. Spacing for open-joisted ceilings is given in the same table.

Under joisted construction sprinklers should be staggered at right angles to, or across, the joists, so that no two adjacent heads will distribute water into the same channel between joists, but in no case should the end or intermediate sprinklers in each line violate the rules for spacing.

Sizes of Pipes. The number of automatic sprinklers in any one room supplied through a given size of pipe should not exceed that given in the following table:

Size of pipe, in.	¾	1	1¼	1½	2	2½	3	3½	4	5	6
No. of sprinklers	1	2	3	5	10	20	36	55	80	140	200

These sizes apply to the ordinary runs of pipe in the average equipment. Longer runs, such as feeders across wide buildings, or feeders to sections remote from a riser, must usually be larger, and should be figured to carry the amount of water without excessive friction loss.

Discharge of Sprinklers at Different Pressures. All of the approved sprinklers give practically the same discharge with the same pressure at the sprinkler. For diaphragm or ring nozzles (½-in. orifice), the discharge is as follows:

Pressure at sprinkler, lb. per sq. in.	5	10	20	30	40	50	60	70	80	90	100
Discharge, gal. per min.	12	18	25	31	36	41	45	49	52	55	58

Cost of Sprinkler Equipment. An average figure for a sprinkler equipment, including the risers and all inside work but no outside work, is $3 per sprinkler. This might be reduced to $2.50 for plain, straightway work under favorable conditions, and run as high as $4 to $5 when the cost of labor is high or roofs are difficult to reach.

Open Sprinklers

Where Needed. Where window openings must be guarded against exposure, if the exposure is moderate and such as not to warrant much expense, considerable protection may be obtained from sprinklers located just above the windows so as to discharge water directly upon the glass and frames. This protection will be greatly increased if the windows are made of wired glass in metal frames.

Size of Discharge Orifices. Where there is but one horizontal line of sprinklers the orifices should be 3/8 in. in diameter. Where there is more than one horizontal line the size of the orifices should be as follows: top line, 3/8 in.; next line below, 5/16 in.; all other lines, 1/4 in. When there are over six horizontal lines of sprinklers they should be divided into groups, each group to be supplied through an independent riser. Even with a system of six horizontal lines subdivision may sometimes be advisable in order to obtain better control of the equipment.

Sizes of Pipe. The number of sprinklers on a branch line should not exceed six. The pipe sizes should be as given in Table 2.

Table 2. Sizes of Pipe for Open-sprinkler Branch Lines

Size of pipe, in.	Maximum number of heads allowed				
	Size of orifice				
	3/8 in.	5/16 in.	1/4 in.		
	Top line	2d line from top	3d line from top	4th line	5th and 6th lines
3/4	....	1	1	2	4
1	1	3	3	5	6
1 1/4	3	6	6	6	....

The pipe sizes on riser and feed mains, should be as follows:

Number of heads	6	10	18	30	48	72
Pipe size, in.	1 1/2	2	2 1/2	3	3 1/2	4

Where the heads are over 12 ft. apart, larger pipe than given in the table should be used. Where the feed main (including risers to the first branch line) is over 25 ft. in length, it should be at least a size larger than the table requires.

The **discharge** from an open-sprinkler equipment with such pressures as are usually available, will vary from about 8 gal. to 12 gal. per min. per head, depending on the pressure and the arrangement of the pipes. For efficient service the pressure should not be less than 5 lb. at any head while water is running.

Pipes of the best quality, galvanized inside and outside, should be used for the equipment as far back as the controlling valve, and the piping should be run inside the building as far as practicable.

Location of Sprinklers. For windows not exceeding 6 ft. in width, one sprinkler should be placed in the center with the deflector about on a line with the top of the upper sash, and 7, 8, 9, or 10 in. in front of the glass, according as the windows are 3, 4, 5, or 6 ft. in width, respectively. Where windows are over 6 ft. in width or where mullions interfere, two or more sprinklers should be used.

Discharge of Open Sprinklers at Different Pressures. The discharge of open sprinklers having smooth-bore conical nozzles and outlets of various diameters, is as given in the following table:

Pressure at sprinkler, lb. per sq. in.	5	10	15	20	25	30	40	50
Discharge, gal. per min.:								
¼-in. outlet	4.3	5.6	6.7	7.7	8.5	9.2	10.4	11.5
5/16-in. outlet	5.8	8.0	9.7	11.1	12.3	13.4	15.3	17.0
⅜-in. outlet	8.3	11.5	13.9	15.9	17.6	19.2	21.9	24.3

Standpipes

Stair towers often furnish excellent opportunity for use of hose streams at fairly close range, especially in case of fire in upper floors, and for this purpose standpipes should be run up through most main stair towers. These standpipes should not be smaller than 4 in. in diam., and when two connections are taken off at each floor, 6-in. pipe would be advisable. At each connection should be provided a 2½-in. hose valve and attached to this a length of 2⅝-in. unlined linen hose not less than 50 ft. long and equipped with a standard playpipe with a ⅞-in. or 1-in. nozzle. Depending on the width of building, a 75-ft. length of hose or two 50-ft lengths coupled together should be provided, stored on suitable racks and arranged to be easily pulled out for immediate use. The hose valve should be absolutely tight, as leakage will wet the hose, causing mildew, which seriously weakens the fabric.

Underground Supply Pipes

Size of Pipes. This will depend upon the size of system, the amount of water per min. liable to be needed, and the allowable friction loss. For the supply of a 2-way hydrant a 6-in. pipe should be used, and for a 3- or 4-way hydrant an 8-in. pipe.

Cost of Cast-iron Pipe Laid. The approximate cost per linear foot of cast-iron pipe laid in earth, including an average number of tees, elbows, etc., as ordinarily required for mill-yard systems, is as follows.

Inside diam. of pipe, in.	4	6	8	10	12	14	16	20	24	30	36
Cost per lin. ft.	\$0.84	1.08	1.42	1.80	2.13	2.57	2.95	4.20	5.37	7.46	9.50

The above figures are based upon iron pipe at \$30 per ton, and include cost of teaming at 30 cents per ton-mile for an average distance of 2½ miles. For rock excavation and back-filling with earth, add \$4 per cu. yd.

Hand Apparatus for Extinguishing Small Fires

Fire Pails. Ordinary pails kept filled with water are very efficacious in extinguishing small fires in factories. Generally, one pail should be provided for every 750 to 1000 sq. ft. of area, with additional pails where there are large amounts of light combustible materials, as in packing and shipping rooms, woodworking shops, etc.

Small Hose (1¼-in. unlined linen hose with a ⅜-in. nozzle) should be provided, and may be connected to the sprinkler system if the pipes are not less than 2½ in. in diam. An independent supply, however, is preferable.

Chemical Extinguishers. For general use the standard 2½-gal. soda-and-acid extinguisher is to be preferred. Extinguishers using carbon tetrachloride are especially useful in connection with electrical and gasoline fires, where water should not be employed.

Sawdust. Fires in inflammable liquids in moderate-sized open tanks such as used for paint dipping, lacquering, etc., can be easily extinguished by spreading sawdust over the burning liquid with a long-handled shovel. The best results are obtained when 10 lb. of bicarbonate of soda are mixed with each bushel of sawdust.

Machines for shaping the materials of machinery construction are classified into the seven following groups:

1. Molding machines
2. Core-making machines
3. Forging machines
4. Bending, forming and shearing machines
5. Welding machines and apparatus
6. Metal-cutting machines
7. Wood-working machines

MOLDING MACHINES

Small Hand Squeezer. This (the simplest) form of molding machine is used to save the greater part of the work of hand ramming. It consists of a metal frame supporting a table upon which the pattern and flask rest during the molding operation. Above the table is a yoke or presser top connected to the frame by strain bars which can be swung back out of the way, or brought over the flask.

To make a mold, the pattern in its match plate is placed on the table and over it the drag part of the flask. The correct amount of sand is then shoveled in, a presser board is put on, and by means of a long lever the sand is squeezed into the flask and around the pattern. This produces a half mold—the drag. The cope is made in the same manner, except that the drag is turned over, the match removed and the cope half of the flask put over it. **Used only on light work**—usually for snap flasks.

Power Squeezer. The power squeezer is next in point of simplicity to the hand squeezer. The platen rests on the top of a plunger fitting in a cylinder beneath and actuated (usually) by compressed air. The yoke at the top that resists the pressure is hinged at the bottom and can be swung back out of the way. It is adjustable on the strain bars at the sides to accommodate flasks of different depths. A **vibrator,** or small air-operated hammer, is provided to jar the mold while the pattern is being drawn and overcome the friction of the sand. It does not appreciably enlarge the mold.

The **operation** is the same as with a hand squeezer, except that the **ramming** is done **by power** and the vibrator is used in drawing the pattern. The air pressure is from 80 to 100 lb. per sq. in.

In **commercial sizes,** cylinder diameters range from 10 to 18 in., spans between strain bars from 32 to 62 in., and platens from 18 × 26 to 24 × 42 in.

The **air consumption** may be figured at 4 cu. ft. of free air per min. This includes squeezing the mold, vibrating when drawing the pattern and blowing off the pattern when drawn. In the larger machines, more air is used per operation, but fewer molds are made in a given time.

Vibrators are made from $\frac{7}{16}$ to 2 in. inside cyl. diam. in size. They are not proportioned to the size of molding machines except incidentally, but to the patterns and pattern carriers that they agitate. The material of the carrier is another factor. It is often advisable to use a large vibrator with a wooden plate of a given size than with a corresponding metal one. The wood transmits the vibrations (5,000 to 30,000 per min.) more slowly. For metal plates and patterns the practice of the Mumford Molding Machine Co. is to make the **mass of** the **vibrator plunger** $\frac{1}{50}$ of that of the plates and patterns. The **production** from these machines exceeds that of hand squeezers by 15 to 30 per cent., depending upon the character of the work. Expert operators can put down from 270 to 325 molds in 6 hr., although the average is probably not greater than 200 molds. On some lines of work it is possible to increase production over hand molding by 100 per cent.; on other lines, as stove work, 20 per cent. is a satisfactory margin.

Split-pattern Machine. The split-pattern machine is a **power squeezer** particularly adapted to make molds from symmetrical patterns that can be split through the center, or for flat-back work. **Patterns** adapted to this machine are not limited to these two classes, however, as any pattern that can be split on a true plane may be molded.

This type of machine is **used for** a **wide variety of work** and for castings ranging from a few ounces in weight to others weighing several hundred pounds. They are made for both hand and power draft, are provided with vibrators, and may be provided with stripping plates.

In **operation** a half flask is put in position on the flask frame, parting sand is shaken over the pattern and the flask shoveled full of sand. The yoke is drawn forward and pressure applied. When the proper sand density is reached, as indicated by the pressure gage, the pressure is released and the platen and connected parts sink to normal position. The yoke is then thrown back, the vibrator started, and the flask lifted from the pattern by hand or power-operated mechanical means. The half mold is now finished and ready to be lifted from the flask frame.

The hand-draft, power-squeezing, split-pattern machine is made in two sizes, for flasks 14 × 16 in. and 13 × 18 in. **Air consumption,** 4 cu. ft. free air per min. per machine; pressures used, 60 to 80 lb. per sq. in.

Commercial **sizes** of power-draft machines range from 13 × 18 to 36 × 36 in. in flask size, 4 to 12 in. in draft and 13 to 36 in. in cylinder diameter.

In using **symmetrical patterns,** but a single plate of patterns is necessary, as the cope and drag are molded from a double set of half patterns. The impressions of the right-hand set in the drag match those of the left-hand set in the cope, and *vice versa.*

Flat-back patterns are mounted on the pattern plate for the drag half of the mold and a blank plate used for the cope half. It is customary to mold a "floor" of drags, then change the plate and mold the copes to complete. Split-pattern machines must be built for flasks of fixed dimensions, or at least fixed in length or width, to fit the flask pins of the machines. For this reason there has recently been a tendency to supersede them with other forms.

In the use of these machines it is not unusual to damage the finished mold when the pattern is drawn. This difficulty is obviated in part by drawing the pattern through a closely fitting hole in a fixed plate known as the **stripping plate.** As the pattern is carefully guided there is little danger of damaging the mold.

Jarring or Jolt Ramming Molding Machine. In this type of machine, developed in recent years and **adapted** especially **for large work,** the flask is struck a forceful blow to compact the sand. It is essentially a **sand-packing machine.**

In some forms the jarring table is struck from beneath by a heavy plunger actuated by compressed air. The blow raises the table a little distance from its support, by which it is struck a second blow when it falls back. Other types are mounted upon a heavy concrete foundation in such a manner that the force of the blow is kept within the machine itself and is not transmitted to the surrounding ground—to the damage of finished molds that may be in the vicinity. However, it is not safe to set up finished molds with hanging sand in the neighborhood of a machine of this type.

They are made with fixed and variable length of stroke, and with and without means to use the air expansively. Wilfred Lewis (*Trans. A. S. M. E.*, 1910, vol. 32, p. 794) gives the **strokes** used in practice as from 3/8 to 4 in., with an average of perhaps 2½ in.

Commercial sizes range from 3 to 36 in. in cylinder diam., 15 × 20 to 96 × 144 in. in platen dimensions, and from 350 to 50,000 lb. rated capacity with 80 lb. air pressure.

Shockless Jarring Machine. The Tabor Mfg. Co., Philadelphia, Pa., has recently developed a jar ramming machine, known as the "shockless," in which the table is mounted on a plunger fitted into a cylindrical base and supported upon vertical springs. When the table is lifted by air pressure the springs are compressed. When the air is released the dropping table is met by the rising anvil. Both come to rest with a ramming effect on the sand, but with little or no shock to the foundations and surroundings. (Wilfred Lewis, *Trans. A. S. M. E.*, 1910, vol. 32, p. 789.)

Commercial sizes range from 6 to 36 in. in cylinder diam., 24 × 32 to 96 × 144 in. in platen dimensions, and 1000 to 50,000 lb. rated capacity with air at 80 lb. pressure.

Combination Jarring and Roll-over Machine. Combination machines are built having a jarring machine for ramming, a roll-over attachment, and a pattern-drawing mechanism. They are **adapted for large "side-floor" work**, or for molds where the ramming, finishing and handling time is worth saving. Commercial **sizes** of machines made by the Tabor Mfg. Co. are given in Table 1.

Table 1. Molding Machine Weights and Prices

(From information supplied by the Tabor Mfg. Co.)

Machine	Weight, lb.	Approx. price per lb.	Machine	Weight, lb.	Approx. price per lb.
Small power squeezer..	800	$0.20	24-in. roll-over.......	800	$0.34
14 × 16-in. split-pattern................	1,600	0.25	Shockless jarring machines:		
Plain jarring machines:			6-in. cylinder......	3,000	0.27
6-in. cylinder........	1,000	0.40	20-in. cylinder.....	30,000	0.08
20-in. cylinder......	10,000	0.12	36-in. cylinder.....	100,000	0.075

Special Molding Machines. In many foundries special molding machines have been developed for individual pieces. Among these are **machines for** making cast-iron **pipe fittings** and **gears.** Of the latter, those for small gears use a complete pattern, while those for large gears often use a block representing a single tooth space.

These machines are of **two general types**, one having resemblance to a vertical boring mill in that it has two housings extending upward from a base and a cross rail along which the head carrying the pattern block can be moved to get the proper setting for the various sizes of gears within the capacity of the machine. The second type resembles a radial drilling machine in that it has a single arm carrying the head for the tooth block. In both of these types the table can be rotated by an indexing mechanism to space the mold for any number of teeth desired.

Automatic Molding Machines. A limited use has been made of automatic molding machines in which the **operations are performed in sequence by the machine itself.** The sand is conveyed to the top of the machine by bucket conveyor, is fed into a hopper, from which it is discharged in proper quantities into an empty flask on a feeding table. After the flask is filled with loose sand, a back board is slipped on, the mold is squeezed, the pattern drawn and the molded half flask is ready to be taken away by helper.

These machines are only adapted for special lines of work, but are capable of producing a very large number of flasks per day under favorable conditions. They are used for both iron and brass molding. The Berkshire Mfg. Co., builders of the Berkshire automatic molding machine, report **outputs** varying from 60 to 100 molds per hour.

Molding Sand

The individual grains of molding sand should constitute approximately 90 per cent. of the mass, and be completely covered with a bond of alumina or clay. The more uniform the size and shape of the grains, the better is the porosity in relation to the average size of the grains.

A. E. Outerbridge, Jr. (*Trans. A. S. M. E.*, vol. 29, p. 868), gives the following **formulæ for molding sands**, known as strong, special strong, and fine sand; proportions by volumes:

	Lumberton sand (new) Strong	Lumberton sand (new) Weak	Gravel (new)	Floor sand (old)	Fine floor sand (old)	Coal dust
Strong sand	14	..	7	6	..	2
Special strong sand	9	..	14	..	..	2
Fine sand	..	14	..	..	4	2

The **strong sand is used for** the majority of **large molds**, such as planer beds, housings and the like, particularly the principal parts of large machine tools. Most of these **molds** are **skin-dried**, that is, baked on the surface by means of portable drying ovens, after having been wet-blacked.

The **special strong sand** is **used** only **for molds for** the very **heaviest castings**, such as large anvil blocks and the like. These **molds** are **wet-blacked, and** when **baked** are as hard as a baked loam mold.

The **fine sand** is **used for** all **light castings** and for much medium work. These molds are all **green-sand molds**, *i.e.*, are not dried before use. It is essential that molding sand be carefully mixed before put into use.

In Mr. Outerbridge's **tests with strong sand**, bars 1 × 1 × 6 in. were used, (*a*) with sand that had been dampened and turned over several times with a spade, and with sand that had been run through a centrifugal mixer from once (*b*) in the case of the first bar, to 10 times (*c*) in the case of the last bar. These bars of sand were slid over the edge of a plate until they broke. The length of the overhang was taken as indicative of the strength of the sand. These overhangs varied in length from 2½ in. for case (*a*), to 3 in. for (*b*), and to 3¾ in. for (*c*). The corresponding increases in strength were 75 and 225 per cent., respectively, over the spaded mixture.

CORE-MAKING MACHINES

Core-making Machines. Two general types of core-making machines are in use. The first produces cores of a uniform section which may be circular, square, or of other shape. The second produces cores of more complex form, and in principle is identical with some of the molding machines previously described. **Screw-feed machines** are used largely **for making plain cylindrical cores.** The mixed core sand is fed into a hopper communicating with an Archimedean screw driven either by hand or power, which forces the sand out in a compact core of any length. A second kind of machine of this type uses a **plunger** for forcing out the core instead of a screw.

It is not unusual to mount these machines to feed the core down a slight incline. The core as it is fed is received upon a metal plate which acts as a guide to keep it straight. After the plate is filled, it is taken to the oven for baking. From the long cores thus produced, pieces are cut off to any length desired.

The second type of machine is employed in making large cores, and includes **simple squeezers and jolt ramming machines.**

Core Ovens. **Permanent ovens** are usually of brick or concrete, fitted with iron shelves on which the cores are placed to be baked, or provided with a track in the floor to receive cars carrying large cores.

Portable ovens are of sheet iron or steel and are placed over very large cores at the points where these are made. There are no standard sizes, except a few small-chamber shelved ovens for light work.

The essential feature in **core-oven construction** is to maintain a uniform temperature throughout the entire drying chamber. There should not be a difference in the various parts of the oven exceeding 60 deg. fahr. Furthermore, there should be a proper circulation of hot air through the oven to insure carrying off steam generated during the first part of the period of baking, and supplying an ample amount of oxygen to oxidize and dry oil binders. A common error in core-oven design is to have the firebox too near the drying chamber. This renders some of the volume unusable because of its being so hot as to burn the cores instead of baking them.

The usual **core-oven fuels** are anthracite coal, coke, fuel oil and gas. For some classes of binders, **steam-heated ovens** are excellent, as their construction nsures easy control of the temperature and precludes the possibility of its rising above a desired maximum. The fuel economy of steam-heated ovens is very low. For this reason direct firing of some other fuel is usually resorted to.

Core Sands. (See paper by Henry M. Lane, *Trans. A. S. M. E.*, 1911, vol. 33.) Cores are composed of sand and a binder which hardens under the action of heat and binds the sand grains together into a hard mass. A core **must be** sufficiently **porous to vent freely.** The individual grains should be bound one to another at the contact points only. **Rounded grains** give a maximum area of the vent passages. For different metals and mixtures, different-sized sand grains must be used.

Core Binders. The demand for large output in this country has brought about the extensive use of green-sand molds requiring an extensive use of **baked cores.** In Europe, skin drying is common practice and **dextrine** or "core gum" is the common core binder. Pea meal, rye flour, and linseed oil are also used.

In America an extensive line of **prepared binders** is on the market. These are divided into **two** general **classes,** depending upon their action on the sand: the true pastes which do not flow to the contact points of the grains of sand, and the binders that do flow.

Molasses has an extensive use but is open to the objection of a lack of uniformity in quality from deterioration through fermentation and of the danger of burning unless care is used in regulating the baking temperature. If underbaked, the molasses is not hardened and does not properly cement the sand grains; if overbaked, it is burnt or charred and its strength is lost.

Another water-soluble bond extensively used is **glutrine.** It forms an excellent emulsion with clay and tends to carry to the contact points of the sand grains.

The flour and dextrine mixtures are pastes which form in small masses on the faces of the sand grains and dry thereon. They do not flow to the contact points. Thus, much of the binder is inactive as binding material and is located in such a way as to tend to reduce the area of the vent passages.

Resin and pitch are also used to bind by melting and flowing over and between the grains, collecting to a certain extent at the contact points as the core cools. But in this respect they are not as efficient as oil.

Oil of a proper quality is undoubtedly the strongest, weight for weight, and the most **efficient binder** when used with clean silica grains. Linseed oil is the best for cores. When thoroughly mixed with the sand each grain is uniformly coated with oil or an emulsion of oil and water. In baking, the moisture is driven off and the oil tends to accumulate at the contact points of the grains only.

Table 2 gives the **relative strength of** a number of core **binders** and the results of a determination of their solid contents.

Table 2. Percentages of Solids in Liquid Core Binders

Name	Dried 24 hr. at 212 deg. fahr.	Dried 1 hr. at 400 deg. fahr.	Burned to ash	Remarks	Relative strength of binders
Glutrine	51.47	41.98	8.03	Skin	....
Raw linseed oil	100.22	96.98	0.22	No skin	....
Boiled linseed oil	93.49	90.23	0.54	Skin	32
Soya bean oil	100.91	96.45	0.65	No skin	....
Fish oil	100.52	92.70	1.20	No skin	14
Paraffin oil	72.05	33.36	0.11	No skin	Negligible
Corn oil	100.72	95.35	0.42	No skin; crawled	20
Cottonseed oil	100.68	96.08	0.07	No skin	16
Light tar oil	31.18	11.65	0.09	Slick; crawled	4
Heavy tar oil	67.21	38.27	0.06	No skin; crawled	26
Resin oil	62.89	19.59	0.06	No skin; crawled	1
Crude tar oil	51.83	34.32	0.06	No skin; crawled	Negligible
Resin oil	63.64	10.12	0.03	No skin; crawled	2
China wood oil	102.20	98.75	0.03	Skin	54

Oil-Sand Cores for the most exacting requirements have a tensile strength of at least 75 lb. per sq. in. In view of the high cost of linseed oil, foundrymen have turned to other varnish oils, including China wood, soya bean, corn, and cottonseed oils. If made from green sand and oil they have no tendency to absorb moisture and will **retain** their **strength for an indefinite time.** Cores with this composition have been used when four years old and seem to give as good results as when new. Core mixtures in foundry use vary in **tensile strength** from 5 to 150 lb. per sq. in.

Baking Temperatures for Cores made with flour, starch or dextrine binders should be from 350 to 375 deg. fahr.; under no circumstances should they exceed 400 to 410 deg. fahr. For pitch and resin binders a temperature of 350 to 400 deg. fahr. is suitable. A temperature of 400 deg. fahr. will destroy the dextrine which is a component in many such compounds. Resin oil does not distill much below 550 deg. fahr.; at 640 deg. fahr. 90 per cent. will be driven off. Cores bonded with oil will not as a rule be injured up to 500 deg. fahr., though a temperature from 400 to 410 deg. fahr. is sufficient. All binders containing carbon begin to char and to lose strength at 600 deg. fahr.

FORGING MACHINES

General Data on the Hot-forging of Metal. The tensile strength of a metal determines to a certain extent its resistance when being forged. The strength decreases with an increase of temperature but the decrease is not appreciable for wrought iron and steel below 375 deg. fahr. For the **relation between temperature and tensile strength**, see pp. 486 and 543.

The **forces required to produce deformation** are greater than the resistances indicated by strength tests: first, because the deformation occurs more quickly than the application of the load during test; second, because the density of the structure of wrought iron and steel increases during the working process; third, because the dies and tools abstract a considerable amount of heat from the piece being worked.

Let S = tensile strength at forging temperature, lb. per sq. in.; K = resistance to be overcome in forging, lb. per sq. in.; P = total forging pressure, lb.,

A = area of surface under pressure, sq. in. (projected area if surface is inclined to direction of pressure); and C = factor from experience (always greater than unity). Then, $K = SC$, and $P = AK = ASC$. If the piece is to be flattened out to a considerable extent, $P = 2AK = 2ASC$. The resistance is still further increased if there are deep impressions in the die to be filled.

If the pressure P is due to a blow, as from a hammer, the value of C is high, up to 10. If the pressure is slow-acting, as from the ram of a press, C = 1.4 to 2. If d represents the distance (in.) traveled by the die in the operation of forging, the work W expressed in ft-lb. is

$$W = dP/12 = dASC/12 \tag{1}$$

The **work required to bend a** sheet or **plate** t in. thick, with a volume of V cu. in. **into a curved shape** with a radius of r in. is $W = K(t/r)V/48$ ft-lb.

Hot-forging Machines, hammers and presses are used for a wide variety of work, mainly on steel, wrought iron and copper where final shape and size are obtained by causing the metal to flow under the action of anvil or die faces.

Forging Hammers divide in the following classes: Helve, strap, belt and rope drop, board drop, steam drop, single-frame steam, double-frame steam, and pneumatic.

Helve Hammers (Bradley Type) are usually belt-driven and carry the hammer face or swage on the end of a beam. The belt is provided with a tightening device, treadle-controlled, permitting the operator to regulate the number and speed of the blows. They are **used for general** and duplicate **forging,** welding, plating, drawing, swaging, collaring, spindle-making, etc.

Commercial sizes are 15, 25, 40, 60, 80, 100, 200, 300 and 500 lb. The 200-lb. size requires approximately 2 h.p. to operate.

Strap Hammers carry the hammer slung from a strap, usually of leather. The control and operation are the same as for the helve type. They are **adapted for general work,** tool dressing and the like.

Commercial sizes are 15, 30, 50 75, 100, 125, 150 and 200 lb.

The Board Drop-hammer is one of the most important types of forging hammer and is used principally to produce **drop-forgings** of wrought iron, steel, and copper.

Let W = work of blow, in ft-lb.; H = weight of hammer and die, lb.; g = acceleration due to gravity (= 32.2 ft. per sec. per sec.); h = actual hammer stroke, ft.; and v = terminal velocity of hammer, ft. per sec. Then, if the hammer and die fall of their own weight, $W = (H/g)v^2/2 = Hh = 0.015Hv^2$ (approx.). Combining with formula (1) by making the work done in forging equal to that of the hammer blow, $Hv^2 = 5.5dASC$, and $Hh = 0.084dASC$.

The hammer head is fastened to a board (usually of hard maple) mounted between two pulleys or rollers, one or both of which are continually revolving. The hammer is lifted by pressing the rollers into contact with the board by means of a treadle-operated mechanism. When the treadle is released, the rolls spread and the hammer falls. Or, the hammer can be operated automatically, the height to which it is lifted being determined by an adjustable dog. Usually, drop-hammer boards are uniform in width for the entire length; occasionally, however, they are slightly tapering toward the upper end. It is essential that they shall be made from clear, straight-grained wood, otherwise they are liable to split. The **lifting power** $L = fF$ when the board is lifted by one roller (when both rollers are driven $L = 2fF$), where f = coefficient of friction of roll and board, and F = force with which rolls are pressed together. Since $f = 0.25$ (approx.), $L = 0.25F$ and $0.5F$ (approx.), respectively.

Part of the lifting power must at first accelerate the motion of the hammer head. Consequently, $L = bH$, where b is a constant which is always > 1.

The motion of the hammer is accelerated with the effort $(b - 1)H$ until the speed v has been attained. The friction driving wheels or belt must consequently slip at first. Disregarding frictional resistances, **time** (in seconds) **required to lift hammer** $= t_1 = [0.016v/(b - 1)] + (h/v)$, and the **duration of drop** $= t_2 = 0.124\sqrt{h}$. Generally, $v = 2.5$ to 3.5 ft. per sec.; $b = 1.2$ to 2; $h = 3$ to 6 ft., and $H = 100$ to 3000 lb.

Weight of hammer, lb.	250	400	600	800	1000	1500
Approximate horse power required	2	2.5	3	3.5	4	5

Steam Hammers may be divided into **three classes.** In the first, the hammer is lifted by steam and drops of its own weight; in the second, steam is admitted above the piston and through its expansion increases the force of the blow; in the third, live steam is admitted above the piston throughout the stroke and the force of the blow is from combined weight of the falling hammer and the pressure of the steam.

In the **first class,** that of the single-acting steam hammer, the lifting power $L = bH$. That part of the force of the steam equal to $(b - 1)H$ is used for accelerating the lifting motion continuing after the steam has been cut off as long as the pressure under the piston is $> H$. These hammers are **used** only **for very large work.** The **weight of** the **hammer** ranges from 25 to 125 tons, and the value of b ranges from 1.5 to 1.2. The disadvantage of this type lies in the fact that the height of the clearance under the piston is directly dependent upon the thickness of the piece of work.

In the **second class,** in which steam is admitted above the piston and allowed to expand, there is an economy in steam consumption, a greater acceleration of the hammer head, and a larger number of blows per unit of time. The reliability of operation is not of the best.

To overcome this defect in operation the **third class** was developed, in which live steam is admitted above the piston. Here the **weight of** the **hammer** head varies from 1 to 25 tons. The control is such that the weight of the hammer itself is available for light blows, and for heavier blows steam is admitted above the piston.

In comparatively small hammers where the head weighs from 150 to 2000 lb., $b = 2$ to 3.5, and the diameter of the piston rod equals 0.5 to 0.65 of the diameter of the piston. The area of the upper piston face is consequently from 1.3 to 1.7 times that of the lower face. Up to 350 **blows per min.** can be obtained, depending on the length of the stroke and the tightness of the stuffing box. These hammers are provided with an automatic reversing gear. The **number and force of** the **blows** can be regulated by throttling the steam, changing the center position of the operating valve and changing the backlash in the operating gear. The frame of these hammers is usually C-shaped.

The **anvil** in small hammers is usually a single casting. In large hammers it is usually divided into upper and lower anvil blocks. In smaller hammers the anvil is connected with the shears and upper part of the machine. In the larger hammers, however, this is not the case, as the concussions tend to injure the hammer mechanism. For good practice the **weight of** the **anvil** ($= Q$) for hammers used in forging iron is at least eight times the weight of the hammer head; for forging steel, at least 12 times.

The pressure Q_1 exerted by the anvil block on the surface which it supports is assumed to be as follows: For blooming hammers, $Q_1 = (30 \text{ to } 60)hH + Q$; for billet-forging hammers, $Q_1 = (60 \text{ to } 95)hH + Q$; for hammers for steel forging, $Q_1 = (95 \text{ to } 125)hH + Q$.

Commercial Sizes. From mechanical arrangement steam hammers are called steam drops, single-frame and double-frame steam hammers. Sizes of steam drops range from 400 to 7000 lb. Sizes of single- and double-frame hammers range from 250 to 4000 lb. and 1500 to 30,000 lb. respectively. A series of small double-frame steam hammers, known as "tilting hammers," is also made. They are used chiefly by forges producing the smaller sizes of steel bars, as squares and octagons of tool steel. Uniformity in force of blow and length of stroke are the impertant features. Commercial sizes range from 500 to 2500 lb.

Pneumatic Hammers. A self-contained type of pneumatic forge hammer (the Bêché) has an air-operated ram with an air-compressing cylinder integral with the frame. The ram is raised by admitting compressed air beneath the ram piston; at the same time a partial vacuum is caused above it. The ram is forced down by a reversal of this action.

This type is made in a number of different models by the Nazel Engineering and Machine Works, Philadelphia. Tests by the maker give the force of the blows for the various sizes, and capacity in maximum sizes of stock, as follows:

Size, lb	66	165	250	350	500	770
Blow, in ft-lb	268	948	1338	2351	4116	6452
Maximum diameter of stock forged, in	2	4	5	7	8	9

In exceptional cases, where very pure water or oil was used, the pistons have been accurately ground in place and used without packing. Many ingenious methods of control have been developed, in some of which all of the motions of the hammer are controlled by a single lever.

Energy of Hammer Blows. Where the striking velocity of a hammer ram is greater than 10 ft. per sec., the energy E of the blow (in in-lb.) may be determined from the compression of lead cylinders. From experiments made by W. T. Sears, of the Niles-Bement-Pond Co. (*Am. Mach.*, Mar. 10, 1910), using $1\frac{1}{2} \times 1\frac{1}{2}$-in. cylinders, the following results were obtained (c = compression or shortening of cylinder, in.):

c (in.)	0.2	0.4	0.6	0.8	1.0	1.2	1.3
E (in.-lb.)	900	3000	6000	10,500	18,000	34,000	54,000

For any value of c close results may be obtained from the formula $E = (10{,}800c - 870)/(1.55 - c)$. Where the speed of compression is slow, as in **presses**, it is necessary to know the speed to estimate the energy. Mr. Sears gives the following values at two rates of speed, and also quotes static-pressure results obtained at Purdue University:

c (in.)	0.2	0.4	0.6	0.8	1.0	1.2	1.25
E (0.0005 ft. per sec.)	600	2100	4000	7000	11,100	19,200	23,500
E (0.00007 ft. per sec.)	400	1600	3000	5000	8000	14,800	18,000
E (Purdue)	400	1400	2600	4100	6600	12,000	15,000

Riveting Machines divide themselves into **two classes**, one resembling steam hammers in that a series of blows is struck to form the rivet head, and the other resembling forging presses in that the snap is slowly guided against the rivet, the other end being held in the rivet die.

These machines are **operated** either **by compressed air or** by **hydraulic pressure.** The frames are usually C-shaped, and may have a **length** up to 15 ft. They may either be set in a vertical or horizontal direction, depending upon the nature of the work, or the riveting machine may be suspended or moved about to any desired position. The usual **air pressure** is from 80 to 100 lb. per sq. in. **Riveting pressures** are commonly taken as 150,000 lb. per sq. in. of the rivet section for hot-working, and 300,000 lb. per sq. in. for cold-working. The plates should be pressed together by a **pressure** of from 0.3 to 0.4 that used in riveting.

Forging Dies. Drop-forge dies are of steel, steel castings and cast iron. A good all-around grade of **steel** is a 0.60 per cent. carbon open-hearth. Dies of this will forge mild steel, copper and tool steel satisfactorily if the number of forgings required is not too large. For a large number of tool-steel forgings tool-steel dies of 0.80 to 0.90 per cent. carbon may be used, and for extreme conditions, 3½ per cent. nickel steel.

For very large pieces with deep inpressions, **cast-steel** dies are sometimes used. For large dies liable to spring in hardening, 0.85 **carbon steel** high in manganese is sometimes used unhardened.

A very recent development is the use of **cast-iron dies.** Several large shops are experimenting with them and report encouraging results. In some cases they have outlasted steel dies on the same kind of forging at a die cost of only ⅙ to ⅟₁₆ that of steel dies.

Good **die-block proportions** for width and depth are

Width, in.	8	10	12	14
Depth, in.	6	7	7	7 or 8

For ordinary work, 1¼ in. of metal between impression and edge of block is sufficient.

Dimensions of **dovetailed die shanks:** For hammers up to 1200 lb., 4 in. wide and 1¼ in. deep, with sides dovetailed at angles of 6 deg. with the vertical; for hammers from 1200 to 3000 lb. in size, 6 in. wide and 1½ deep, with 6 deg. angles.

The **minimum draft for** the **impressions** is 7 deg., although for parts difficult to draw this may be increased up to 15 deg. It is not uncommon to have several drafts in the same impression.

Open-hearth and tool-steel **dies** are **hardened** by heating in a carbonizing box packed in charcoal and dipping face downward over a jet of brine. The jet is allowed to strike into the impression, thus freeing the face of steam and producing uniform hardness. After hardening, they are drawn in an oil bath to a temperature of 500 to 550 deg. fahr.

The forging production per pair of dies is largely affected by the size and shape of the impression, the material forged, the material in the dies, the quality of heating of stock to be forged, and the care exercised in use. It may vary from a few hundred pieces to 50,000 or more. A normal **life** for a pair **of dies** under average conditions may be 20,000 pieces.

BENDING, FORMING AND SHEARING MACHINES

Plate-straightening machines. In these, the plate or sheet is passed through a system of **rolls,** the lower row generally consisting of three rolls in stationary bearings with a common drive, and the upper row consisting of four adjustable rolls. These can usually all be adjusted in one operation, but in some cases the two outside ones must be independently adjusted. Work-supporting rolls are also usually provided. For **rolled sections** such as beams and angles, suitably grooved rolls are used.

The horse power required for plate-straightening machines is as follows:

Thickness of plate, in.	0.25	0.4	0.6	0.8	1.0	1.2	1.4	1.6
Width of plate, in.	48.0	52.0	60.0	72.0	88.0	102.0	120.0	140.0
Diameter of rolls, in.	5.0	8.0	10.0	12.0	13.0	14.0	15.0	16.0
Horse power (approx.)	6.0	8.0	12.0	20.0	30.0	55.0	90.0	130.0

Power required for angle-iron-straightening machines: For 4-in. angles, 12 h.p.; for 6-in., 18 h.p.; for 8-in., 25 h.p.

Power or hydraulic presses are used to straighten **large rolled sections.** The presses make from 20 to 30 strokes per min., and the amount of flexure is regulated by inserting wedges or pieces of flat iron. The beams are supported on rolls so they can be easily handled. The **power required for presses** of this kind is as follows:

Depth of girder, in.	4	6	8	10	12	16	20	24
Horse power (approx.)	3	5	7	11	13	19	23	35

Horizontal Plate-bending Machines consist of two stationary rolls and a third vertical adjustable upper roll which can be fitted obliquely for taper bending, and is held in bearings with spherical seats. The diameter of the rolls can be approximately determined from the equation $r^2 = bt$, in which r is the radius of the roll, b the width of the plate or sheet, and t its thickness, all in in.

The **power requirements** of horizontal plate- and sheet-bending machines are as follows:

Thickness of plate, in.	0.5	0.6	0.8	1	1.2
Horse power for plate 120 in. wide	10.0	12.0	18.0	27.0	40.0
Horse power for plate 240 in. wide	30.0	30.0	40.0	55.0	75.0

Vertical Plate-bending Machines have a hydraulically operated piston which moves an upper and a lower pair of rolls between inclined surfaces of the stationary upright and the cross head. The bending is done piece by piece against a second stationary upright. Heavy ship plates are rigidly clamped down and bent by a roll operated by two hydraulic pistons. For angular bends or for the production of warped surfaces, the pistons can be operated independently or together. In vertical machines, angles and other rolled shapes are bent between suitably shaped rolls. Pipes are filled with sand to prevent flattening when being bent. For some work, pipes are bent hot between suitable forms operated by hydraulic pressure.

Drawing Presses. Eccentric or crank **presses for rough punching and rough drawing** of comparatively short pieces are provided with tools to cut out or form in single or successive operations. Chain drawing machines **(draw benches)** are generally used to produce drawn pieces of considerable length. The **number of draws and** the graded **size of** the **tools** depend largely on the quality of the material. If d is the original diameter, and d_1 that after drawing, then, according to Musiol, $d_1/d = m$, in which m is a factor depending on the diameter, thickness and nature of the work. The average value of m for the first draw is 0.5 to 0.63, and for subsequent draws 0.65 to 0.85.

In making metal molding and parts for metal building trim and fireproof features, **draw frames** are largely used. Two **types of dies** are employed, the first being solid with an opening or openings, the final one giving the finished shape of the desired section. In the second form, hardened steel rolls are used, the number of sets depending upon the shape and size of the final section. These rolls are not driven by power but are free to turn in suitable bearings. The raw material is strip. It is customary to weld the ends of strips together, either electrically or by the oxy-acetylene process. In this way a strip of any length desired can be produced.

Otto S. Beyer (*Am. Mach.*, vol. 34, p. 447) gives the following formula for **determining the dimensions of drawn shells:** $h = D[1 + (d/D)^2]/4(d/D)$, in which D = diameter of the blank, d = shell diameter, and h = shell height—all in in.

Experience shows that the ratio (h/d) must not exceed 0.5 for the first operation with shells of steel, and when h approaches ¾ D, annealing becomes necessary for further operations. R. R. Pratt (*Am Mach.*, vol. 31, Part 2, p. 858) gives the smallest diam. of cup that can be drawn from a given soft-steel blank as equal to $D/1.9$, and for successive reductions, $D_1/1.28$.

Screw Presses. In the screw press the ram is forced downward by a steep-pitch-threaded spindle having on its upper end a heavy flywheel. The **effective power** is that due to the energy in the revolving parts (flywheel and spindle). The energy produced by the parts in downward motion (flywheel, spindle and ram) is relatively small, and can be disregarded. If I_f is the moment of inertia of the flywheel rim, I_s the moment of inertia of the spindle, v the angular velocity of both, and P the work done in stamping, then $P = \frac{1}{2}I_fv^2 + \frac{1}{2}I_sv^2$. The friction between the ram and the spindle and between the ram and its guides may be disregarded.

Hand-operated screw presses are used for stamping, embossing, lettering and forming on work requiring more power than can be easily developed in foot presses. The larger sizes are used for "hubbing" dies and punches. Some forms are provided with a lever and balls instead of a flywheel. In Europe, this type of press is frequently **power-driven** through a friction device acting on the flywheel.

The hand-operated machines are made in two types, the "arch," and "overhanging pattern." Commercial **sizes** are from 5 × 5 in. to 10 × 10 in. for the opening in the bed, and from 65 to 700 lb. for flywheel weight for the arch pattern. For the overhanging pattern, the bed opening ranges from 5 × 5 in. to 15 × 16 in., and the flywheel weight from 65 to 500 lb.

Hydraulic Presses using high pressures are **used to shape hollow objects,** as silverware, long tubular pieces, etc., **and for extruding metals.**

For hollow ware the work is placed in a die (or mold) and protected by packing (rubber, cement, putty, etc.) against the infiltration of water between it and the die. Both work and die are then introduced into the press cylinder and subjected to pressure, which forms the metal to the mold and makes it take the desired shape. The pressure required depends upon the elastic limit and yield point of the material, and may be as high as 120,000 lb. per sq. in.

Drop Presses are extensively **used in drawing and forming sheet-metal** articles, hardware, cutlery, silverware, etc., and for stamping and embossing thin sheet metal used in building construction. They are made **in sizes** having the following hammer weights: 50, 80, 120, 175, 225, 400, 600, 800, 1,000, 1,200 lb.

The **efficiency of drop presses** is given as 90 per cent. by R. H. Thurston (*Trans. A. S. M. E.*, vol. 5, p. 53), and of **drop-hammers** as 70 per cent. by A. W. Moseley and J. L. Bacon (*Trans. A. S. M. E.*, vol. 27, p. 605).

Spinning Lathes perform operations similar to drawing, that is, the forming of sheet metal cold, starting either from a flat blank or a shell that has been drawn in a press. They are used for seamless-drawn tin and sheet-iron ware, and hollow objects of brass and aluminum, as automobile horns, phonograph horns, and for some silversmithing work.

The **work** is formed into a mold or metal or wooden chuck in inside spinning, or around shaping rolls in outside spinning. Hand **tools** and burnishing rolls are used to press and draw the metal into shape. Turning, beading and wiring are also done on these machines in the finishing of hollow ware. They are made commercially in the following **sizes:**

Swing over bed, in.	16	20	24	30	38
Length of bed, in.	42	60	70	90	132

Punch Presses and Shears. In subsequent paragraphs the following notation is used: t = thickness of sheet, in.; d = diam. of punched hole, in.;

d_1 = diam. of punch, in.; d_2 = diam. of hole in die, in.; P = resistance at cutting edge, lb.; s = shearing stress, lb. per sq. in.; W = approximately $1.7s$.; h = stroke of punch or shear blade, in.; u = cutting speed, ft. per min.

The following tabulation gives the values of s and $1.7s$ for common sheet metals:

Metal	s Lb. per sq. in.	$1.7s(= W)$ Lb. per sq. in.
Sheet steel, soft	57,000	85,000 to 100,000
Wrought iron	34,000 to 50,000	57,000 to 85,000
Wrought iron heated to a dark red	11,000 to 14,000	17,000 to 28,500
Sheet copper	28,500 to 35,500	35,500 to 57,000
Sheet zinc	8,500 to 12,800	12,800 to 21,500
Tin	1,850 to 2,850	2,850 to 4,250
Lead	1,140 to 2,560	2,130 to 3,400

To obtain **smoothly punched holes**, make $d_1 = d - 0.005t$, and $d_2 = d + 0.005t$; or $d_1 = d$, and $d_2 = d + 0.01t$. To avoid **burrs**, the clearance between punch and die must be kept down to a small amount. Both punch and die are slightly tapered away from the cutting edge to reduce friction. The **maximum resistance** in lb. at the cutting edge of the punch is $P = Wd\pi t$. The **stroke** h is generally taken between $2t$ and $3t$, and the **cutting speed** u from 3 to 4 ft. per min.

The **horse power required to punch** is $N = N_0 + N_1$, where N = total h.p., N_0 = friction h.p. of machine, and N_1 = h.p. used in punching the metal. For thickness of sheet t = 0.16 to 2.2 in., Hartig gives for wrought iron $N_1 = 0.513fF$, $f = 0.167 + 0.245t$, where F = area of sheared surface produced per hour, in sq. ft. (= $1.31\ ndt$; d = diam. of punch in in. and n = number of holes punched per min.).

Thickness of plate, in.	0.40	0.80	1.20	1.60
No. of holes punched per min.	10.0	9.2	8.3	7.5
Friction h.p. of machine = N_0	0.16	0.32	0.55	0.82
H.p. per sq. ft. of surface sheared per hr. (= f)	0.265	0.363	0.460	0.558

Plate Shears have the angle of the front cutting edge B about 75 deg. (see Fig. 1), the clearance angle Y about 2 deg., and the angle x between the edges of the shear blades from 5 to 10 deg. For shears with parallel blade edges, the **maximum pressure required** is $P = Wbt$. For shear blades inclined to each other, $P = 0.225Wt^2/\tan x$. For x = 9 deg., $P = 1.4Wt^2$. The **cutting speed** varies from 3 to 6 ft. per min.

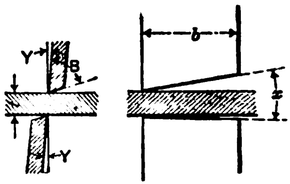

FIG. 1.—Angles of Shear Blades.

Power Required for Punch Presses, straight side, eccentric type:

Thickness of plate, in.	0.32	0.4	0.6	0.8	1.0	1.2	1.6
Diam. of hole, in.	0.65	0.8	0.88	1.04	1.2	1.4	1.6
Approximate horse power	3.0	4.0	7.0	10.0	14.0	25.0	40.0

Circular Shears are used for cutting sheets and plates up to ¼ in. in thickness. The diam. of the blades should $\geq$ 70 times the thickness of the sheet. Circumferential **cutting speed** is from 90 to 180 ft. per min. **Power requirements** are as follows:

Thickness of plate, in.	0.1	0.15	0.3
Gap or opening of throat, in.	12.0	20.0	28.0
Approximate horse power	3.0	5.0	8.0

These machines are made in a wide variety of styles and sizes for all classes of work to be punched and sheared. The tools are also made in great variety of form, and the output is dependent upon so many factors that it is impossible to generalise in regard to it.

WELDING MACHINES AND APPARATUS

Welding processes may be divided into pressure welding and casting welding. In the first category is electric resistance welding; in the second are electric arc welding and all of the gas or flame welding processes.

Electric Welding

Resistance Electric Welding Machines. Resistance welding (Thomson process) involves the passage of an electric current through the abutting parts of the pieces of metal to be welded. Heat is generated at the points of contact, where the greatest resistance to the flow of the current is encountered. Meanwhile, pressure is applied to force the pieces together and form the weld.

Various forms of machines are built, the main element in all being a transformer provided with a pair of clamps (each insulated from the other) for holding the pieces to be welded, and a mechanical, hydraulic or other device to force the abutting ends together. In some forms there are additional devices (striking dies) to shape the weld after it has been formed and to remove the fin. The pieces of work begin to heat at the interior, thereby tending to expel impurities from the weld. No current is used except when heating is being done.

In range these machines have a **capacity** from small wire to sections 3 in. square. A reactive coil is used to control the current for varying sections of stock. In the smaller types pressure is applied and the current shut off automatically. In all but the smaller types a circulation of water is maintained in the secondary coil of the transformer. Only **alternating electric current is used**, taken from a single phase of constant potential and usually from 40 to 60 cycles and 100 to 500 volts.

The process and machines are particularly **adapted to butt welding** of small and similar sections, although by no means confined to these. Common applications are the welding of metal tires, hoops, bales, parts of the running gear of wagons, single-pointed cutting tools, automobile parts, parts used in street railway construction, and a wide variety of products made from wire, such as fencing, screens, chain, and the like. Machines have been made for welding pipe and tubular sections such as house hot-water heaters.

The horse power and time required to make a given weld vary nearly directly as the cross-sectional area. Within certain limits, the greater the power the less the time, and *vice versa*. A ¾-in. round steel bar can be welded in 15 sec. using 15 kw. of current. The same bar can be welded in 6 sec. using 23 kw.

A variety of metals can be welded either to themselves or in many cases to other metals. In practice, iron, steel and copper are the most commonly worked upon. Copper requires more power and less time to weld a given section than iron or steel.

Table 3 gives data for power consumption and seconds per weld for iron and steel rods, while the following values, from German sources, are for copper:

Area of section, sq. in.	0.031	0.062	0.124	0.233	0.388	0.775
Power required, kw	1.5	3.0	7.5	15.0	40.0	60.0

Some of the latest applications of the process are in welding platinum points on steel or brass pins, and welding halves of casters, handles, etc., in semi-automatic machines to make the whole article. Many manufacturers of hollow ware attach handles or bail ears by "spot" welding.

Another method of incandescent welding is that of La Grange and Hoho, in which the bar to be heated is attached to the negative pole of an electric circuit and then plunged into a tank containing acidulated water and a metal plate connected to the positive pole of the circuit. Strictly speaking, it is a method of heating preparatory to welding, for the welding proper must be done by mechanical means similar to those employed for welding pieces that are fire-heated.

Table 3. Power and Time Required for Electric Butt-welding Iron or Steel Rods

(Thomson Electric Welding Co.)

Diam. of rod, in.	Kilo-watts required	Seconds per weld	Approximate kw-hr. for 1000 welds	Diam. of rod, in.	Kilo-watts required	Seconds per weld	Approximate kw-hr. for 1000 welds
1/4	4	2	2	1	20	20	113
3/8	6	3	5	1 1/8	25	24	167
1/2	9	6	15	1 1/4	30	33	275
5/8	12	10	30	1 1/2	38	40	422
3/4	15	15	65	1 3/4	48	48	640
7/8	18	18	90	2	60	60	1000

Electric Arc Welding. There are **three** different **processes** of electric arc welding, namely, the Zerener, in which an arc is drawn between two carbon electrodes; the Bernardos, where an arc is drawn between the work (metal) and one carbon electrode; and the Slavianoff, in which an arc is drawn between the work (metal) and one metal electrode.

These processes are made **use** of in steel foundries to fill blowholes and to weld on projections which were improperly formed by failure of the metal to fill the mold. Also to cut holes in metal, to cut bars, plates, or castings in two, to cut sink heads from steel castings, and for repair work on machine parts, particularly locomotives.

In the **Zerener process** an arc is first drawn between two carbons by bringing them into contact with each other and then separating them a given distance. The arc is then blown upon the metal by means of an electromagnet. As a result, the metal in the vicinity of the point of the arc is raised to a welding temperature. This apparatus has been called the **electric blowpipe**.

The metal to be welded is placed so that the arc can be readily directed upon it, the blowpipe being suspended from a chain or rope so that it may be moved as desired. Because of the difficulty in obtaining a close regulation of the arc—as well as of the construction of the apparatus, which does not lend itself conveniently to handling large currents—the Zerener process is **limited in its application** to a narrow range of small, rough work such as the welding of small steel and brass castings and wrought-iron plates, tubes and tanks.

In the **Bernardos process** the metal to be welded is made one terminal of a direct-current circuit, the other being formed by a carbon or sometimes a metallic electrode. The carbon or metallic electrode is brought into contact with the metal, thus closing the electric circuit. It is then instantly pulled away and an arc is thus drawn between the terminals. The temperature reached by the arc is between 5500 and 7000 deg. fahr. and the metal may be either entirely melted away, molded into a different shape, or fused to another piece of metal.

In spite of the best of care, hard welds are at times produced by the Bernardos and Zerener processes, due to the entrance of the electrodes. The **Slavianoff process** was developed in an endeavor to overcome this difficulty. It is a modification of the Bernardos process, in which an electrode of the same metal as the one being welded is substituted for the carbon electrode. In operating, the metal bar melts and drops on the place to be welded. This process is particularly **suitable for repairing broken** pieces of **cast and wrought iron.** For welding iron and steel, the electrode should be of the best grade of soft iron wire, not larger than 3/16 to 1/4 in. in diam. and about 1 ft. long. Moreover, it should be covered with a flux, applied in paste form and allowed to dry on before use. A **flux** originated by the Westinghouse Elec. & Mfg. Co. and used with good results particularly on cast and malleable irons, has the following percentage composition: Oxide of copper (CuO), 5; oxide of manganese (MnO_2), 15; oxide of iron (Fe_2O_3), 30; borax ($Na_2B_4O_7 + 5H_2O$), 50. The ingredients should be mixed, ground to pass through an 80-mesh sieve, and during welding applied dry. Direct current of about 130 amp., 24 to 26 volts across the arc, is satisfactory. The arc itself is short, not over 1/8 to 3/16 in. long.

In all of these processes **protective coverings** must be provided **for the operator,** as the light from the arc produces severe burns on exposed skin. This light is peculiarly injurious to the eyes.

Data on variations in voltage and current for arcs of different lengths, comparison of fire-welded and electric-welded bars and labor costs of blacksmith-welded versus arc-welded rings are given in Tables 4–6 (from article by C. B. Auel, *Am. Mach.*, Mar. 16, 1911, p. 479).

Table 4. Variations of Voltage and Current for Arcs of Different Lengths

Length of arc, in.	6	5	4	3	2
Volts across arc, including carbon	101	98	93	86	80
Current, in amperes	300	350	400	605	750
Size of carbon, in.	1×6½	....	....	....	....

Table 5. Results of Tests of Fire-welded and Electric-welded Bars

Brand and size F. = fire-welded E. = electric-welded Brand	Inches		Ultimate tensile strength per sq. in., T, tons	Contraction of area at fracture, C, per cent.	Extension in 10 in., per cent.	Ratio of weld to solid, per cent.	Figure of merit ($T \times C$) F.	E.
Lowmoor iron	2 × 3/16	F.	20.3	15.2	7.3	77.9	308	
		E.	21.1	17.3	7.3	81.1		365
Lowmoor iron	2 × 5/16	F.	21.5	22.3	11.3	90.7	479	
		E.	21.8	20.7	9.7	91.8		451
Netherton best iron	2 × 1/4	F.	18.4	10.1	3.4	84.4	185	
		E.	20.1	10.8	4.5	92.0		217

		E.	22.3	18.4	3.8	73.6		410
Parkgate steel	2 × 1/2	F.	20.4	15.9	8.1	82.3	324	
		E.	21.0	15.4	7.3	86.4		323
							1490	1766

Ratio of electric-welded to fire-welded bars = 1766/1490 = 118.5 per cent.

Table 6. Labor Costs of Blacksmith-welded vs. Arc-welded Rings

Section of ring, in.	1 × 1½	1¼ × 1½	1½ × 2	1¾ × 2½	2 × 6
Cost, smith-welded	\$0.59	0.66	1.13	1.25	3.05
Cost, arc-welded	\$0.51	0.30	0.45	0.45	0.85

With the **Bernardos process** a drilled hole 1¼ in. in diam., 2 in. deep in an axle cap was filled in 56 sec. A sink head was cut from an axle cap in 4 min. 45 sec.; cross-section cut, 2¼ × 6 in. A hole 1¾ in. in diam. by 1½ in. deep was burned in a wrought-iron plate in 3 min. 30 sec. (including 45 sec. used in reversing plate). Size of carbon in all three cases 1½ × 6 in.

The peculiar **field of arc welding,** according to C. B. Auel, is work of the rougher kind where appearance, finish and strength are not of paramount importance. Material of the same kind as the metal to be filled is usually used for **filling.** For wrought iron or steel this may be soft iron rod, punched iron scrap or broken parts of steel castings. For cast and malleable iron it may be soft iron rod, punched iron scrap, copper or special cast iron high in silicon. For brass it may be lead and zinc rods or castings of the same material.

Precautions to be Observed in Making Electric Arc Welds. The positive terminal should always be fastened to the metal to be welded; the negative terminal to the carbon electrode. The arc should be as long as possible. The weld should be made with the fewest possible applications of the arc. The arc should be given a rotary motion and should have as large an area as possible instead of being concentrated on one spot. The metal to be welded should be free from dirt and slag before commencing to weld. A suitable flux should be used. Vigorous hammering should accompany the making of each weld.

Gas Welding

Oxy-hydrogen Process. This is the older of the gas-welding processes. It makes use of a blowpipe flame from the combustion of oxygen and hydrogen gases, a temperature of about 4000 deg. fahr. being reached. Hydrogen must be in excess to avoid oxidizing the metal. The usual ratio is 4 volumes of hydrogen to 1 of oxygen. The flame has a great power of penetration and for this reason is capable of cutting considerable thicknesses of steel and wrought iron. It is especially **useful in welding thin sections** and metals of low fusibility. It has the advantage over processes giving a higher flame temperature that less skill is required in handling.

The essentials of the **apparatus** are a torch for producing the flame with suitable safeguards against back-firing. In some types the speed of flow of the gases at the orifice is greater than the velocity of flame propagation; in others, screens are introduced similar to the screens of miners' lamps. Torches with different-sized openings and kinds of tips are used for different work. Gas is supplied either from metal bottles or from generating apparatus, usually the former. Connection from the bottles to the torches is made by means of flexible hose so that the torches can be easily moved to the work. In addition, clamping devices are provided to hold the work.

Oxy-acetylene Process. In oxy-acetylene welding apparatus the flame, which has an intensely high temperature (6300 deg. fahr. maximum), is obtained by the combustion of acetylene and oxygen. There are two **types of torches** in use, usually spoken of as low-pressure and high-pressure, or better, as injector and pressure. In the first the oxygen is admitted under pressure and draws in the acetylene after the general principle of the steam injector. An objection to this form is the difficulty of maintaining the proper relative proportions of the two gases. In the pressure-type torch both gases are introduced under pressure, and the proportion of the mixture can be varied by varying the pressure of either.

As a rule, the tips of torches are inclined at an angle of from 45 to 60 deg. with the frame. In the injector type the **proportion of oxygen used to acetylene** is 1.5 or 1.7 to 1. The pressure type only requires 1.28 oxygen to 1 of acetylene.

Gas welding has found its most general **application** in working thin metal, as parts of steel railway cars, repairs on railway rolling stock, and the cutting up of large masses of steel, as the wrecked frames of buildings, bridges, and the like.

Metal thicker than ⅛ in. to be welded should be joined by **scarfing** or chamfering to give a V-groove in which to work. This permits the flame to penetrate to the bottom of the joint. It is necessary to add metal to fill, except in the case of very thin sheets which are not scarfed. This metal is melted in from a wire or strip usually of the same material as those being joined. In **making the weld,** after the metal contiguous to the joint is in a running condition, molten metal is added drop by drop until the groove is filled, and, where allowable, more is added to make the joint a little thicker and stronger than the normal section. If dissimilar metals are joined, it is usual to use a welding metal of the same material as the one which melts at the lower temperature.

Long seams are usually spot-welded or tacked at intervals of 6 or 12 in. Care must be taken to permit the work to adjust itself for expansion and contraction during the process of heating and welding. Iron castings are pre-heated in a forge or other fire before welding. The temperature of heating should not exceed 500 deg. fahr.

The flame processes of welding are especially valuable for metal of from No. 20 gage up to 5/8 in. thick. Plates up to 1/8 in. are butt-welded.

The process is also of value in **cutting**. Hydrogen gas torches have been used to cut plates up to 24 in. thick. Oxy-acetylene torches reach their limit at 12 to 15 in. **Acetylene** develops more heat, does the work more quietly, is cheaper and **more suitable for thicker articles than hydrogen.** It tends, however, to increase the amount of carbon in the weld.

Thus far but little has been done commercially in developing gas-flame-welding machines. A few have been made for cutting circular sections, consisting of mechanism to guide the torch in a circular path. Others have been developed to cut pipe, and still others resembling a radial drilling machine in arrangement for making long cuts or welding long seams.

The following **labor and material costs** for common locomotive repairs are given by H. W. Jacobs (*Am. Mach.*, Nov. 15, 1911, p. 913): Building up piston rods at cross-head fits, \$3.00; building up worn places on links, \$4.02; building up reverse lever, \$2.25; putting two teeth in reverse lever latch, \$0.71; putting two teeth in quadrant; \$0.71; repairing cracked cylinder heads, \$2.55.

Herbert L. Whittemore, in *Bulletin* No. 45, Engineering Experiment Station, University of Illinois, gives results of an extensive series of **tests on oxy-acetylene welds.** The following information is derived from that source.

Gas Consumption. Table 7 gives sizes, capacities and approximate gas consumption for Fouché or injector-type torches or blowpipes for the welding of steel plates. For copper plates, larger blowpipes are required for corresponding thicknesses.

Table 7. Sizes, Capacities and Approximate Gas Consumption of Fouché Blowpipes

Blowpipe No.	2	3	4	5	6	7	8	10	12	15
Thickness of plate, in.	1/32	3/64	3/32	1/8	3/16	1/4	3/8	1/2	5/8	3/4
Oxygen, cu. ft. per hr.	2	4	6	10	16	25	36	45	65	100
Acetylene, cu. ft. per hr.	1½	2½	3¾	6	10	15	22	28	40	60

Creep. The satisfactory allowance for "creep," or the drawing together of the edges as the metal expands, was found to be 2.2 per cent. Some blowpipe manufacturers recommend 2.5 per cent. If the allowance is too small the thin edges of the plate crowd together more or less with no bad results, but if the edges fail to meet it is almost impossible to weld at a satisfactory rate.

Strength of Welds. Strength tests on welds show that **85 per cent. efficiency** is about as high as can be expected from a weld of the same thickness as the plate. **Forging after welding increases** the **strength** apparently about 10 per cent. The **welding rate** is nearly constant at 17.5 sq. in. of welded section per hr.

Cost of Welding. With acetylene at 1 cent per cu. ft., oxygen at 3 cents per cu. ft., and labor at 30 cents per hour, the cost for beveled plates is about 25 cents per cu. in. of filler. The cost of operation rises very rapidly as the thickness of the plate increases, reaching possibly \$4 per hour for gas and labor on plates 3/4 in. thick.

Welding with Water Gas. This method is used especially for **welding thick plates** which cannot be easily heated in an open fire, where the heating is from only one side. If the sections are narrow, flame can be applied from both sides. Water gas for welding has a composition of 3 per cent. CO_2, 44 per cent. CO, 50 per cent. H and 3 per cent. N. The temperature of the flame is 3300 deg. fahr. The mixture takes place in a proportion of about 5 volumes of air to 2 of gas. For producing a thin flame, both gas and air are compressed.

Aluminothermic Welding

Thermit Welding. Very large sections are successfully welded by the thermit process, which employs a compound consisting of finely powdered aluminum and oxide of iron mixed in such proportions and manner as to give the reaction $Fe_2O_3 + 2Al = Al_2O_3 + 2Fe$. The temperature generated by this reaction is estimated at 5400 deg. fahr.

There are two general **methods** by which thermit is used. The first is designated **butt-welding** and is **used** chiefly **on pipes, tubes,** and **small rods.** The ends of the pieces to be united are closely fitted and fastened in contact by means of suitable clamps. The joint is then surrounded with a casting mold designed to hold just enough of the molten mass to bring the parts to be united to a welding heat. The necessary amount of thermit is then ignited in a small, flat-bottomed crucible and as soon as the reaction is over the contents of the crucible are poured into the mold. The aluminum oxide, on account of its low specific gravity, flows first, and coming in contact with the cold iron adheres to it. This forms a refractory coating which prevents the flowing molten steel from adhering to the mold or parts to be welded. As soon as the molten mass has been in the mold long enough to allow heat to penetrate to the parts to be welded (a period determined by experience), the pieces are forced together by the clamps and the weld completed. Rods up to 2 in. and pipe up to 6 in. in diam. are welded by this method.

In the second method, called **intermediate welding,** the parts to be united are not brought close together nor are they fitted in any way. Instead, a space varying from 1 to 2 in. is provided to permit a free flow of the molten thermit between the ends. After the parts have been thoroughly cleaned of grease, dust, etc., they are surrounded by a refractory mold similar to that used in making steel castings. The mold is provided with a pouring gate and riser, and also an opening at the bottom used for preheating.

If the parts to be welded are of a uniform section, the molds are made from wooden patterns as in standard foundry practice. If the parts are irregular, the wax method is used. In this the space between the parts to be united is filled with wax and a reinforcing collar is formed of the same material. As soon as the wax is hard, the parts are surrounded with a flask or mold box and the mold rammed in place, wooden patterns being used for the risers and gates. Heat is then applied through the preheating gate at the lowest part of the mold. This melts the wax, which flows out and leaves a cavity of the dimension desired. The mold is thoroughly dried and the ends to be united are brought to a bright red heat by the continuation of the preheating. The amount of thermit necessary to fill such a mold is found by weighing the wax and multiplying this weight by 32. A so-called automatic crucible is placed over the mold and into it are poured the thermit and filling metal. The latter consists of carbon-steel punchings, nickel, chromium, manganese, etc., to give a resulting steel of approximately the same analysis as the parts to be welded. This mixture after being melted is tipped into the mold. In making welds in this manner, precautions have to be taken to provide for the contraction of the metal.

This method has been **used for welding engine frames, crank shafts,** rudder posts of vessels, **and large castings** of every description. It has been extensively used for filling steel rails and for repairs which have to be done rapidly or in place. Table 9 gives the results of physical tests of thermit welds.

Table 9. Bending Tests of Thermit-welded Bars

Description	Diam. of bar, in.	Span, ft.	Total load, tons	Angle bent through, deg.	Effects
Solid bar	2	15	10.18	180	Uncracked.
Thermit-welded bar, bulb turned off	2	15	10.09	46	Broken at weld.
Thermit-welded bar, bulb left on	2	15	17.30	125	Bent as far as practicable. Uncracked.

Soldering and Brazing

Soldering is the operation of uniting two pieces of metal with a third soft metal that is applied in a molten state. Solders are alloys of lead and tin. W. F. Brannt (Metal Workers' Handbook) gives the following list of solders with their melting points (see also p. 552):

Composition	Tin	1	1	1	1	1	1	1½	2	3	4	5	6
	Lead	25	10	5	3	2	1	1	1	1	1	1	1
Melting point, deg. fahr.		558	541	511	482	411	370	334	340	356	365	378	380

The parts to be soldered are brought in contact and the melted solder is flowed over and into the joint. On small pieces the solder is melted by an "iron" which is copper-tipped. Heat may be from a small forge or furnace or from electric current. Large pieces are frequently dipped in a bath of melted solder. This is true of some parts of electrical machinery, tin cans, etc.

The common **fluxes** used to prevent the oxidisation of the metals are borax, cream of tartar, sal ammoniac, resin, chloride of zinc and hydrochloric acid. There are many soldering pastes and solutions on the market.

Brazing is the uniting of two pieces of metal by a thin film of soft brass. **Brazing alloys** have the following composition (see also p. 552):

	Tin	Copper	Zinc
Hard	0	3	1
Medium	0	1	1
Soft	1	4	3

There are numerous brazing alloys or spelters on the market. The common **fluxes** are borax and boracic acid. The parts to be brazed are brought into contact, dusted with borax or coated with some other flux and the spelter is melted into the joint. On large quantities of work **immersion brazing** is used. This consists in dipping the parts to be brazed into a tank of molten spelter after fitting the parts together, brightening them, clamping or wiring them securely and coating with flux.

METAL-CUTTING MACHINES

The most important machines used in making machine parts are included in the chip-removing group. The following classification is that adopted by the National Machine Tool Builders' Association:

Boring machines	Grinding machines	Screw machines
Boring and turning mills	Milling machines	Shaping machines
Broaching machines	Hobbing machines	Slotting machines
Cutting-off machines	Planing machines	Tapping machines
Drilling machines	Key-seating machines	Turning machines (Lathes)
Gear-cutting machines	Rack-cutting machines	

A number of these names are different from those in common use in technical literature and in shops. Throughout this section the nomenclature used is that of the *American Machinist*.

Standardization of Machine Parts

A movement is now under way in the National Machine Tool Builders' Association to standardize machine parts. The requirements as stated by the author before the Convention of the Association in October, 1911, are as follows:

1. Standardize corresponding designations and capacities and establish a method of power rating. 2. Standardize devices for holding cutting tools.

3. Standardize devices for holding work and fixtures. 4. Standardize operating movements. 5. Standardize parts concerned in the setting up of machines with reference to the permanent shop equipment. 6. Accept the geometric progression as a fundamental requisite in designing feeds and speeds.

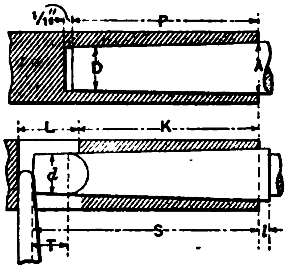

FIG. 2.—Machine Taper.

A few **standards** are **already in use** to a greater or less degree. There are six spindle and shank **tapers**: Morse, Brown & Sharpe, Jarno, Sellers, Reed and the metric. The designating numbers and corresponding dimensions of these tapers are given in Tables 10–15.

The **Morse taper** is largely used for drill shanks, taper holes in drilling-machine spindles, collets, and other machine parts arranged to take drills, and for the shanks of lathe centers. The **Brown & Sharpe** taper is commonly used in milling-machine spindles. The **Jarno** taper is used by a few firms in lathe and small drilling-machine spindles. The **Sellers** taper is used in lathes and drilling and boring machines made by the firm of Wm. Sellers & Co., Inc., and some others. A spline is provided in connection with each taper, as shown in Fig. 3. The **Reed** tapers are used in lathe spindles. The taper per foot is the same as that of the Jarno, but the diameters are different and in most cases the lengths are somewhat less. The **Metric** tapers are used in Europe.

Proportions of T-slots.

Table 17. Proportions of T-slots, Wm. Sellers & Co.
(All dimensions in inches)

d	A	B	C	D	E	F	G	H
1/2	9/16	3/4	1/2	1	5/8	1 1/16	9/16	1
5/8	11/16	15/16	5/8	1 3/16	3/4	1 5/16	11/16	1 3/16
3/4	13/16	1 1/8	3/4	1 3/8	7/8	1 9/16	7/8	1 7/16
7/8	15/16	1 5/16	7/8	1 9/16	1	1 13/16	1	1 5/8
1	1 1/16	1 1/2	1	1 3/4	1 1/8	2	1 1/8	1 13/16
1 1/8	1 3/16	1 11/16	1 1/8	1 15/16	1 1/4	2 1/4	1 1/4	2
1 1/4	1 5/16	1 7/8	1 1/4	2 1/8	1 3/8	2 1/2	1 3/8	2 3/16
1 3/8	1 7/16	2 1/16	1 3/8	2 5/16	1 1/2	2 3/4	1 1/2	2 3/8

For $d = \frac{1}{2}$ and $\frac{5}{8}$ in., $X = d + \frac{1}{16}$ in. and $Y = 1.5d + \frac{1}{4}$ in.
For other values of d, $X = d + \frac{1}{8}$ in. and $Y = 1.5d + \frac{5}{16}$ in.

During the last few years **geometrical progression** has been largely used **in designing** machine-tool **feeds and speeds.** No ratios have been used to a sufficient extent to consider them as standard. Carl G. Barth recommends a leading ratio of 2 and a secondary ratio of 1.189, equal to $\sqrt[4]{2}$. (See *Am. Mach.*, vol. 36, p. 52.)

Electric Motors for Machine Tools

The National Machine Tool Builders' Association has adopted (1910) the following recommendations for the **standardization of motor drives** for machine tools:

1. Horse Power. The following ten sizes of motors are considered sufficient for practically all requirements of machine tools: 1, 1½ (for direct current only), 2, 3, 5, 7½, 10, 15, 20, and 25 h. p.

2. Voltage: For direct-current motors, 115 and 230 volts; for alternating-current motors, 110 and 220 volts.

3. Horse-power Ratings:

(a) Where approximately standard load conditions exist, motors are to be given a continuous constant horse-power rating.

(b) For variable-speed motors used for intermittent service the standard two-hour continuous-duty rating is to be used for ordinary shop conditions.

4. Direct-current Motors. Variable-speed motors are to be standardized for two ranges, namely, 2 to 1 and 3 to 1.

5. Speeds. The following table includes the recommended speeds for variable-speed direct-current motors:

Horse Power	Speed Ratio 2 : 1	Speed Ratio 3 : 1	Horse Power	Speed Ratio 2 : 1	Speed Ratio 3 : 1
1	1500–750	1500–500	7½	1200–600	1200–400
1½	1500–750	1500–500	10	1200–600	1200–400
2	1500–750	1500–500	15	1200–600	1200–400
3	1500–750	1500–500	20	900–450	900–300
5	1200–600	1200–400	25	900–450	900–300

6. Alternating-current Motors. The following table gives the recommended speeds for polyphase 60-cycle alternating-current motors:

Horse power	Speeds	Horse power	Speeds	Horse power	Speeds
1	1800 and 1200	5	1200	15	900 and 600
2	1200	7½	1200 and 900	20	900 and 600
3	1200	10	1200 and 600	25	900 and 600

7. Alternating-current Motors. In considering constant-speed alternating-current motors, 60 cycles is to be used as the basis.

Methods of Applying Motors to Machine Tools. A. L. DeLeeuw (*Trans. A. S. M. E.*, vol. 32, p. 137) outlines the method of applying motors to machine tools as follows:

Bench Lathes to be driven from a countershaft attached to the bench and driven in its turn by motor. Any type of motor may be used except one series-wound or heavily compounded.

Speed Lathes to be driven from a countershaft located upon each by a direct-connected motor. In the latter case a variable-speed machine is to be preferred.

Engine Lathes. Both variable-speed and constant-speed motors are used, although in general engine lathes are group-driven. Where individual motors are used, each is placed on a bracket attached to the lathe and connected with a geared or chain drive.

Heavy Engine Lathes, Forging Lathes, Etc., to be driven by direct-connected motors. The type should be direct-current. The position of the motor should be low to reduce vibrations in its support. The output of these lathes may be increased from 20 to 25 per cent. by motor drive.

Axle Lathes, Wheel Lathes and Driving-wheel Lathes, to be driven by direct-current motors.

Chucking Lathes, in general, not to be motor-driven. If motors are used they should be variable-speed.

Automatic Screw Machines. Small machines to be group-driven; the larger preferably driven by variable-speed motors.

Sensitive Drilling Machines, in general, should not be motor-driven. However, if machine is placed in an isolated location, a motor may be directly applied to the machine itself or the machine may be driven from a motor on the floor through a countershaft.

Vertical and Radial Drilling Machines. In general, these machines are group-driven unless set up in an isolated location. If motor-driven, the variable-speed type should be selected. The motor may be direct-connected to the machine itself or set up to drive the machine countershaft.

Boring Machines. If used for specialized work a belt drive is preferred. If used for a variety of operations, motor drive from a variable-speed motor is of value.

Grinders to be driven by constant-speed motor belted to the regular machine countershaft.

Planers. Small planers, particularly if set up under a crane, to be driven by variable-speed motors. A recent development is the reversing-motor planer drive which is now being extensively tested and promises success.

Shapers, Slotters, Etc. In general, these machines are not to be motor-driven.

Milling Machines, Knee-and-Column Type. In the larger sizes to be driven by variable-speed motors, especially if used on gang work.

Milling Machines, Planer Type. To be motor-driven. Either the constant-speed or variable-speed type is successful.

Table 18, prepared by the Westinghouse Electric & Mfg. Company gives the horse power recommended for machine-tool motors in average practice.

Table 18. Sizes of Motors for Driving Machine Tools

CLASSES OF MOTORS REFERRED TO IN TABLE

(*A*) Adjustable-speed shunt wound direct-current motor, wherever a number of speeds are essential.

(*B*) Constant-speed shunt-wound direct-current motor, where the speeds are obtainable by a gear box or cone-pulley arrangement or where only one speed is required.

(*C*) Squirrel-cage induction motor, where direct current is not available. A gear box or cone-pulley arrangement must be used to obtain different speeds.

Bolt and Nut Machinery

BOLT CUTTER (*A*, *B* OR *C*)

	Size, in.	H.p.
Single	1, 1¼, 1½	1-2
	1¾, 2	2-3
	2¼, 3½	3-5
	4, 6	5-7½
Double	1, 1½	2-3
	2, 2½	3-5
Triple	1, 1½, 2	3-7½

BOLT POINTERS (*B* OR *C*)

	1¼, 2½	1-2

NUT TAPPERS (*A*, *B* OR *C*)

Four-spindle	1, 2	3
Six-spindle	2	3
Ten-spindle	2	5

NUT FACING (*B* OR *C*)

	1, 2	2-3

BOLT HEADING, UPSETTING AND FORGING (*A**, *B*† OR *C*‡)

Size, in.	H.p.	Size, in.	H.p.
¾-1½	5-7½	2½-3	20-25
1½-2	10-15	4 -6	30-40

* Speed variation is sometimes desired when different sizes of bolts are headed on the same machine. † Compound-wound direct-current motor. ‡ Wound secondary or squirrel-cage motor with approximately 10 per cent. slip.

Bulldozers or Forming or Bending Machines (*B** or *C*†)

Width, in.	Head movement, in.	H.p.
29	14	5
34	16	7½
39	16	10
45	18	15
63	20	20

* Compound-wound motor. † Wound secondary or squirrel-cage motor with approximately 10 per cent. slip.

Drilling and Boring Machines (*A*, *B* or *C*)

	H.p.
Sensitive drills up to ½ in	¼-¾
Upright drills, 12-20 in.	1
Upright drills, 24-28 in.	2
Upright drills, 30-32 in.	3
Upright drills, 36-40 in.	5
Upright drills, 50-60 in.	5 -7½

Radial drills	HORSE POWER Heavy	HORSE POWER Avg.
3-ft. arm	3	1-2
4-ft. arm	5-7½	2-3
5, 6 and 7-ft. arm	5-7½	3-5
8, 9 and 10-ft. arm	7½-10	5-7½

Multiple Spindle Drills (*A*, *B* or *C*)

Size of drills, in.	Number of spindles, up to	H.p.
1/32-1/4	6-10	3
1/16-3/8	10	5
3/16-1/2	10	7½
1/4 -3/4	10	10
3/8 -1	10	10-15
2	4	7½
2	6	10
2	8	15

Boring and Turning Mills (*A*, *B*, or *C*)

Size	Horse power	
	Average	Heavy
37-42 in.	5 - 7½	7½-10
50 in.	7½	7½-10
60-84 in.	7½-10	10 -15
7- 9 ft.	10 -15	....
10-12 ft.	10 -15	30 -40
14-16 ft.	15 -20	....
16-25 ft.	20 -25	....

Cylinder Boring Machines (*A*, *B* or *C*)

Diam. of spindle, in.	Max. boring diam, in.	H.p.
4	20	7½
6	30	10
8	40	15

Pipe-threading and Cutting-off Machines (*A*, *B* or *C*)

Size pipe, in.	H.p.	Size pipe, in.	H.p.
1/4-2	2	3-10	5
1/2-3	3	4-12	5
1 -4	3	8-18	7½
1¼-6	3-5	24	10
2 -8	3-5	....	....

Planers (*A**, *B** or *C*)

Width, in.†	H.p.	Width, in.†	H.p.
22	3	48	15-20
24	3-5	54	20-25
27	3-5	60	20-25
30	5-7½	72	25-30
36	10-15	84	30
42	15-20	100	40

Normal length of bed in ft. is about 1/4 the width in inches.

*Compound-wound motor. † Distance under rail = width.

Buffing Lathes (*B* or *C*)

Diam. of wheels (2), in.	H.p.	Notes
6	1/4-1/2	For brass tubing and other special work use about double these values.
10	1-2

PLATE SHEARS (*B** or *C*†)

Size of metal cut, in.	Cuts per min.	Length of stroke, in.	H.p.
⅜ × 24	35	3	10
1 × 24	20	3	15
2 × 14	15	4½	30
1 × 42	20	4	20
1½ × 42	15	4½	60
1¼ × 54	18	6	75
1½ × 72	20	5½	10
1¼ × 100	10-12	7½	75

* Compound-wound motor. † Wound secondary or squirrel-cage motor with approximately 10 per cent. slip.

Shapers (*A*, *B* or *C*)

Stroke, in.	H.p.*	Transverse head shaper: Stroke, in.	Transverse head shaper: H.p.
12-16	2		
18	2-3		
20-24	3-5	20	7½
30	5-7½	24	10

* Horse power for single head.

Rolls—Bending and Straightening (*B** OR *C*†)

Width, ft.	Thickness, in.	H.p.
4	⅜	5
6	5/16	5
6	7/16	7½
6	¾	15
8	⅞	25
10	1⅛	35
10	1½	50
24	1	50

* Standard bending roll motor.
† Wound secondary induction motor.

Saws—Cold and Cut-off (*A*, *B*, or *C*)

Saw diam., in.	H.p.	Saw diam., in.	H.p.
20	3	36	10-15
26	5	42	20
32	7½	48	25

Slotters and Key Seaters (*A*, *B* or *C*)

Stroke, in.	H.p.	Stroke, in.	H.p.
6	3	16	7½
8	3-5	18	7½-10
10	5	20	10 -15
12	5	24	10 -15
14	5-7½	30	10 -15

Horizontal Boring, Drilling and Milling Machines (*A*, *B* or *C*)

Size of spindle, in.	H.p.
3½-4½	5 -7½
4½-5½	7½-10
5½-6½	10 -15

For machines with double spindles use motors of double the horse power given.

Rotary Planers (*A*, *B* or *C*)

Cutter diam, in.	H.p.	Cutter diam., in.	H.p.
24	5	60	20
30	7½	72	25
36-42	10	84	30
48-54	15	96-100	40

Emery Wheels, Grinders, Etc. (*B* OR *C*) (With two wheels)

Wheel size, in.	H.p.	Wheel size, in.	H.p.
6	¼-1	18	5-7½
10	2	24	7½-10
12	3	26	7½-10

Miscellaneous Grinders (*B* or *C*)

	H.p.
Wet tool grinder................	2-3
Flexible swinging, grinding, and polishing machine.............	3
Angle-cock grinder...............	3
Piston-rod grinder...............	3
Twist-drill grinder...............	2
Automatic tool grinder...........	3-5

Grinding Machines (GRINDING SHAFTS, ETC.) (*A*, *B* OR *C*)

Wheel diam., in.	Length of work, in.	H.p.
10	50-120	5-7½
14	72	10-15
18	120-168	10-15

For heavy work use larger h.p. values.

Hammers (*B** or *C*†)

Size, lb.	H.p.
15-75	½-5
100-200	5 -7½

* Compound-wound motor. † Wound secondary squirrel-cage motor with approximately 10 per cent. slip.

Bliss drop-hammers require approximately 1 h.p. for every 100 lb. weight of hammer head.

Lathes (*A*, *B* or *C*)

ENGINE LATHES

Swing, in.	Horse power

Line-shaft and Individual Motor Drives for Machine Tools. For discussion of line-shaft, individual motor and group drives, see p. 1467.

Depreciation of Machine Tools and Shop Buildings. A report on cost accounting adopted by the National Machine Tool Builders' Association in 1908 recommended charging off 10 per cent. of the original cost per year on all machinery, 5 per cent. on frame factory buildings and 3 per cent. on brick buildings. The cost of fixtures, special tools and patterns should either be charged off at once, or in 24 equal parts during a period of as many months.

Lathes

Classification of the National Machine Tool Builders' **Association:**

Cone drive	Axle	Precision
Small	Gap for car axle	Brass finishers'
Speed	Pulley turning	Automatic threading
Single pulley drive	Bench	Gun boring
Chucking	Projectile turning and boring	Extension gap
Turret	Special bevel-gear turning	Driving wheel
Heavy turret	Automatic	Steel-tire turning
Vertical turret		Shafting turning
Turret on carriage shears		

Most of these terms are descriptive either of the tool itself or of the work for which it is intended.

There is no fixed method of stating sizes and capacities of lathes, but it is common practice to give the **swing** (diameter) and length of bed, that is, a lathe might be 16-in. × 6-ft. bed. The actual swing is often as much as 2 in. greater than the nominal swing. The capacity in length is determined by the maximum distance between centers when the footstock is in its extreme position, and not by length of bed.

The common **sizes of engine lathes** are as follows: 11, 12 and 13 in. × 5 ft.; 14 in. × 6 ft.; 16, 18 and 20 in. × 8 ft.; 22. in. × 10 ft.; 24, 26, 28, 30, 36, 42, 48, 60 and 72 in. × any length of bed desired.

The following **details** of lathe design should be **standardized** so far as possible in any given shop: The diameter, thread and length of spindle nose; taper of hole in spindle; diam. of hole through spindle; taper of centers; hole, keyway, face, pitch and kind of change gears for the ordinary screw-cutting type; number of threads per in. of the lead screw; size of T-slots in wings of carriage; position and direction of motion of operating handles controlling movements of the footstock spindle, carriage, tool block and compound rest.

Cone-driven lathes are commonly back-geared, with the gearing either single or double. The first multiplies the number of cone speeds by two and the second by three.

All-geared lathe heads have lately been developed with the purpose of increasing the power of the drive and to provide easy means for obtaining a large number of finely graduated spindle speeds. Similarly, all-geared devices have been produced for the feed.

In Germany, lathes are divided into roughing and general-purpose lathes. The mean value for the **cutting resistance** in lb. of the roughing lathes is fixed as 725 times the heights of the centers in inches. For general-purpose lathes half this value should be taken.

The maximum **power required to move** the **carriage** may be taken as 2½ to 3 times the cutting resistance, the maximum axial pressure on the headstock center about three times and on the back center about twice this same amount.

Feeds for light work have a minimum of about 0.002; for average work, 0.008; and for heavy work, 0.02 in. Maximum feeds are about 0.02, 0.07 and 0.12 in. per revolution of the spindle. The thickness of the chip may vary from almost nothing to 2½ in.

Power Required by Lathes. According to German practice, the power required for small and medium-sized lathes is approximately as follows:

Swing, in.	12	16	24	32	48	60	80	100*	120*	140*	160*
Horse power	1.5	2	3	4	5	7	10	12	15	20	25–30

* With double beds.

Table 19 (Charles Robbins, *Trans. A. S. M. E.*, vol. 32, p. 211) gives the power required for lathes according to American practice.

Table 19. Sizes and Speeds of Motors on Lathes

Swing, in.	Engine lathes							Driving-wheel lathes	
	Light duty		Medium duty			Heavy duty			
	H.p.	Constant speed, r.p.m.	H.p.	Adjust. speed	Constant speed, r.p.m.	H.p.	Constant speed, r.p.m.	Size, in.	H.p.
14	2.0	1800	3.0		1600	5.0	1200	51	15
16	3.0	1800	5.0		1200	5.0	1200	60–69	20
18–20	3.0	1800	5.0	Ratio 1:3	1200	7.5	1200	79 & 84	25
22–24	5.0	1200	7.5		1200	10.0	1200	90	30
27–30	7.5	1200	10.0		1200	15.0	1200	100	50
36–48	7.5	1200	10.0		1200	20.0	900	....	......

Special Lathes: Car wheel, 48-in., 20 h.p.; double axle, moderate duty, 15 h.p.; heavy duty, 25 h.p.

Lathe Gearing for Thread Cutting. To select the change gears for thread cutting if the lathe is simple-geared and the stud runs at the same speed as the spindle, select some convenient gear for the screw and multiply its number of teeth by the number of threads per inch of the lead screw. Divide this product by the number of threads per inch to be cut. The quotient will be the number of teeth in the gear for the stud.

If the lathe is compound-geared, select at random a set of driving gears and multiply together all of the numbers of teeth and multiply this product by the number of threads per inch to be cut. Then select at random all of the driven gears except one. Multiply together the numbers of teeth of these gears and this product by the number of threads per inch on the lead screw. Divide the first result by the second. The quotient is the number of teeth in the remaining driven gear.

Metric Screw Threads may be cut on lathes having lead screws cut to a number of threads per inch by using change gears having 50 and 127 teeth, respectively. This is because 127 centimeters = 50 in. (127 × 0.3937 in. = 49.9999 in.).

Cutting Tools. Three factors must be determined by every machinist operating a metal-cutting machine on every metal-cutting operation. These are: (*a*) The tool to be used; (*b*) the cutting speed; and (*c*) the feed.

F. W. Taylor, in a paper entitled "The Art of Cutting Metals" (*Trans. A. S. M. E.*, vol. 28, p. 32), points out that there are twelve elements or variables which affect the choice of cutting speed and feed for the lathe. The influence of certain of these elements on the amount of metal cut is set forth in the following recapitulation:

(*a*) Quality of metal to be cut: 1 in the case of semi-hardened steel, to 100 in the case of very soft carbon steel.

(*b*) Depth of cut: In the proportion of 1 for ½-in. depth to 1.36 for ⅛-in. depth.

(*c*) Thickness of chip: In the proportion of 1 with a thickness of 3⁄16-in., to 3½ with a thickness of 1⁄64 in.

(*d*) Elasticity of work and tool: In the proportion of 1 for a chattering tool to 1.15 for a smooth-cutting tool.

(*e*) Shape or contour of cutting edge: In the proportion of 1 for a thread tool to 6 for a broad-nosed tool.

The **angles of tools** for materials of three different degrees of hardness are given in the following tabulation:

Material Cut	Clearance angle, deg.	Back slope, deg.	Side slope, deg.	Lip angle, deg.
Medium and soft steel	6	8	22	61
Cast iron and hard steel	6	8	14	68
Very hard steel and tire steel	6	5	9	74

Fig. 4 shows these angles with reference to the point of a tool.

The hard steel classed with cast iron begins with a low limit of carbon content of about 0.45 per cent., tensile strength of 100,000 lb. per sq. in. and an elongation of 18 per cent. The medium and soft steels listed have their upper limit with these same properties.

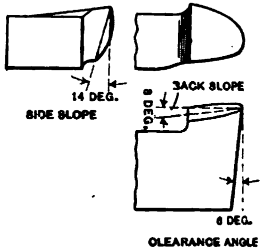

FIG. 4.—Clearance and Slope Angles of Cutting Tools.

For chilled iron a lip angle of from 86 to 90 deg. is to be used. For very soft steels with a carbon content from 0.1 to 0.15 per cent., lip angles keener than 61 deg. may be used. The most important consideration in choosing the lip angle is to make it sufficiently blunt to avoid crumbling and spalling. In choosing between side slope and back slope to produce a sufficiently acute lip angle, the following considerations given in order of importance call for a steep side slope and are therefore opposed to a steep back slope: (*a*) With side slope the tool can be ground many times more without weakening it. (*b*) The chip runs off sidewise and does not strike the tool posts or clamps. (*c*) As the pressure of the chip tends to deflect the tool in one direction, a steep side slope tends to correct this by bringing the resultant line of pressure within the base of the tool. (*d*) The tool is easier to feed.

Mr. Taylor gives the following equations for the radius r of the point of a roughing tool in terms of the width a of the tool, both in inches. For cutting hard steel and cast iron, $r = 0.5a - 5/32$. For cutting medium and soft steel, $r = 0.5a - 3/16$.

Pressure on the Tool. The pressure per sq. in. of cross-sectional area of the chip increases slightly as the thickness of the chip decreases. There is but little difference in pressure between slow and fast cutting speeds, but the total power required to remove a given amount of metal is less at the faster speeds. A slower cutting speed is necessary for hard metals than for soft, even when the total pressure of the chip on the tool is the same, for the following reasons: (*a*) In cutting a hard metal the intensity of the pressure per sq. in. of the lip surface of the tool which comes in contact with the chip is much greater than in cutting soft metals. (*b*) The center of pressure is closer to the cutting edge. (*c*) The section of metal directly below the center pressure is smaller for carrying away the heat.

Taylor's equation for the **pressure on a tool when cutting** cast iron is

$$P = CD^{14/15}F^{3/4},$$

and for steel,

$$P = CDF^{14/15},$$

in which P = pressure, lb.; D = depth of cut, in.; F = feed, in., and C = a constant = 230,000 for steel, 45,000 for soft cast iron, and 69,000 for hard cast iron. Table 21 gives the values of numbers n when raised to the fractional powers $3/4$ and $14/15$. The **specific cutting pressures,** in lb. per sq. in., have been determined as follows:

Authority	Cast Iron	Wrought Iron	Steel
Nicolson	106,000 to 188,000	....	242,000 to 336,000
Fischer	99,500 to 170,500	156,000 to 240,000	226,000 to 340,000
Taylor	70,000 to 197,500	....	240,000 to 296,000

Cutting Speeds for Cast Iron and Steel. Tables 21 and 22 give practical cutting speeds for Taylor high-speed steel tools of the shape shown in Fig. 4. These speeds (**for roughing cuts**) are given for various combinations of depth of cut and feed, and are those at which the tools will cut properly for 90 min. before regrinding is necessary.

Effect of Cooling Water. In cutting steel the gain through the use of a heavy stream of water thrown directly upon the chip at the point where it is removed for modern high-speed steel tools is 40 per cent.; for old-style self-hardening steel tools 33 per cent.; and for carbon-steel tools 25 per cent. Not less than 3 gal. of water per min. should be used for a 2 × 2½-in. tool. The gain is practically the same for all qualities of steel regardless of hardness.

Table 21. Practical Cutting Speeds for Cast Iron. Taylor

(Speeds for tools to last 1½ hr. before regrinding)

Duration of Cut. The formula expressing the relation between cutting speed and duration of cut between grindings for a given material, feed and depth of cut is $V = C/T^{1/8}$, in which V = the cutting speed in ft. per min., T = duration of cut between grindings in min., C = a constant. Consequently there is a material gain in cutting speed if the tools are ground frequently. Table 23 gives the most economical duration of cut and the number of regrindings for various sizes of tool.

Table 23. Duration of Cut Between Grindings. Taylor

S = Size of tool shank in inches; N = Number of regrindings for each dressing; I = Interval between grindings for most economical cutting speed, min.

S........	½×¾	⅝×1	¾×1⅛	⅞×1⅜	1×1½	1¼×1⅞	1½×2¼	1¾×2¾	2×3
N.......	13	15	17	18	19	20	20	20	20
I........	75	75	75	90	90	105	120	150	165

Let t = feed, a = area of cut, S = cutting speed; then, according to E. G. Herbert (*Am. Mach.*, vol. 32, p. 1063), for the same durability of the cutting tool under two sets of working conditions, represented by subscripts 1 and 2, respectively, $S_2{}^3t_2a_2 = S_1{}^3t_1a_1$.

Speeds for parting and thread tools are respectively ½.7 and ¼ the values given in Tables 21 and 22.

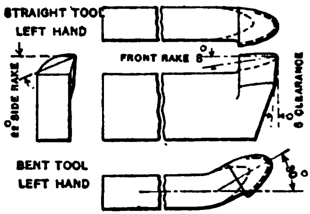

FIG. 5.—Sellers Angles for Round-nosed Roughing Tools for Wrought-iron and Steel (Lathe and Planer Tools).

During the past 4 or 5 years numerous high-speed steels have been put on the market, known generally as **"superior" steels.** Results of careful tests are wanting, though isolated trials have indicated that cutting speeds on soft materials 50 to 60 per cent. higher, and on hard materials 25 per cent. higher, are possible than with the Taylor high-speed steels. Another group of steels, known as **"intra" steels,** has been developed; these have many of the qualities of high-speed steel, but can be successfully hardened in water.

Experiments are also reported with alloys of cobalt, tungsten and chromium used for cutting tools. These have the trade name **"stellite."** Tools ground from a cast bar containing 25 per cent. tungsten, 15 per cent. chromium and 60 per cent. cobalt, have cut annealed nickel-chrome steel at a speed more than double that possible with high-speed steel tools.

of William Sellers & Co., Inc. Tools used for roughing in cast iron and the harder grades of steel (lathe and planer tools) are similar to the tools of Fig. 5, except that the angle of side rake is 14 deg. Fig. 7 and Table 24 show common dimensions for round-nose high-speed roughing tools.

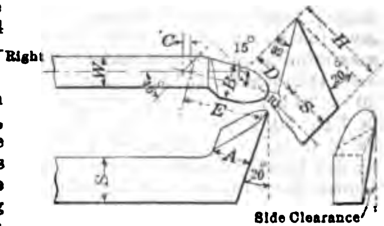

Fig. 7.—Standard Forged Straight Round-nose Roughing Tools.

Boring Tools. Dempster Smith (Manchester Assoc. of Engineers, October, 1911), from trials with single and two-lipped boring tools, deduces equations for the cutting pressure and thrust for two-lipped boring cutters in soft steel. The cutting pressure

$$F = 362{,}000wt + 20{,}000t + 80w,$$

in which F is the cutting pressure, lb., w the width of each cutting lip, in in., and t the feed in in. per rev. An approximation of this is: $F = 400{,}000wt$. The end thrust in lb. is: $P = 38{,}000wt^{0.7}$.

Approximate equations for medium cast iron for two-lipped boring cutters are

$$F = 57{,}000wt^{0.7} \qquad P = 27{,}500wt^{0.7}$$

Trials with single-lipped cutters both for trepanning and facing show that if an initial groove is cut, into which the chips are free to spread, the cutting pressure is about 80 per cent. of that necessary when trepanning from the solid. The formula for cutting pressure for a single cutter for a cutting angle of 75 deg. used in trepanning from the solid, is

$$F = 10{,}000t(30w + 5) + 600w,$$

The thrust when cutting in the solid is: $P = 1000(40w + 1)t^{0.7}$

For facing with a two-lipped cutter the equations are:

$$F = 300{,}000wt \qquad P = 32{,}500wt^{0.7}$$

The corresponding equations for trepanning medium cast iron are:

$$F = (62{,}000w + 2000)t^{0.7} \qquad P = 28{,}800wt^{0.7}$$

For facing, the equations are:

$$F = 55{,}000wt^{0.7} \qquad P = 31{,}000wt^{0.7}$$

Horse Power Required to Remove Metal by Lathe Tools. Charles Robbins (*Trans. A. S. M. E.*, vol. 32, p. 202) gives the following values of the power required to remove 1 cu. in. of metal per min., using ordinary lathe tools:

Metal	Horse power	Metal	Horse power
Brass and similar alloys	0.2 to 0.3	Mild steel (0.30 to 0.40 per cent. carbon)	0.6
Cast iron	0.3 to 0.5	Hard steel (0.50 per cent. carbon)	1 to 1.25
Wrought iron	0.6		
Very hard tire steel	1.5		

Planers, Shapers and Slotters

In using these machines the work is fastened to a platen or table which is traversed in the case of planers and fed in shapers and slotters. As a rule, **cutting is only** done **on one stroke,** although some large planers, especially plate planers, are arranged for double-cutting. Some large shapers cut on the return stroke only, or with a draw cut. On planers, the feed motion acts upon the saddle carrying the cutting tool.

Planers. The **classification** of planers of the National Machine Tool Builders' Association is as follows: Geared, rotary, open side, crank, frog, crossing and switch point, second belt drive, locomotive connecting rod, duplex, textile feed roll fluting. The common **method of designation** is to give the width of the table or platen, or distance between housings, the maximum height cleared under the rail (these dimensions usually being equal), and the length of the platen between pockets. **Common sizes** are 20 × 20 in. × 4 ft.; 22 × 22 in. × 5 ft.; 24 × 24 in. × 6 ft.; 26 × 26 in. × 7 ft.; 30 × 30 in. × 8 ft.; 36 × 36 in. × 8 ft.; 42 × 42 in. × 10 ft.; and 48 × 48 in., 54 × 54 in., 60 × 60 in., 72 × 72 in., 84 × 84 in., 96 × 96 in. by any length of platen desired. The largest and heaviest planer built in the United States is 14 × 20 × 30 ft., weighs 422 tons and has a 100-h.p. motor for the main drive.

In general, planers are **used to produce flat surfaces,** although arcs and special forms can be made with proper tools and attachments. Surfaces to be finished by scraping, particularly parts of machine tools, are with few exceptions planed.

Planers are divided into **two types,** depending upon the way in which they are driven. The **spur-gear drive** is the more common, consisting of a rack running the length of the table on its under side, usually along its center line, into which meshes a large toothed wheel known as the "bull" gear. Power is transmitted to the bull gear from the driving belt through intermediate shafts. In the second, or spiral, type, the **drive** is **through a worm** set at an angle to mesh with the rack.

Large planers may have an additional gear reduction using a second intermediate shaft. This is known as a **four-shaft drive.** Small and medium-sized planers usually have but one **tool head.** Larger machines usually have two on the cross rail and frequently one on each housing below the rail, known as **side heads.** The latter are used to plane down the sides of work and for undercutting.

The smaller machines, up to about 60 × 60-in. gap, usually have but one return speed, this being 3 or 4 times greater than the cutting speed. Larger machines are usually driven by double racks and gears with a return speed 2 or 3 times greater than the forward.

At the moment of reversing the platen the accumulated energy in the driving pulley and train of gears must be overcome, and the reversing belt must supply power to accelerate the table to its normal return speed. This factor limits the **return speed.** To aid this reversal, machines have been built with springs that were compressed by the platen on the cutting stroke. These are commonly referred to as **regenerative planers.**

To smooth out the **reversal,** flywheels have sometimes been mounted on the shaft with the intermediate gear. This arrangement is effective in reducing shocks on the driving motor. Another method employs driving pulleys made from aluminum composition, that is, pulleys that are light in weight and have but little momentum to be overcome at reversal.

To bring about **easy reversal,** other devices used are pneumatic clutches, magnetic clutches, and reversing motors. The latter is the newest and most promising. Table 25 gives a comparison of cutting results on belt-driven and reversing-motor-driven planers.

Table 25. Comparison of Cutting Results on Belt-driven and Reversing-motor-driven Planers

* 48-in. planer, motor drive. † 48-in. planer, motor drive; tools not reground. ‡ 60-in. planer, belt drive. § 60-in. planer, belt drive; tools not reground.

For squaring and finishing the edges of boiler, tank, bridge and ship plates and the like, **plate-edge planers** are used. The work is usually clamped by hydraulic pressure and the machine cuts on both the forward and return strokes. Sizes and power requirements of plate-edge planers are as follows:

Length of stroke, inches........................	160	200	280	to 400
Approximate horse power......................	7	8	10	to 20

Rotary Planers. In these, the cutting tools, of which there are a number, are held in a circular disk or "cathead." The work is clamped to a table provided with automatic feed. There are frequently two heads, so that both sides of the work can be finished at a single setting. They are used largely in structural steel shops to trim and finish the ends of rolled sections.

Motors for Planers. Table 26, for motor sizes and speeds, is adapted from one by Charles Robbins (*Trans. A. S. M. E.*, vol. 32, p. 211).

Table 26. Sizes and Speeds of Motors for Planers

Width and height planed, in....	24×24	30×30	36×36	42×42	48×48	56×56	144×120
Horse power, medium duty.....	5	7.5	10	......	15	15	....
Horse power, heavy duty......	7.5	......	......	25	....	25	60

14 × 12-Ft. Heavy-duty Planer, motor horse-power required: For main drive, 100; for slotting and cross planing, 50; for clutches and feed, 30; for vertical travel of rail, 20; for horizontal travel of heads, 7½.

Cutting Speeds for planers range from 18 to 75 ft. per min.; **feeds** from 0.005 to 3/32 in. for roughing and from ⅛ to 2 in. for finishing. The **depth of chip** ranges from ⅛ in. to 1¼ in., and may be even greater.

The following values for cutting speeds are from the Cincinnati Planer Co.'s "Treatise on Planers." Table 27, from the same source, gives the number of feet of **platen travel** per hour on cut for various cutting and return speeds.

Material	Cutting speed, ft. per min.	Material	Cutting speed, ft. per min.
Cast iron, roughing cut	40 to 50	Wrought iron, roughing cut	30 to 45
Cast iron, finishing cut	20 to 25	Wrought iron, finishing cut	20
Steel castings, roughing cut	30 to 35	Bronze and brass	50 to 60
Steel castings, finishing cut	20	Machinery steel	30 to 35

Table 27. Number of Feet Planer Platen Travels per Hour on Cut

50	1500	1636	1750	1846	1928	2000	2117	2250

Shapers are classified by the National Machine Tool Builders' Association, as follows: Crank, and back-geared crank, triple-geared rack, traverse, open-side, friction, draw-cut.

The cutting tool is mounted on the free end of a horizontal ram which is operated usually by a crank and link, or, in the larger sizes, by a rack and pinion. The slotted-link device produces a **return speed** equal at the most to three times the cutting speed. As each revolution of the driving mechanism produces one stroke of the ram, changes in speed are obtained by means of a cone pulley, variable-speed motor, or other device. The **length of stroke** is changed by changing the position of the crank pin.

The shaper is used for miscellaneous facing, surfacing, notching, key-seating and the production of flat surfaces on all kinds of small machine parts. It is more especially a tool-room, repair-shop and job-shop machine, although in some places it is used on manufacturing operations. It is well adapted to handle special and unusual jobs within its capacity and requiring the operations mentioned above.

The **cutting speeds** employed are usually up to 50 ft. per min., with **return speeds** up to 160 ft. per min. **Feeds** range from 0.005 to 3/32 in. **Commercial sizes** are 14, 16, 20, 24, 28 and 36 in., the size being stated in terms of the length of the stroke. The **horse power** required for shapers is as follows: 14 to 20 in., 3 h.p.; 24 to 28 in., 5 h.p.; 36 in., 7.5 h.p.

Slotters are classified by the National Machine Tool Builders' Association respectively as vertical, frame, and traveling head. This classification does not include the small machines used to saw slots in screw heads, which are also known as slotters.

The machines covered by the above classification are similar in type to shapers, except that the ram carrying the cutting tool is operated vertically.

They are used on general work for keyseating, notching, facing and surfacing, and in some cases, for manufacturing, such as finishing brush holders for generators and motors. **Cutting speeds,** up to 50 ft. per min.; **return speeds,** up to 160 ft. per min.; feed, 1/100 in. to 1/4 in. per cut.

Motors for Slotters. Commercial sizes determined by length of stroke and motor sizes for both light and medium work are as follows: 10 in. stroke, 3 to 5 h.p.; 12 to 16 in., 5 to 7.5 h.p.; 20 in., 7.5 to 10 h.p.; 26 to 30 in., 15 h.p.; and for geared slotters, 24 to 60 in. stroke, 20 h.p.

FIG. 8.—Angles of Sellers Straight-face Planer and Slotter Tools.

Planer and Slotter Tools. The practice of William Sellers & Co., Inc., with respect to tool shapes and angles, is given by Fig. 8. The shapes and angles for round-nose roughing tools are the same for planers as for lathes and are given in Fig. 5, p. 1430.

Boring Machines

Boring Machines are of two general types, horizontal and vertical, and are frequently referred to as horizontal boring machines and vertical boring and turning mills. The classification of the National Machine Tool Builders' Association is: Horizontal boring machines, vertical boring and turning mills, vertical multi-spindle cylinder boring mills, vertical cylinder boring mills, vertical turret boring mills (vertical turret lathes), and car-wheel boring mills.

The **horizontal type** is made both for precision work and general manufacturing. The first type of machine is particularly adapted for work not conveniently revolved, for long holes, and for work having more than one hole to be bored, particularly if the holes are in different planes. The "Precision" type of machine, first built by the Lucas Machine Tool Co., is adapted for both boring and milling on tool-room, experimental, repair and special work. Also for interchangeable work that must be produced without jigs and fixtures. The second type is used for general manufacturing with fixtures that determine the accuracy of the operation. In automobile building this type is used to bore differential housings, crank cases, etc.

Motor Sizes for Horizontal Boring Machines. Table 28, due to Charles Robbins, gives sizes and speeds of motors for horizontal boring, drilling and milling machines.

Table 28. Sizes and Speeds of Motors for Horizontal Boring, Drilling and Milling Machines

Spindle diameter, in.	3½	4	5	6	7
Horse power of motor	3	5	7½	10	15
R.p.m. of motor (constant-speed)	1800	1200	1200	1200	1200

Adjustable speed ratio, 1 : 3

The precision type of machine is made in the following sizes:

Spindle diam., in.	3	3¾	4½
Horse power of motor (constant-speed)	5	7½	10

Table 29. General Dimensions of Standard Boring Mills, Rapid-production Mills and Vertical Turret Lathes

Size of machine, in.	Table diam., in.	Capacity: Diam. of work, in.	Capacity: Under rail, in.	Capacity: Under slide, in.	Capacity: Vertical feed, in.	Table speeds, ft. per min.	H.p. of motor
Standard Boring Mills							
30	28	34	16	25	18	114.4 -4.16	3½
42	37½	42	32½	40½	24	54.6 -2.2	5
51	50	51½	40	47½	26	54.9 -1.58	7½
60	58	61	40	47½	26	47.1 -1.38	7½
Rapid-production Mills							
42	37½	43	33½	44½	30	54.6 -2.2	7½
54	52	56	42	53	36	23.33-1.72	12
Vertical Turret Lathes							
24	24½	26	18	26½	18	62.5-4.67	5
36	34	36½	24	35	26	38.8-2.9	7½
42	40½	44	32	43	27	60-3	10-12

Vertical Boring Mills are adapted to a wide range of face-plate work—work that can be revolved. The advantage lies in the ease with which work is fastened to the horizontal table, and in the lessened effect of centrifugal forces arising from unsymmetrically balanced work. Pulleys, flywheels, gear blanks, piston heads, bearing shells, centrifugal-pump casings, steam-turbine disks, steam-turbine casings, electric-motor and -generator frames and spiders are commonly finished on these machines. Table 29 gives **commercial sizes,** capacities and sizes of motor required—from the practice of the Bullard Machine Tool Co.

Table 30 gives sizes and speeds of **motors for vertical boring mills** (Charles Robbins, *Trans. A. S. M. E.*, vol. 32, p. 212), and following is the practice of the Colburn Machine Tool Co:

Size of mill, in.	42	48	54	60	72
H.p. of motor (Speed, 1200 r.p.m. for all sizes)	7½	10	10	15	15

Table 30. Sizes and Speeds of Motors for Vertical Boring Mills

Size,	24–30 in.	36–42 in.	60–90 in.	100 in.	10 ft.	12 ft.	14 ft.	16 ft.
Horse power	5	7.5	10	15	20	20	25	30
Horse power for rail	.....	.....	5	5	7½	7½	7½	10
Motor speed, r.p.m.	1200	1200	1200	1200	900	900	900	900

Tools for Boring Mills. The forged tools used are either the same as those for lathes, see Figs. 5 and 6, or small bits in holders. In addition, many special tools are used made for particular jobs, and these are frequently furnished by the machine builder.

Drilling Machines

Drilling machines are made in a wide variety of kinds and sizes and are intended for drilling holes with flat, twist or other drills, for tapping, counterboring, reaming, and general boring operations. In some shops they are employed on manufacturing work commonly sent to the lathe, including facing, threading, and outside turning.

The classification of the National Machine Tool Builders' Association is as follows:

Vertical, light cone drive
Vertical, heavy cone drive
Vertical, all-geared
Vertical, light electric drive
Vertical, triple-geared
Radial
Radial, electric drive
Sensitive, plain bearing
Sensitive, ball bearing
Sensitive, electric
Horizontal
Multiple spindle, gang type
Multiple spindle, adjustable gang type
Multiple spindle, adjustable with independently varying spindle speeds.
Multiple spindle, adjustable cluster type
Horizontal multiple spindle
Automatic, revolving table
Boiler makers' radial countersinking
Bench
Bench, electric drive

Sizes of Drilling Machines. Vertical drilling machines are usually designated by a dimension, in inches, which roughly indicates the diameter of the largest circle which can be drilled at its center under the machine. This dimensioning, however, does not hold universally true for all makes of machines. The sizes begin with about 20-in. and continue to 50-in.—the largest size commercially built. The common sizes are: 20, 22, 24, 26, 28, 30, 32, 36, 42 and 50-in.

The size of a **radial drill** is designated by the length of the arm, this dimension being expressed both in feet, as 2, 3, 4, 5 and 6-ft. machines, and in inches.

Sensitive and multiple-spindle machines are not regularly designated by trade sizes.

Motors for Drilling Machines. Sizes and speeds of motors are given by Charles Robbins, as follows:.

Radial drilling machines:

Size, ft.	4	5	6	10
Horse power	3	5	5	7.5

Vertical drilling machines:

Size, in.	15	20–26	28–34	42–50
Horse power	0.5	1	2	3

The **power required for drilling** can be expressed in terms of the number of cubic inches of metal removed per minute.

Material	Horse power per cu. in. of metal removed per minute
Brass and similar alloys	0.4 to 0.6
Cast iron	0.6 to 1.0
Wrought iron	1.2
Mild steel (0.3 to 0.4 per cent. carbon)	1.2
Hard steel (0.5 per cent. carbon)	2 to 2.5

Twist Drills are the most common tools used in drilling, and are made in many sizes and lengths. The smaller are designated by number, as shown in Table 31. Smaller drills than No. 80 have been made, one firm regularly

Table 31. Numbered Twist Drill Sizes

No. of drill	Diam. in inches	No. of drill	Diam. in inches	No. of drill	Diam. in inches	No. of drill	Diam. in inches	No. of drill	Diam. in inches

F	......	0.257	M	19/64	0.295	S	......	0.348	Z	......	0.413
G	......	0.261	......	......	......	T	23/64	0.358	......	......	......

Regular twist drills listed in **fractional sizes** begin at 1/16 in. and advance by 1/64 in. to 3 in. for both straight and taper shanks. **Taper-shank drills** from 3 1/16 to 5 in. advance in size by sixteenths, and from 5 1/8 to 6 in. by eighths. Some makers recommend that three- and four-flute drills be used in sizes larger than 2 in.

Twist drills are backed off from the cutting edge (radial relief) and also are decreased in diameter from point to shank to prevent binding. This longitudinal **clearance** varies from 0.00025 to 0.0015 per in. of length.

The web is increased gradually in thickness from point to shank to increase the strength. It is customary to increase the pitch of the spiral as it approaches the shank. The shape of the groove is important, that one which allows a full curl to the chip being the best. The **spiral angles** of the flutes vary from 18 to 35 deg. The usual **lip-edge angle** is 59 deg. The best all-round **clearance angle** is 12 deg., though 15 deg. is sometimes used for soft metals. There are a number of automatic and hand **twist-drill grinders** on the market designed to give the proper angles.

Among the common types of drills are the **center drill**—a short drill used to center shafts before squaring and turning; the **core drill**, used to cut a core from a piece of metal instead of reducing all of the metal removed to chips; the **gun-barrel drill**, run at a high speed under a light feed and used to drill small, long holes; the **hog-nosed drill**, used to bore out cored holes; the **oil-tube drill**, having holes or tubes in its body through which oil is forced to the cutting lips; **three- and four-grooved drills**, used to enlarge large holes after a leader hole has been drilled with a two-fluted drill; **twisted drills** made from flat high-speed steel.

Speeds and Feeds for Drills. Table 33, giving speeds and feeds for drilling, is copyrighted, 1911, by the Henry & Wright Manufacturing Co., and reproduced here by permission. It gives speeds and feeds for various classes of materials and sizes of drills, which are the results of extensive experiments and probably can be considered as maximum practice.

Table 33. Speeds and Feeds for Drilling with Carbon-steel Drills

For high-speed-steel drills double the tabulated speeds
(Figures in parentheses are speeds in ft. per min.)

The Colburn Machine Tool Co. report the following **drilling records in cast iron** with high-speed twisted drills under a vertical machine:

Size of drill, in.	1	1 1/4	1 3/8	1 1/2	1 3/4	3	3	3
Speed of drill, r.p.m.	520	520	520	520	370	140	140	188
Feed per rev., in.	0.060	0.060	0.060	0.060	0.060	0.041	0.060	0.060
Cutting speed, ft. per min.	130	162	178	190	160	105	105	141
Inches drilled per min.	31.2	31.2	31.2	31.2	22.2	5.75	8.40	11.25

A similar report for **drilling steel** is:

Size of drill, in.	1 1/4	1 1/4	1 1/2	1 1/2	1 1/2	1 3/4	1 3/4	2 1/2	3	3
R.p.m. of drill	370	370	262	262	262	188	188	140	100	100
Feed per rev., in.	0.019	0.028	0.019	0.028	0.041	0.028	0.041	0.041	0.028	0.041
Cutting speed, ft. per min.	115	115	98	98	98	81	81	87	75	75
Inches drilled per min.	7	10.4	5	7.3	10.75	5.25	7.7	5.75	2.8	4.1

Thickness of block drilled in all tests, 4 in.

In all these tests the drills were in good condition after the holes were finished.

What may be considered as **maximum results in high-speed drilling** under radial drills, are given in Table 35 (F. E. Bocorselski, in *Am. Mach.*, vol. 33, part 1, p. 479).

Table 35. Power Required to Drill 0.70 Carbon Steel

Size of drill, in.	Rev. per min.	Cutting speed, ft. per min.	Feed, in. per min.	H.p.	H.p. per cu. in. of metal removed per min.	H.p. per lb. per min.
1 1/2	290	113.0	6.0	25.0	2.43	8.74
1 1/2	312	123.0	10.08	56.6	3.19	11.4
1 5/16	312	107.0	10.08	57.6	4.23	15.1
1 1/4	330	107.0	6.83	24.8	4.10	10.6
1 1/8	208	61.3	4.58	17.3	3.57	13.6
1 1/16	330	91.0	6.83	23.2	3.86	13.8

From these tests Mr. Bocorselski concluded that it is best to run a 1-in. drill at about 300 r.p.m., with a feed of 0.015 in. per rev., and a 1 1/2-in. drill at 225 r.p.m., with a feed of 0.02 in. per rev.

Dempster Smith and P. Poliakoff (*Am. Mach.*, vol. 32, part 1, pp. 739 and 830) give the results of an extensive series of experiments with twist drills of high-speed steel, cutting both steel and cast iron. The cast iron was of medium hardness with the skin removed. The steel was Whitworth's fluid-pressed, of medium hardness, 0.29 per cent. carbon and 0.625 per cent. manganese.

Tables 36 and 37 give the results of these experiments. The revolutions in column 2 of Table 36 for cast iron are based on a cutting speed of 48 ft. per min., and those in the corresponding column in Table 37 (for steel) on a speed of 60 ft. per min.

Table 36. Results of Drilling Tests in Cast Iron

End Thrust and Torque of Twist Drills. Approximate equations for **the end thrust** P, in pounds, **and** the **torque** T, in lb.-ft., for ordinary twist **drills of any diameter** cutting soft cast iron without lubricants, are:

$$P = 35{,}500d^{0.7}t^{0.75}$$

$$T = 740d^{1.8}t^{0.7} = 10d^2 + 100t(14d^2 + 3),$$

where d = the drill diam., in., **and** t = the feed in in. per rev. of the drill.

The corresponding equations for mild steel are:

$$P = 35{,}500d^{0.7}t^{0.6};\quad T = 1640d^{1.8}t^{0.7} = 28d^2(1 + 100t)$$

High-speed Drilling. Speeds up to 10,000 r.p.m. in cast iron and soft steel are in use for drills No. 37 and smaller. Experimentally, speeds up to 20,000 r.p.m. have been used. The advantages of high speed in drilling small holes (in addition to the increased production) are: drill breakage is reduced; heating effect is lessened; practicable rates of feed are increased; burring is practically eliminated. Similar speeds have been used for tapping small holes. Taps Nos. 10–24 and smaller have been run at 10,000 r.p.m. in aluminum and soft brass.

Milling Machines

Milling machines use cutters with multiple teeth, in contrast to the single-pointed tools of the lathe and planer. The cut is not continuous. Though originally developed as a tool-room machine, the miller is to-day largely used as a manufacturing machine. It is **used for** an exceedingly wide variety of work, both of a job-shop and repetitive nature. Irregular sections, including spur and bevel **gears**, are easily produced by using formed cutters. **Flat surfaces** are economically produced by the modern wide-spaced toothed cutters. The universal machines are used to cut **spirals**, including threads, worms, helical gears, etc. In the tool room the vertical type is frequently used to bore jigs. Most milling machine work is held in a vise or fixture.

The **classification** of the National Machine Tool Builders' Association is: Column-and-knee type, Lincoln, hand, planer type (slab millers) and thread millers.

The Association has fixed the **maximum limits for** the vertical, cross and longitudinal **feeds** (in inches) of the common sizes of column-and-knee-type machines as follows:

Number of machine	Plain machines			Universal machines		
	Longitudinal	Cross	Vertical	Longitudinal	Cross	Vertical
0	18	6	15	..	..	..
1	24	7	19	20	7	18
1½	24	7	19	20	7	18
2	28	8	19	25	8	18
3	34	10	20	30	10	19
4	42	12	20	35	12	20
5	50	12	21	..	..	..

The vertical millers of one prominent builder have the following capacities:

Number of machine	Longitudinal traverse, in.	Cross traverse, in.	Vertical traverse, in.	Head traverse, in.
2	28	12	14	6
3	34	13	14	8
4	42	15	14	10

Column-and-knee-type Machines for manufacturing are **plain**, that is, they are provided with three traverses with power feed: vertical, longitudinal and cross. For milling spirals and similar work, the **universal machine** is necessary, in which the table can be swiveled at an angle with the face of the column.

Vertical Milling Machines are frequently provided with a rotary table, permitting them to be used for making cylindrical surfaces. It is not uncommon to provide them with fixtures of such a nature that finished work can be removed and unfinished work inserted while the machine is in operation.

Within a short time, a few American firms have placed vertical-type **circular milling machines** upon the market. These are intended for continuous milling similar to that of vertical machines with rotary tables. In Germany, a horizontal type is extensively used on parts having formed cross-sections, such as sheaves, belt pulleys, rollers, wheels, gear blanks, flywheels, and the like. The work is mounted on the end of a slowly revolving spindle, supported by a foot center if necessary. The cutter is brought in contact with the rim, or edge, which is entirely finished in one or two revolutions, the quality determining whether or not a finishing cut is required. These machines are adapted for manufacturing on a large scale, as one operator can attend to as many as six. The **power required** for a machine for a capacity of work up to 24 in. in diam, is about 2½ h.p.

Lincoln-type Millers are rigid machines for their size and weight, and are particularly adapted for repetitive manufacturing.

Hand Millers have the feeding movements hand-controlled. They are sensitive, as the cuts can be felt. They are used only on light work.

Planer-type Machines are used only on the heaviest work. Many are specially built to machine a number of surfaces on a particular part or small group of parts, and have a number of cutter spindles.

Thread Millers are used to cut threads and worms.

The **tapers used in** the **spindles** of horizontal machines are generally as follows:

Machine number	0	1½	2	3	4	5
Brown & Sharpe taper number	9	10	10	11	12	12

Motors for Millers. Motor sizes and speeds for various types of milling machines, as determined by Charles Robbins, are given in Table 38.

Table 38. Sizes and Speeds of Motors for Milling Machines

Horizontal machines, plain or universal				Vertical machines			Slab milling machines

....	....	....	....	70	6	20	42 heavy	50

Power Required to Remove Metal with Milling Cutters. The power requirements of different forms of cutters vary with their construction. Table 39 gives values obtained from tests made by A. L. DeLeeuw with Cincinnati plain and high-power millers.

Milling Cutters are made from both carbon and high-speed steel. Common kinds are enumerated below.

Angular, for cutting tooth spaces in other cutters, ratchets and the like; **convex and concave,** used to cut half-round grooves and projections, the convex often used to flute taps; **corner rounding; cotter mills,** for cutting keyseats, slots and grooves; **dovetail; end mills,** for milling edges of work, cutting slots, cam outlines and grooves; **formed cutters,** made solid in small sizes—with inserted teeth in large, used to produce irregular and other contours; **fish-tail cutters,** used at high speed and with light feed for slots, grooves and keyways; **helical cutter,** consisting of a cylindrical body with teeth in the form of a screw thread wound around it at an angle of about 60 deg. with the axis—used on all classes of work, free cutting and remarkably efficient; **shell end cutters,** made to be screwed to a shank or keyed to end of an arbor, used for same work and heavier cuts than end mills; **side mills or straddle mills,** comparatively thin cutters used to finish sides of work or to cut slots, frequently used in pairs to straddle the work; **slabbing cutters,** having a comparatively long face for surfacing; **saws, T-slot cutters.**

The tendency in milling cutter design is toward **wide-spaced teeth.** Chip space is necessary for free cutting. A. L. DeLeeuw (*Trans. A. S. M. E.*, vol. 33) gives propor-

tions for end mills, shell cutters, side mills, face mills, and helical cutters. The number of teeth recommended are respectively as follows:

Diam. of cutter, in.	1	1¼	1½	2	2½	3	3½	4	5	6
Number of teeth:										
End mills	4	5	6	8	...	..	...	..	..	..
Side mills and spiral shell cutters	..	...	...	..	8	8	9	10	11	12

The metal-removing capacity of these is given in Table 39.

The **helical cutters** are made with a helix angle of the teeth with the axis of the body of 60 deg., rake of 15 and clearance of 5 deg. for cutting steel, and rake of 8 and clearance of 7 deg. for cutting cast iron. They push off the chip in the direction of the cutter axis and at right angles to the feed. Roughing cuts in steel take only about one-third the power required by old-style spiral mills.

Table 39. Power Requirements of Various Types of High-speed Steel Milling Cutters

Material cut	Size and type of cutter	H.p. per cu. in. of metal removed	Material cut	Size and type of cutter	H.p. per cu. in. of metal removed

Performance of Large High-speed-steel Milling Cutters with Inserted Helical Blades. Results of numerous experiments made with large milling cutters with inserted helical blades, known as Taylor-Newbold cutters, are given in Table 40 (Wilfred Lewis and W. H. Taylor, *Trans. A. S. M. E.*, vol. 30, p. 867). The angle of the helix of these blades is 19 deg. 15 min., given by the formula: Diam. × 9 = pitch. The blades are set in grooves in the steel body and held by pouring around them a molten, fusible, non-shrinking alloy. A gain of 33 per cent. in cutting speed in milling steel and wrought iron is made by throwing a heavy stream of lubricant upon the cutter along its entire face. A similar gain of 15 per cent. is made in milling cast iron. For a large milling cutter, the nozzles in the lubricating pipe should be spaced about 4 in. apart and in sufficient number to cover the face of the cutter.

Speeds and Feeds of Milling Cutters. Good general practice with carbon-steel cutters is, for wrought iron and mild steel, a surface velocity of 30 ft. per min., with a feed of 0.01 to 0.02 in. per rev.; for cast iron, 40 to 50 ft. per min. and 0.02 to 0.03 in. per rev.; for brass and bronze, 60 to 75 ft. per min. and 0.03 to 0.04 in. per rev. With high-speed steel cutters these speeds may be increased from 50 to 75 per cent.

High-speed Milling. Under a system worked out by the Cincinnati Milling Machine Co. with very rigid machines, and with the employment of about 10 times as much lubricant as usual, peripheral cutting speeds up to 800 ft. per min. in soft steel and feeds up to 112 in. per min. were successfully reached in tests. In daily practice cutting speeds up to 450 ft. per min. and feeds up to 30 in. per min. are now common.

Gear-cutting Processes

Teeth in gears are formed by either a milling, shaping or hobbing process. **The Four Principles of Action** of gear-cutting machines are:

(*a*) The formed-tool principle, using a tool or cutter shaped to the tooth space.

(*b*) The template principle, in which the motion of the cutting tool is controlled by a template corresponding to the tooth curve.

(*c*) The odontographic principle, in which the tool is guided by suitable mechanism so that its path closely approximates the tooth curve.

(*d*) The generating principle, in which a tool or series of tools representing a rack are moved with reference to the gear blank being cut in the same manner as a rack meshing with its gear; or a cutter representing a mating gear is rolled with the gear blank while cutting. As a finishing operation, an abrasive wheel sometimes takes the place of the cutting tools.

Machines using method (*a*) produce spur, spiral, helical and worm gears; (*b*) and (*c*) spur and bevel gears; and (*d*) spur, helical, bevel and worm gears.

Processes for Cutting Spur Gears. The most common rocess is **milling,** which uses a circular formed cutter corresponding with the shape of the tooth space. The gear blank is carried upon an arbor in the main spindle of the machine, which has a dividing wheel on its other end. This wheel is usually larger than the largest gear to be cut, to diminish inaccuracies in indexing.

The template principle is rarely used, except for very large gears, as in rolling-mill work. A pair of such gears are designed to run together without being interchangeable with others. The machines operate on the **planing or shaping process.**

The **generating** principle has numerous applications. The shaping **process** is employed, using a tool shaped like a rack tooth. The operation is continuous, succeeding cuts being taken in successive tooth spaces. The rolling action takes place after the gear has been cut around, thus setting for the second cut in each tooth space, and so on. The blank is rotated and the tool ram carrying the tool is fed sidewise, the motion corresponding with the motion of the gear meshing with an imaginary rack.

The **shaping process** is employed in another way, where multiple tools are used representing a rack. There are two sets, one on each side of the blank. The blank is rotated and the tools fed sidewise simultaneously. For large gears, the tools reciprocate in a vertical direction and the blank only rotates. For small gears, this arrangement is reversed. The most widely used machine employing a shaping process and the generative principle is the Fellows gear shaper. The cutter is a pinion which reciprocates and also rotates as if in mesh with the gear to be cut from the blank. In cutting, it is usually fed in to its full depth at the start and then rotated, finishing the gear with one cut around.

During the past few years **hobbing machines** have grown rapidly in favor. They employ the generative principle and the milling process. A section through a hob along a plane passing through the center of figure and making an angle with the axis equal to its helix angle at the pitch surface, is the section of a rack. Thus the hob is in effect a generating rack. Both hob and blank are rotated to give the effect of a meshing gear and rack. The hob starts the cut at one edge of the blank and is fed across its face.

Processes for Cutting Bevel Gears. The **milling process and formed circular cutter principle** are employed most widely in cutting bevel gears, except for those that are required to be especially accurate; at least two cuts are necessary through each tooth space, one on each side. Bevel gears cut in this way have only approximately correct tooth curves. As a rule, the cutter is designed to give the correct shape at the large end of the tooth, and necessarily leaves the smaller end too thick. This is corrected by filing.

The **template principle and planing process** are used in the Gleason bevel-gear planing machine. Three templates are used, a straight-faced one for gashing, and two formed ones, one for each side of the tooth space. Simple planing tools are used. After all of the spaces are gashed, one side of each tooth is completely finished, and then the other side to complete the gear.

The **generating principle and shaping process** have been used in a number of different machines. The general arrangement consists in providing a crown gear or its equivalent with the cutting tools representing its sides in successive positions. Meshing with the crown gear is a master bevel gear carrying on its shaft or arbor the blank to be cut. The master and crown gears rotate in mesh, thus presenting the blank to the cutting tool in successive positions to generate the teeth. Details of this general arrangement have been worked out in a number of different ways.

The **generating principle and milling process** are used in an ingenious machine built by the Brown & Sharpe Mfg. Co. The sides of the teeth of the imaginary crown gear are represented by the plane faces of milling cutters. In operation, the imaginary crown gear is stationary and the master bevel gear is rolled over it, presenting the work to the cutting tool. Large milling cutters are used to minimize the deepening of the tooth space at the center. They interlock and cut on opposite sides of the same tooth space. The Warren machine is similar in its action, except that the two cutters operate on facing sides of alternate teeth.

Processes for Cutting Internal Gears employ the following principles and processes: (1) Formed circular cutter principle and milling process; (2) generative principle and shaping process (Fellows machine); (3) formed cutter principle and shaping process. This is the one most commonly used.

Processes for Cutting Racks. The following principles and processes are used: (1) Formed circular cutter principle and milling process, this being by far the most common; (2) generative principle and shaping process (Fellows machine).

Processes for Cutting Helical Gears employ the following principles and processes: (1) Formed cutter principle and shaping process; (2) formed circular cutter principle and milling process, this being the most common; (3) generative principle and milling process (hobbing); (4) generative principle and shaping process (Fellows machine).

Processes for Cutting Worms use the (1) formed circular cutter principle and milling process; and the (2) formed cutter principle and turning process.

Processes for Cutting Worm Wheels employ the generating principle and milling process (hobbing). Three **forms of cutters** are used, the straight hob, tapered hob and fly cutter. The first requires the simplest mechanism; an ordinary miller is sufficient, but the hobs are expensive. The fly cutter is easily and accurately made, but requires a complicated machine to use it. The taper hob is adapted to large work and a large number of pieces.

Motors for Gear Cutters. Most gear-cutting machines are of comparatively small capacity, and for this reason are driven in groups. For power requirements, see Table 18.

Gear Cutters. Circular formed cutters for involute toothed gears in an interchangeable standard system are made in sets of eight, to cut gears ranging from a 12-toothed pinion to a rack.

Number of cutter.........	1	2	3	4	5	6	7	8
Number of teeth..........	135–∞	55–134	35–54	26–34	21–26	17–20	14–16	12 and 13

For more accurate gears, a 15-cutter set is made by introducing a half number between each two in the foregoing list, each cutter therefore having a smaller range of teeth, as follows:

Number of cutter...	1	1½	2	2½	3	3½	4	4½
Number of teeth....	135–∞	80–134	55–79	42–54	35–41	30–34	26–29	23–25

Number of cutter.........	5	5½	6	6½	7	7½	8
Number of teeth..........	21 and 22	19 and 20	17 and 18	15 and 16	14	13	12

For still more accurate gears, cutters are made for the exact number of teeth to be cut.

The **duplex gang cutters** made by Gould & Eberhardt are to be used in gangs of two or more, the number depending upon the number of teeth in the gear to be cut. The following tabulation gives the number that may be used in cutting different numbers of teeth:

Number of cutter..............	1	2	3	4	5
Number of teeth..............	Under 30	30–49	50–69	70–94	95–119
Number of cutter..............	6	7	8	10	12
Number of teeth..............	120–149	150–179	180–229	230–259	Over 260

To rough out the tooth spaces, **stocking cutters** are used. These leave only a small amount of metal to be removed by the regular cutter, increase the accuracy of the gears, and save wear on the finishing cutters. One stocking cutter serves for all gears of the same pitch. The term stocking cutter is also applied to a concave cutter ganged beside a regular gear cutter and used to finish the periphery of a gear blank by milling ahead of the gear cutter. **Hobs** are cutters with helical teeth arranged like the thread of a screw and fluted to give cutting edges. They are backed off and can be ground on the faces of the teeth without changing the shape.

Grinding Machines

The **classification** of grinding machines of the National Machine Tool Builders' Association is as follows: Grinding wheel stand (for bench); electric drive (for bench); cock; cup and cone; cutter; cylinder; cylindrical; center; drill; grinding wheel stand (for floor); frog and switch; hob; internal; multiple spindle; polishing stand; roll; semi-universal; surface (both vertical and horizontal); surface, rotary table type; disk; tool; universal.

All of these machines except the disk type use **grinding wheels** made by fixing an abrasive in a binder which is usually hardened by baking. The disk type uses an abrasive or abrasive cloth pasted to the surface of a metal disk. **Cutter grinders** are designed to grind all kinds of milling and similar toothed cutters. **Cylinder grinders** are a special type for grinding the cylinders of automobile engines. One form has a planetary motion for the grinding spindle. The **cylindrical grinder** is a companion machine to the engine lathe. Shafts, cylinders, rods, rolls, studs, and a wide variety of other cylindrical parts are first roughed out on the lathe, then finished accurately to size by the cylindrical grinder. **Drill grinders** are provided with rests so mounted that by a simple swinging motion correct cutting angles are automatically produced on the lips of drills. A cupped wheel is usually employed. **Internal grinders** are used for finishing the holes in bushings, rolls, sleeves, cutters and the like. High speed is a feature of these machines. Speeds from 15,000 to 30,000 r.p.m. are common and speeds of 100,000 r.p.m. are claimed for the Rivett machines. **Horizontal surface grinders** are in general of small capacity and are used mainly in tool making. **Vertical surface grinders** are used for producing flat surfaces on manufacturing work. **Vertical and horizontal disk grinders** are used for surfacing on both cast iron and steel. **Universal grinders** are cylindrical machines arranged with a swiveling table so that both straight and taper internal and external work can be ground. They are used on tool work and in refined manufacturing.

Motors for Grinders. Charles Robbins (*Trans. A. S. M. E.*, vol. 32, p. 215) gives motor sizes for cylindrical grinders for medium (heavy) work as follows: 10 in. diameter, 5 (7.5) h.p.; 14 and 18 in. diameter, 10(15) h.p. For a 44-in. wheel grinder 30 h.p. is required.

Grinding Wheels. Grinding wheels are made from the commercial abrasives, emery, corundum, carborundum, alundum, and others marketed under special trade names. For **grades** and for **abrasives in grain form**, see p. 616. The marks left by these various grits have been compared with file marks, as follows:

Table 41. Grit Marks and Corresponding File Marks

Size of grains	File which leaves corresponding marks	Size of grains	File which leaves corresponding marks
8 to 10	Wood rasp	46 to 60	Second-cut
16 to 20	Coarse-rough	70 to 80	Smooth
24 to 30	Rough	90 to 100	Superfine
36 to 40	Bastard	120, F and FF	Dead smooth

A wheel of hard **bond** is retentive of the grains, while in the softer bonds the grains are more easily broken out. In a wheel of proper grade for the work being done, the grains are automatically replaced when dull. A **wheel glazes** when it is too hard. Dressing a wheel breaks off the surface and exposes fresh, sharp grains.

Table 42 gives a comparison of the selection of grades and number as used by both the Norton Co. and Carborundum Co. for the general run of work that is ground.

Table 42. Abrasive Wheels for Various Kinds of Work

Class of work	Norton Co.		Carborundum Co.	
	Number usually furnished	Grade usually furnished	Number usually furnished	Grade usually furnished
Large cast-iron and steel castings	16 to 20	Q to R	16 to 24	G to H
Small cast-iron and steel castings	20 to 30	P to Q	20 to 30	G to H
Large malleable-iron castings	16 to 20	Q to R	16 to 24	G to H
Small malleable-iron castings	20 to 30	P to Q	20 to 30	H to I

Twist drills (special machines)	46 to 60	K to M	50	L to O
Reamers, taps, milling cutters, etc. (hand grinding)	46 to 100	N to P	50 to 80	K to N
Reamers, taps, milling cutters, etc. (special machines)	46 to 60	H to K	50 to 60	L to M
Edging and jointing agricultural implements	16 to 30	Q to R	141 to 24	G to I
Grinding plow points	16 to 30	P to Q	20 to 24	H
Surfacing plow bodies	20 to 30	N to O	16 to 20	G
Stove mounting	20 to 36	P to Q	24 to 30	G
Finishing edges of stoves	30 to 46	O to P	24 to 30	G
Drop-forgings	20 to 30	P to Q	24 to 36	G to I
Gumming and sharpening saws	36 to 60	M to N	403—603	J to L
Planing-mill and paper-cutting knives	30 to 46	J to K	202—60 to 80	M to R
Car-wheel grinding	20 to 30	O to P	16 to 24	H

Combination Grit Wheels, as their name implies, are composed of grits of varying degrees of fineness. For finishing purposes these wheels have the compactness and smooth face of a wheel made solely from their finest grit, and for roughing the ability to take a depth of cut determined by the capacity of the largest grains. As a general standard, the harder the material to be ground the softer should be the bond of the wheel. This is modified by the fact that cast iron and hardened steel require the same grades.

Too large an assortment of wheels is liable to lead to confusion in their use. With a Norton plain cylindrical grinder, **four grades**, J, K, L and M, of a 24 combination grit are found **sufficient** for all the materials **usually** ground. These include chilled iron, cast iron, high-and low-carbon steels, bronzes and the common compositions.

In the grinding process cutting is done with the lightest tool pressure of all cutting methods. This advantage may be lost if too hard a wheel is used, that is, one in which the bond will not crumble under the pressure of the cut but must be forced with a pressure sufficient to displace the work. Destructive vibrations and inaccurate work are often chargeable to too hard wheels. Grinding is a **true cutting process.** Under the microscope, the particles of metal removed by an abrasive wheel are seen to have the shape and character of chips cut by a lathe tool from the same material.

Alden (*Trans. A. S. M. E.*, 1914) comes to the following conclusions: (*a*) Increase of work speed increases grain depth of cut, and makes a wheel appear softer; (*b*) decrease of wheel speed increases grain depth of cut; (*c*) diminishing the diameter of the grinding wheel increases grain depth of cut, and (*d*) diminishing the diameter of work increases grain depth of cut.

Wheel Speeds. Surface speeds of 5000 to 6000 ft. per min. are commonly employed, although lower speeds are sometimes used. F. B. Jacobs gives the following **data for wheel speeds,** work speeds, traverse feeds and depth of cut. The proper surface speed for a carborundum wheel is 5000 to 5500 ft. per min. Wheels made of alumina abrasives, corundum, aloxite, alundum, etc., give better results when run at a higher speed, say, 5500 to 6000 ft. per min. A general rule is to reduce the wheel speed if glazing occurs frequently, and to increase the speed if the wheel does not hold its shape well and wears away too readily.

Work Speeds. For roughing cast iron, 40, and for finishing, 50 ft. per min. surface speed; for roughing steel, 20 to 30, and for finishing, 30 to 40 ft. per min. surface speed are good practice. These are rules for grinders equipped with the coarse traverse feeds that are used with wide-faced grinding wheels. With the older types of machines having fine traverse feeds, it is necessary to use higher speeds. High work speeds cause chattering, glazing, and undue wearing of wheels.

Traverse Feeds depend entirely on the width of the wheel. In roughing, the work should travel past the wheel ¾ to ⅞ of the width of the wheel for each revolution of the work. As the work, or rather cut, travels past the wheel with a helical motion, the above rule allows a slight overlap. In finishing, a finer feed is used, generally ⅛ to ¼ of the width of the wheel for each revolution of the work.

Depth of Cut. In the roughing operation the depth of cut should be all the wheel will stand without crowding. This varies with the hardness of the material and the diameter of the work; the operator's experience is the only guide. In the finishing operation the depth of cut is always slight, from 0.001 in. to 0.002 in. Excellent results as regards finish are obtained by letting the wheel run over the work several times without cross-feeding. This practice of letting the wheel "grind out" has been found by the majority of expert operators to give satisfactory results even with a comparatively coarse wheel.

Grinding Allowances. On heavy work and heavy machines, grinding allowances are commonly from $\frac{1}{64}$ to $\frac{1}{32}$ in. On fine work, from 0.003 to 0.007 in. is sufficient.

Grindstones are still used for some kinds of work, particularly for the rough grinding of forgings, but the tendency is to replace them with steel wheels carrying segmental abrasive blocks. The Ohio sandstones can be safely run up to a peripheral **speed** of 2500 to 3000 ft. per min. and Huron stone up to 4000 ft. per min. These speeds presuppose careful setting up, large flanges and only moderate wedging. The older form of square shaft hole is dangerous, in that it furnishes points from which fractures may easily start. The strength of grindstones is reduced by wetting, some investigations indicating by as much as 40 to 50 per cent.

The Sand Blast consists of particles of sand, powdered quartz, chilled iron globules, emery or other hard granular material blown by a jet of compressed air or of steam against a hard surface which it is desired to abrade. It is commonly used for cleaning metal, castings, frosting smooth surfaces, etc. Portions of the surface which are not to be abraded can be protected by coating with a soft material such as wax, lead or rubber. For cleaning castings compressed air at about 10 lb. pressure is used; with a 2-h.p. compressor 2 sq. ft. of surface can be cleaned per minute, or 100 lb. of small castings in a slowly rotating barrel can be cleaned in 10 to 15 min. To completely remove the hard skin of the castings takes about twice as long.

Polishing Wheels are run at the following peripheral **speeds** (ft. per min.): Walrus hide. 8000; wood, leather-covered, 7000; rag wheels, 4 to 8 in. in diam., 7000.

Exhaust Fans for Grinding Wheels. The exhaust pressure commonly used for removing dust in polishing, buffing and light grinding is 3 oz. per sq. in.; in heavy grinding, 4 to 4½ oz.

Hood inlets for buffing, polishing and grinding wheels up to 26 in. in diam. should be made for the following sizes of pipe:

Wheel diam., in.	4 or less	4 to 6	8 to 10	12 to 16	18	20	22 to 26
Pipe diam., in.	2	3	3½	4	4½	5	6

The **hoods and piping** of dust-exhausting systems are usually made of galvanized iron. The **size of fan inlet** is usually made equal to the sum of the areas of the hood inlets or from 10 to 20 per cent. less.

Files are designated by their length, longitudinal and sectional contours, the kind of cut and the spacing of the teeth. Longitudinally, files are **blunt** (with parallel sides) or **taper**. The **length** is the distance (in in.) from the cutting end of the file to the **tang**, or pointed end for fitting into a handle. **Safe-edge** files have one of the narrow edges uncut, so that one surface near a corner may be filed without marring the other surface. Standard **shapes** of files in general use are as follows:

Metal saw—Blunt; triangular section (equal sides).
Three-square—Taper; triangular section (equal sides).
Barrette—Taper; thin trapezoidal section.
Slitting—Blunt; rhombic section, diagonals in ratio 1 : 3 or more.
Square—Blunt or taper.
Round—Blunt or taper (rat-tail).
Knife—Taper; width = thick edge × 3 or more.
Half-round—Blunt or taper; section, segment of circle.
Crossing—Taper; section, two half-rounds with flat faces back to back.
Crochet and Warding—Taper, thin rectangular sections.
Mill, Hand and Pillar—Blunt or taper; medium to thick rectangular section.

Files are either **single-cut** (with teeth at about 25 deg. to direction of width), **double-cut** (single-cut with a second cut crossing first at angle of 45 to 50 deg. to direction of width), or **rasp-cut** (individual teeth forced up from the surface by a blunt-ended punch). They are ordinarily **graded** as follows (the finer cuts for machinists' use being numbered 00 to 8):

Single-cut:	Rough;	middle;	halfway;	bastard;	second cut;	smooth.	
Double-cut:	Rough;	middle;	halfway;	bastard;	second cut;	smooth,	dead smooth.
By number:				00	1	2–3	6–8

The **tooth spacing** varies according to the length and kind of file. For 12-in. files the number of teeth per in. are approximately 17 (rough), 30 (bastard), 96 (smooth). Taper files run from 64 teeth per in. for 2½-in. length, to 34 teeth for 10-in. length; mill and flat bastard files, from 48 to 50 for 4-in. length, to 18 to 22 for 20-in. length.

Files cut better after a little use, as the burrs left on some of the tooth edges become worn away, thus permitting other teeth to come into action. They may be **resharpened** by directing a sand blast against the backs of the teeth; there is a wide difference of opinion as to the value of a resharpened file.

Broaching Machines

Broaching machines are used to produce irregular-shaped holes, keyways, the teeth of internal gears, square, hexagonal and other polygonal holes, and similar work. The cutting tool—the broach—is long and is provided with many teeth so graded in size that each takes a small chip when the tool is (usually) pulled or (sometimes) pushed through a drilled leader hole. The employment of sliding gears in automobiles has extended the use of broaching machines, for these are used to produce the square holes or multiple keyways in such gears. These machines are made in numbered sizes from 1 to

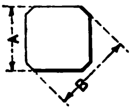
4, inclusive. The capacity of the Lapointe machines is as follows, the second dimension being the length of hole or keyway:

		1	2	3	4
Size Number		1	2	3	4
Capacity	Keyway, in.	$\frac{1}{4} \times 6$	$\frac{5}{8} \times 6$	$\frac{3}{4} \times 12$	$1\frac{1}{4} \times 14$
	Square hole, in.	$\frac{1}{2} \times 2$	$1\frac{1}{8} \times 5$	2×6	3×8

Broaching is also sometimes substituted for reaming in finishing round holes to size. Where a great deal of metal is to be removed, two or more broaches are employed, in series, the smallest tooth of the second being slightly larger than the largest tooth of the first, and so on.

The Lapointe Machine Tool Co., manufactures **standard broaches for round-cornered square holes**, such as are used in automobile gears. Table 43 gives the sizes of holes produced by these broaches.

Table 43. Dimensions of Lapointe Standard Round-cornered Square Holes



Size No.	*A* inches	*B* inches	Size No.	*A* inches	*B* inches	Size No.	*A* inches	*B* inches
1	1	$1\frac{1}{4}$	7	$1\frac{3}{8}$	$1\frac{3}{4}$	13	$1\frac{3}{4}$	$2\frac{1}{4}$
2	$1\frac{1}{16}$	$1\frac{5}{16}$	8	$1\frac{7}{16}$	$1\frac{13}{16}$	14	$1\frac{13}{16}$	$2\frac{5}{16}$
3	$1\frac{1}{8}$	$1\frac{3}{8}$	9	$1\frac{1}{2}$	$1\frac{7}{8}$	15	$1\frac{7}{8}$	$2\frac{3}{8}$
4	$1\frac{3}{16}$	$1\frac{15}{32}$	10	$1\frac{9}{16}$	$1\frac{15}{16}$	16	$1\frac{15}{16}$	$2\frac{7}{16}$
5	$1\frac{1}{4}$	$1\frac{9}{16}$	11	$1\frac{5}{8}$	2	17	2	$2\frac{1}{2}$
6	$1\frac{5}{16}$	$1\frac{5}{8}$	12	$1\frac{11}{16}$	$2\frac{1}{8}$	......	....	....

In *Am. Mach.*, vol. 33, part 2, p. 688, some **records are given for broaching** to finish size $2\frac{3}{32}$-in. holes in bronze bearings. The roughing broach roughs from 3000 holes up, and must be honed after each 1000. The corresponding finishing broach finishes from 1000 to 2000 pieces, and must be honed after each 400 to 500 holes. These broaches are made with six sets of teeth, of which the lower three increase successively 0.002 in. each. The last three teeth are all of the same size, 0.002 in. larger than the immediately preceding tooth, and of the finished diam. wanted. With broaches of this kind, it is customary to grind them 0.0004 in. large, leaving this amount to hone to finished size to produce a smooth, keen edge. Mr. Lapointe states that 3-in. internal gears of alloy steel have been broached at the rate of 25 to 30 per hour.

The making of broaches depends to a great extent upon experience. The **number and spacing of teeth** depends upon the length of the hole, the longer the hole the more chips each tooth will cut and therefore the more chip space necessary. The **steel for broaches** is usually high-grade tool steel which will not warp in hardening. There is more difficulty with hardening broaches with fine teeth than with the larger ones, as in the former case the teeth cool more quickly than the body, thus tending to the formation of water cracks.

Cutting-off Machines

These machines—used to cut up merchant bar and rolled shapes—are made in **three types**: the lathe type, using single-pointed cutting-off tools; friction sawing machines, using notched disks of soft steel running at a high speed and cutting by the heat generated by friction; and cold-sawing machines, using circular saws. As regards production, there is but little choice between the first and third types.

The **lathe-type cutting-off machines** are graded into inch sizes, according to the largest diameter of round stock that the machine will handle. These are:

Size of machine, in.	2	3	4	5	6
Capacity: size of bars, in.	$\frac{1}{4}$ to 2	$\frac{3}{8}$ to 3	$\frac{1}{2}$ to 4	$\frac{3}{4}$ to 5	1 to 6
Horse power of motor	1	2	3	3	3

The **friction sawing machine** (fusing disk machine) is largely used on structural shapes. A 15-in. beam can be cut through in 28 to 38 sec., and smaller sections in proportionate times. A machine carrying disks from 44 to 52 in. in diam. is provided with a 52-h.p. motor. Peripheral speeds of about 25,000 ft. per min. are used. **Cold saws** are made in a wide variety of styles and sizes. Some makers list them in numbered sizes; others, according to the diameter of saw blade which the machine will carry. Table 44 gives the sizes of standard inserted-tooth saws made by the Tindel Morris Co., and also sizes of saws to cut structural shapes. With all these machines it is necessary to have a special grinder to grind blades automatically.

The **sizes of stock** for which **blades of different diameters** are **suitable** are as follows:

Diam. of blade, in.		13½	15	18	20	24
Thickness of blade, in.		⅛	⅛	5/32	3/16	7/32
Capacity	Rounds (diam. in in.)	4	4½	6	6½	8½
	I-beams, size in in.	6	7	12	12	12

The practice of the Brown & Sharpe Mfg. Co. for **cutting speeds and feeds** of cold saws is given in Table 45. **Motor sizes,** according to Charles Robbins (*Trans. A. S. M. E.*, vol. 32, p. 215) are given in Table 46.

Table 46. Sizes and Speeds of Motors for Cold Saws

Diam. of blade, in.	12	15	18	20	24	32	36
Thickness of blade, in.	5/32	5/32	3/16	3/16	3/16	3/16	3/16
Horse power	2	2	3	3	5	7½	10

Hack Saws for use in **hand frames** are made in lengths ranging by inches from 6 to 14 in., ½ to ⅝ in. in width, and either 0.026 or 0.028 in. in thickness. Number of teeth per inch: For cutting soft steel or cast iron, 14; tool steel and angle iron; 22; brass, copper, heavy tubing, 28; sheet metals and thin tubing, 32.

Blades for **power hack saws** are made in 10, 12, 14, 16, 17, 18, 20, 22 and 24-in. lengths, 0.033 (light), 0.05 and 0.065 in. in thickness, and with 14 teeth per in. for regular work (10 for coarse sawing). In power hack saws, the frame in which the blade is strained is reciprocated above the work which is held at the desired angle in a vise. Feed downward is effected by weighting the frame. On the (quick) return stroke the blade is automatically lifted to clear the bottom of cut. The larger sizes will cut off bars or rolled sections up to 12 in. across. The power requirements are inconsiderable.

Turret Lathes

Flat Turret Lathes. The flat turret lathe has a low, rigid turret using ordinary turning tools. Special tools are unnecessary. Representative dimensions are 2¼ × 24 in. (2¼-in. hole through spindle and 24-in. diameter turret) and 3 × 36 in., the first requiring a 2½-h.p. and the second a 3-h.p. constant-speed motor. The head is made cross-sliding, thus adapting it to chuck work.

Semi-automatic Turret Lathes are used on both bar and chuck work. The piece of work must be chucked and unchucked by hand. The cutting operations are automatic.

Screw Machines

Screw machines are turret lathes usually equipped with automatic chucks, bar feeds, oil pans and oil pumps. They were originally designed to make screws and similar parts at one setting from bar stock, the principal operations being turning and threading under a flood of lubricant. At present they are not confined to bar stock, for forgings and parts made from the bar and requiring second operations are handled with a magazine feed. They are operated either by hand or automatically.

Sizes, Capacities and Motor Requirements of Hand Screw Machines

Size number		1	2	3	4	5
Capacity	Diam., in.	⅝	1	1½	2¼	2⅝
	Length, in.	7	13½	18	25	26
Horse power of motor		1	1¼	2	2¾	5

Screw-machine Tools. **Spring collets** and **feed chucks** grip the bar while feeding and machining. **Box tools and hollow mills** are used for external cutting. Box-tool practice favors carbon steel for radial-type cutters, and high-speed steel for tangent cutters for roughing. Recommended **sizes of the cutters** for box tools are: For stock up to 5/16 in. diam., 3/16 in. sq.; for 5/16 to 3/8 in. diam., 7/32 in. sq.; for 3/8 to 1/2 in. diam., 1/4 in. sq.; for 1/2 to 3/4 in. diam., 5/16 in. sq.; 3/4 to 1 in. diam., 3/8 in. sq.; 1 to 1 1/4 in. diam., 1/2 in. sq.

Table 47. Cutting Speeds and Feeds for Screw Stock

For brass the cutting speed should be three times as great and the feed per revolution from 25 to 50 per cent. greater.

For hollow mills on screw stock the cutting speed should be as in the table and the feed per revolution 30 per cent. greater than the tabulated values.

1/32-in. Chip				1/16-in. Chip				1/8-in. Chip

In **tapping and threading**, the hole should be a little larger and the part to be threaded a little smaller than the theoretical root and outside diameters, respectively, of the thread to be cut. Suitable allowances are given in Table 53.

Speeds and Feeds for Screw-machine Tools. Tables 47 to 53, inclusive, give speeds and feeds for automatic screw-machine stocks and tools, and represent good practice. They are taken from "Automatic Screw Machines and Their Tools," by Goodrich and Stanley, and used here by permission. With the exception of Table 52 for dies, the values are based on carbon-steel tools. The die table is based on the use of high-speed steel dies. For

Forging, Hardening and Tempering High-speed-steel Tools

A high-speed-steel bar ought always to be nicked hot on all four sides for cutting off. If this is not done there is danger of splitting at the ends. A temperature of 1400 to 1500 deg. fahr., or a dull cherry red, is best. The following instructions for forging round-nose roughing tools such as have been introduced into the United States Navy are given by W. H. Taylor (*Am. Mach.*, vol. 33, part 1, p. 432). Set stop to length of tool, *L*, (see Table 24). Heat slowly to forging heat (1800 deg. fahr.). Cut-off piece in gage (see *A*, Fig. 9). Heat slowly to forging heat *X* in. back from end (see Table 24). Put bending die on anvil. Put tool in die and drive down (*D* and *E*, Fig. 9). Flatten sides at bend (*F*). Draw down heel (*G* and *H*). Straighten bottom (*J*). Straighten front (*K*) and spread nose to width *B* as given in Table 24. Heat slowly to forging heat. Mark off height *H* (Table 24) with 20 deg. height gage (*L*). Cut back slope and side slope roughly (about ⅛ in. higher than finished height) as in *M*. Trim nose to shape. Offset to suit limit gage (*P*). Keep base of tool straight. Test clearance angle, back and side slope with cone and limit gages.

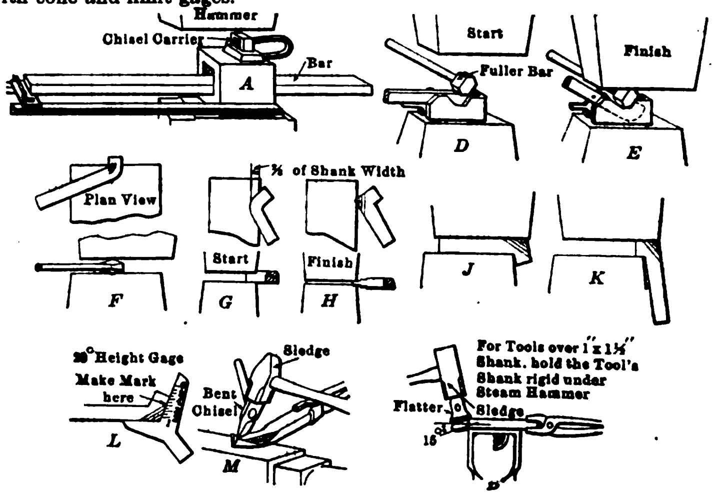

Fig. 9.—Forging Operations for Straight Round-nose Roughing Tool.

The rules governing the heating of high-speed-steel bars preparatory to cutting off and for forging are as follows:

In forging high-speed steel, care must be used not to heat the steel too rapidly nor to work it too cold. A yellow heat, or 1800 to 1900 deg. fahr., is the temperature at which best results will be obtained. Tools should not be left in the furnace more than a minute or two after reaching the forging heat, as the steel is injured if it is allowed to soak at a temperature above 1500 deg. fahr. Below this temperature high-speed steel does not work readily and there is danger of its breaking or developing cracks if heavy work is done on it.

In working, when a tool cools to a cherry red it should be put back in the furnace and another taken that is heated to the forging temperature. From 4 to 6 tools should be kept heating at a time. When one is finished, another should be placed in the fire and still another on the hearth to preheat.

Hardening High-speed-steel Tools. (See also p. 482.) To get the best and most uniform results (F. W. Taylor, *Trans. A. S. M. E.*, vol. 28, p. 227) the tools should first be heated to a temperature between 1500 and 1700 deg. fahr. and then cooled rapidly to a point *below* the breaking-down point (1550 deg.), preferably in a bath of molten lead kept below a temperature of 1550 deg. The quality of the tool is but little affected whether cooled rapidly or slowly from this point down to the temperature of the air. After all parts of the tool have reached a uniform temperature below the breaking-down point, it may be laid in some place free from moisture and allowed to cool in the air or in an air blast. The temperature of a tool should *never* be allowed to rise after the cooling-down process has started; failure to observe this caution will result in injury to the tool.

The second, or low-heat, treatment consists in reheating the tool which has had the high-heat treatment in a lead bath to a temperature between 700 and 1240 deg. fahr., preferably near the higher temperature. To avoid the danger of cracks if the tool is a complicated shape, it is well to heat it slowly before it is plunged into the lead.

The good effects of the second treatment can be obtained by running the tool under cut until its nose has been raised to between 700 and 1240 deg. fahr. and then allowing it to cool in the air; the next time it is used it will have a materially increased degree of red-hardness.

Higher temperatures are now used for heating than those originally recommended by Mr. Taylor. The newer high-speed steels are treated by heating them slowly to 1500 deg. fahr., and then rapidly to a temperature between 1850 and 2450 deg.; they are then cooled rapidly in a blast down to 1500 deg., and then cooled either slowly or rapidly to the temperature of the air. There must be no reversal of the cooling process, once it has commenced.

The hardening and tempering temperatures for ordinary forms of cutting tools in deg. fahr. are as follows:

Lathe, planer, shaper and slotter tools: hardening temperature, just below melting point (2450 deg. down) depending on the steel. Milling cutters and similar tools for heavy cuts: hardening temperature, 2375 to 2450; drawing temperature, 400. Milling cutters for light work, screw-machine tools, brass-working tools: hardening temperature, 2100 to 2300; drawing temperature, brass-working tools, 450; others, 400. Drills, reamers, dies and taps: hardening temperature, 2150 to 2200; drawing temperature, large drills and reamers, 440; small drills and reamers, 460; dies and taps, 490. Punches and dies, shear blades and tools subjected to blows: hardening temperature, 1750 to 1900; drawing temperature, tools subject to blows, as snaps and chisels, 570; others, 530. Woodworking tools: hardening temperature, 2100 to 2300; drawing temperature, 525 to 625.

Quenching. Air and oil are used for cooling mediums. Cold water should be avoided, but hot water has been successfully used in special cases to get extreme hardness. Oil is now preferred, as it is believed that its use results in more uniform hardening and greater toughness. Linseed, cottonseed, whale, rape, paraffin and kerosene oils are all used, the necessary properties being thinness and freedom from gumming. The disagreeable odor of whale oil can be minimized by covering the surface with a layer of tempering oil.

Barium Chloride Bath. Because of trouble from oxidization on thin edges of cutting tools, experiments have been carried out with baths covering the heated portion with a protecting coating. The most extensively used salt is barium chloride mixed with about 2 per cent. of soda ash. Its melting point is 1635 deg. fahr.—considerably higher than that of lead. A vertical gas-fired furnace is generally used, with the chloride in a graphite crucible. A temperature in the bath of 2200 deg. is easily obtained.

This bath is used particularly for milling cutters and other tools having keen, thin edges. It is not used for heavy roughing tools.

Occasionally there is trouble from pitting, which seems to be due to melting in spots. This can be largely avoided by not allowing the temperature to run too high.

Care must be exercised in grinding high-speed steel cutters to prevent checking. The best practice is to heat the tools before grinding to a temperature of 200 to 250 deg. fahr., and grind under a copious supply of water. Intense local heating must be avoided in grinding.

Heating Furnaces. Coke, anthracite, oil and gas-fired furnaces are used to heat high-speed steel tools for hardening. In general, oil fuel is not well suited to obtain and regulate the high temperatures required, and considerable oxidation results. Coke and anthracite fuels are satisfactory, but the furnace must have a floor or hearth to keep the tools away from the fire bed. Gas is the most commonly used fuel, and is unquestionably the most convenient.

The minimum equipment for hardening high-speed steel tools is a combined forging and heating furnace, an air blast and an oil quenching bath.

The flame should be directed around the interior of the furnace chamber rather than directly into it, so as to prevent the impinging of the flame upon the tool. The air supply should be at a pressure of 1½ to 2 lb. Both gas and air must be controll-

Table 54. Sizes and Gas Consumption of Furnaces for Tool Hardening

Kind of furnace	Dimensions of heating chamber, in.	Gas consumption,* cu. ft. per hour	Work for which furnace is intended
Bench forge	2½ × 2 × 6	50	Dressing small tools.

* Based on the heating value of city illuminating gas. The air pressure should be about 1 lb. per sq. in., and in the nature of a positive blast.

able. Table 54 gives data on a few sizes of hardening furnaces made by the American Gas Furnace Co.

The air nozzle should not be less than ¾ in. in diameter. **Milling cutters** are mounted on a revolving spindle to bring all parts under the action of the blast.

The **oil tempering bath** is held in a metal tank or pot in a simple furnace which is usually provided with a hood connected with an exhaust system to remove the fumes. Small parts are suspended in a wire-mesh basket or perforated pan; large tools are suspended by wires, or in any convenient manner. Whale and black cylinder oils and tallow are used.

WOOD-WORKING MACHINES

Wood-working machines are characterized by the high speed of the cutters, and this peculiarity requires careful fitting of journals, their bearings and cutting tools, with balancing of all rotating parts. The greater part of the motive power is needed to overcome frictional resistance. Ample lubrication is important and is most satisfactorily obtained by using dust-proof ring oilers; grease should be avoided. The frictional resistances are greater at starting than during normal running, and considerable power is required to accelerate the moving parts; consequently the starting power is much greater than that needed for ordinary operation.

Because of the rapidity with which operations are performed, the supply of lumber, removal of chips and finished material should be adequately provided for; chips are usually handled by a suction or exhaust system through galvanized iron pipes into a dust separator, then into a storage room. The uncut material and finished material are stacked on trucks or transported by some form of mechanical conveyor. Considerable floor space is needed around wood-working machines for stock.

Motor Drive. Both group and individual electric motor drives are used. The general comparison is the same as for metal-cutting machines (see p. 1467). Because of the high speeds used, direct connection can often be made from cutter shaft to armature shaft.

Saws

Circular Saw Blades are of two kinds, solid and with inserted teeth. Tables 55 and 56 give particulars regarding commercial sizes of **solid-tooth saws** and Table 57 of **saws with inserted teeth.**

Band-saw Blades. Dimensions of narrow band-saw blades are given in Table 58. Band saws 2 to 18 in. wide increase in width by steps of ½ in. up to 6 in., and by 1-in. steps thereafter. The usual B.W.G. thicknesses are as follows: 2 to 3½ in. wide, 18 to 20; 4 to 6 in., 17 to 19; 7 in., 16 to 18; 8 to 11 in., 14 to 16; 12 to 14 in., 13 to 15; 15 to 18 in., 12 to 14.

Table 58. Dimensions of Narrow Band-saw Blades

Width, in.	Usual thickness, B.W.G.	Number of teeth per in.	Width, in.	Usual thickness, B.W.G.	Number of teeth per in.
⅛	22 or 23	6 or 7	⅞	20 or 21	2½ or 3
3/16	21 or 22	6	1	20 or 21	½" or ⅝" pitch
¼	21 or 22	5 or 6	1⅛	19 or 20	½" or ⅝" pitch
⅜	21 or 22	4 or 5	1¼	19 or 20	½" or ⅝" or ¾" pitch
½	21 or 22	3½ or 4	1⅜	19 or 20	½" or ⅝" or ¾" pitch
⅝	20 or 21	3–3½ or 4	1½	19 or 20	1" or 1¼" pitch
¾	20 or 21	2½ or 3	1¾	19 or 20	1" or 1¼" pitch

Notation.

h = thickness of cut, in.
H = stroke of gang saw, in., $\geq h$
t = pitch of saw teeth, in.
s = thickness of blade, in.
u = peripheral speed of blade, ft. per min.
n = r.p.m.
f = feed per min., in.
f_1 = feed per stroke, in.
D = diam. of circular saw blade or band-saw wheel, in.
L = free length of gang-saw blade, in.
P = cutting resistance, lb.

Pitch of Teeth in Saw Blades. For solid blades with set teeth, $t = 0.97\sqrt{kh}$, and for swaged or inserted teeth cutting their full width, $t = 1.38\sqrt{kh}$. For band saws, $k = 0.02$ to 0.1; for gang saws, $k = 0.08$ to 0.4; for circular saws, $k = 0.1$ to 0.6.

Speed-Feed Ratios for Saws. For the maximum permissible rate of feed the following relation holds: $f/u = f_1/H = 0.0072(t/h)$.

Practical values of these ratios are:

For heavy circular saws for logs	f/u =	0.00083	to 0.000083
For circular rip saws	f/u =	0.00023	to 0.000047
For fine-toothed circular saws	f/u =	0.000083	to 0.000012
For heavy band saws for logs	f/u =	0.00023	to 0.000023
For gang saws	f_1/H =	0.03	to 0.003
For veneer saws	f_1/H =	0.002	to 0.0005

Cutting Speeds. The cutting speeds commonly employed (ft. per min.) are as follows:

Circular rip saws for hard, knotty wood	3,000 to 6,000
Circular rip saws for oak	4,000 to 8,000
Circular rip saws for soft woods	6,000 to 12,800
Circular cross-cut saws	3,000 to 6,000
Band rip saws	4,000 to 8,300
Band cross-cut saws	2,000 to 5,000
Gang saws (when $u = 2Hn$):	
Heavy frames	500 to 700
Light vertical frames	700 to 800
Horizontal frames	800 to 1,400

According to *Wood Craft* (Oct., 1912), satisfactory speeds (r.p.m.) for other types of saws are: For resawing machines, 250 to 300; scroll saws, 200 to 400; jig saws with spring tension, 500 to 800; jig saws with unstrained blades, 800 to 1500.

Cutting Resistance. The cutting resistance of a saw in lb. $= P = Cshf/u = Csf_1$, where $C = 1{,}200{,}000$ to $2{,}900{,}000$.

Thickness of Saw Blades. For circular saws, $s = 0.02\sqrt{D}$; for gang and band saws, $s = L/800$. The **tension** in gang saws (lb.) should equal $1{,}138{,}000s^2$; for band saws, when $D \geq 1000s$, tension $= 569{,}000s^2$.

Resistance to Feeding. For circular saws, resistance $= 1.25P$; for gang or band saws, resistance $= P$, where P = cutting resistance, lb. The force (lb.) required to feed a log to a circular saw (including that required to move the timber carriage and the log) $= 0.006W + 1.25P$, where W = weight of log, lb.; for a band or gang saw, force $= 0.006\,W + P$.

Power Requirements of Saws. The horse power required by a saw $= N = N_0 + N_1$, where N_0 = h.p. required to overcome the friction of the machine and N_1 = h.p. expended in cutting. In the following formulæ b = width of saw cut, in., and F = area (length cut × thickness of lumber) cut per hour, sq. ft.

For circular saws,

$$N = \frac{nD}{32{,}000} + \frac{2.36bF}{(14 \text{ to } 28)}$$

For **band saws** N_0 = 0.3 to 3 h.p. (up to 9 h.p. for large log saws);

$$N_1 = \frac{37 + 0.01b(u/f)}{10{,}764}F \text{ for pine}$$

For oak, substitute 52 for 37 and 0.0124 for 0.01. For red beech, substitute 62 for 37 and 0.0148 for 0.01.

For **gang saws**, N_0 = 0.25 to 3 h.p. and

$$N_1 = \frac{46 + 5.7b(H/f_1)}{10{,}764}F \text{ for air-dry pine}$$

According to Hermann's investigations, for **gang saws with freshly sharpened teeth,**

$$N_1 = K\left[1 + \frac{b + 0.118}{t}\left(4 + \frac{H}{100f_1}\right)\right]F$$

where K = 1/315 for pine, 1/361 for fir and 1/347 for deciduous trees. After z hours of operation the value of N_1 should be multiplied by $(1 + 0.145z - 0.005z^2)$.

According to Dodge, for circular rip saws running at from 7000 to 9000 ft. per min., h.p. (approx.) = $D^2/40$, and for band saws (at 3500 ft. per min.), h.p. = $D^2/300$.

Drum or Cylinder Saws are used for sawing staves and work having a concave or convex surface. They are made up to about 3 ft. in length and are run at a maximum peripheral speed of 6000 ft. per min.

Planers

Jointers and Buzz Planers are common pattern-shop tools used to surface, to edge, and for general work. Some styles admit of the use of special cutters, so that surfacing and beading, surfacing and molding, and surfacing and grooving may be done at one time. The feed is by hand. Common **sizes** and horse power required are:

Size, table width in inches	8	12	16	20	24	30	36
Horse power required	1	1½	2	2	3	4	4

The table is in two sections adjustable for height with reference to the cutter to admit of different thicknesses of chip. Table lengths range from 6 to 7 ft. **Cutting speeds,** 3500 to 5000 ft. per min.

Cylinder Planers or **surfacers** are built as single and double machines. The first has one cutter arbor or cylinder and two feed rolls set close to it, the upper one being fluted. The second has two cylinders, an upper and lower, and four, six or eight feed rolls in different sizes and designs. The roll pressure should be from 27 to 55 lb. per inch of roll length. Cylinder planers are used for surfacing the heavier sizes in planing mills, box shops, sash, door and blind factories, furniture and cabinet factories and general jobbing. The smaller sizes are used on patterns, furniture, chairs, and fine door and panel work. Common **sizes** (maximum width and height planed) and horse power required for single machines:

Sizes, inches	16 × 16,	20 × 6,	24 × 6,	24 × 8,	26 × 8,	30 × 7,	36 × 7
Horse power	2 to 4,	2 to 4,	2 to 4,	5,	5,	5 to 7,	5 to 7

Common sizes (maximum width and height planed) and horse-power required for double machines:

Size, inches	24 × 8,	30 × 8,	30 × 10,	36 × 7
Horse power	7,	5 to 8,	6 to 8,	7 to 10

Heavy-type machines may take 50 per cent. more power than the above values. An approximate rule is: h.p. = 1/4 × width of cut in inches.

The rates of **feed** in the single machines range from 16 to 50 lin. ft. per min. usually in two, three or four rates. The double machines usually feed at a somewhat higher rate, from 20 to 80 lin. ft. per min. being a normal range, with four or six rates. Four-cylinder planers for squaring timbers have feeds up to 150 ft. per min. **Cutting speeds** range from 3500 to 10,000 ft. per min. The diameter of the path of planer knives ranges from 3.5 to 10 in. Planers to be used chiefly on walnut, ash, oak or other hardwoods will give better results if run at about 75 per cent. of the speeds used on softwoods.

Shapers

Shapers are made with one or two vertical spindles carrying knives ground to any desired contour. The work is slid over the table and drawn past the revolving cutter heads, the depth of cut being controlled by a collar under the knives. When two spindles are used they rotate in opposite directions, and at speeds of from 5000 to 7000 r.p.m. According to Dodge, h.p. (approx.) = width of cut (in.) + depth of cut (in.).

Lathes

Pattern-makers' Lathes differ from metal-turning lathes in being simpler in construction, lighter in design and in usually having provision to swing a large face plate from the outer end of the spindle across the end of the bed. The ways are frequently made flat to provide a convenient place to lay tools. These machines are used for all kinds of hand and power turning in wood where a single or only a few pieces of a kind are needed. Common **sizes** are 16, 20, and 24 in. swing, requiring respectively 1 1/2, 2 and 2 1/2 h.p. The standard bed length is 8 ft., but longer ones (10, 12, 14 and 16 ft.) can be furnished. Spindle **speeds**, up to 2000 r.p.m.

Automatic Back Knife Lathes are used in manufacturing cylindrical parts of wood of both simple and complicated shapes. A formed knife set at an angle with the axis of the work is fed downward to form it. Sizes and horse-power requirements are as follows:

Length turned, in.	Diameters turned, in.	Size of squares that can be left, in.	H.p.
28 and 36	3/16 to 2 3/4	2 × 2	3 to 5
40 and 50	1/4 to 3	2 1/4 × 2 1/4	4 to 6
40 and 50	3/4 to 5	3 1/2 × 3 1/2	5 to 8
45 and 52	3/16 to 2 3/4	2 × 2	3 to 5

Boring Machines

Boring machines for wood are lighter in construction than metal-drilling machines and are built for higher spindle speeds.

Bench Machines consist of a frame carrying a single pulley, and arranged to feed by sliding the spindle through its bearings. A common size will bore holes up to 1 1/2 in. in diam.

Vertical Machines are made in the form of simple machines to fasten to posts and taking from 1/2 to 1 h.p.; as machines resembling sensitive drilling machines for metal, taking from 1 to 1 1/2 h.p.; as heavy machines with universal tilting tables, requiring from 2 to 3 h.p.; and as multiple-spindle machines designed to bore heavy timbers in bridge and car work, and taking from 2 to 5 h.p. In most types the spindle is fed down by foot pressure, though some have a hand lever arranged for a direct pull.

Horizontal Boring Machines are used for small work where a number of holes are wanted closely spaced. In general, the table is mounted on a knee and arranged to tilt for angle boring, and has an adjustable fence. The feed is by a foot lever. Smaller sizes capable of driving a 2-in. bit require up to 1 h.p. to drive; larger sizes to drive up to a 3-in. bit require up to 2 h.p. Ordinary spindle speeds range from 2500 to 4000 r.p.m.

Bits and Drills. Both auger bits and twist drills are used. The bits are listed in sixteenth sizes running from 3/16 to 24/16 in. and in any lengths desired. Short dowel bits are made 3 in. long over all, and long dowel bits 4½ in. over all. They have a gimlet point to draw into the wood and aid in feeding.

Mortising Machines

Mortising machines have a vertical spindle which carries a short chisel at its lower end and is given a rapid reciprocating motion from an overhead crank disk. Provision is made for reversing the chisel face so that cutting can be done in either direction of the table motion. The work is clamped to the table, which is moved to the right or left by a hand wheel. A boring spindle is usually provided to make a hole in which the chisel may start cutting. In another type a square hollow chisel is used, in which an auger bit revolves at a high speed and removes the chips as the chisel is slowly forced into the wood. The following speeds for reciprocating mortisers are recommended in *Wood Craft* (Oct., 1912): Machines with movable tables, 300 to 450 r.p.m.; machines with chisel-feed tables, 250 to 350 r.p.m.; heavy machines for car work, 200 to 300 r.p.m.

Pattern-making Machine

There are several machines known as **mechanical or universal wood workers** that are extensively used in large pattern shops. Each style is universal in its adjustment and motions and is adapted to produce irregular and regular sections as gear patterns, worm patterns, core boxes, pulley patterns, and for mortising, tenoning, radius cutting, forming bends, etc. The spindle can be used in a vertical, horizontal or any intermediate inclined position. Speeds range from 1250 to 3600 r.p.m. The feed movements are ndependent of any movement of the head, and are obtained through either quick-acting lever or sensitive feed screw.

Pattern-makers' Disk Grinders

These are a type of abrasive disk grinders for smoothing, forming and sizing wooden patterns and their parts. They will work knots, cross grain, end grain, and even projecting nails and screws. They are also used on metal patterns. Both single- and two-disk machines are made, for motor drive and for overhead or through-floor drive. The grinding wheel is a metal disk to which an abrasive-coated cloth or paper is pasted.

Size (disk diam.), inches	24	30	40
Disk speed, r.p.m	950	750	525
Horse power	2	3	5

ELECTRIC DRIVES

By

C. DAY

Advantages of the Electric Drive. The general advantages possessed by the electric drive are as follows:

It imposes no restriction on the location of equipment, but permits the best location of machinery from the standpoints of sequence of operations, handling of materials, light and facility of operation.

It imposes no restrictions as to character of buildings and permits of the adoption of the least expensive type of building construction and the minimum headroom consistent with the efficient housing of the machinery, equipment and process work.

The use of mechanical transmission frequently involves additional cost of building construction, owing to the loads imposed on ceilings, roof trusses or columns, through hanging line shafting and countershafts from same. In addition, it is necessary in certain cases to provide greater headroom than would otherwise be required in order to obtain proper belt centers or for the purpose of securing greater window area in order to compensate to as great an extent as possible for the light obstructed by belts and countershafts.

It permits of the most efficient overhead handling facilities. Machines can be located under traveling cranes, jib cranes, etc.

It imposes no restrictions in connection with the construction of independent buildings.

It permits of the most efficient operation of machinery from the standpoints of power and speed.

By means of the direct-current, adjustable-speed motor it is possible to drive any type of machinery to its maximum power capacity and to obtain any gradations of speed desired. In the case of machine-tool equipment, however, the problem of adjustable-speed control has been accomplished with fair satisfaction by means of change gearing.

It permits of the greatest facility in starting, stopping and adjustment of the speed of machinery.

It permits of more continuous operation.

It permits of the operation of one or more machines while the rest of the plant is shut down.

For general data on the **application of the electric drive to machine tools,** see p. 1418. See also pp. 1617, 1629 and 1640 for **motor characteristics.**

Cost of Drive. When making a comparison of the cost of drives there should be included the cost not only of the entire equipment required in connection with the generation and distribution of power, but all collateral costs such as those incurred through special building construction; for example, belt or rope towers, necessary members to carry line shafting, additional headroom to secure adequate natural lighting, etc.

Cost of Maintenance. The cost of maintenance should include all expenditures for supplies such as oil, grease, waste, etc., and for labor in lubricating transmission devices, keeping shafting in alignment and in making repairs. Records covering 8 years show that the annual maintenance cost of mechanical installations varies from 2 per cent. to 15 per cent. of the first cost of equipment; for electrical installations the range is from ½ per cent. to 8¼ per cent.

Individual Drive vs. Group Drive. The use of the individual drive is imperative when variable or adjustable speed is required. It is also needed in connection with portable equipment and for the operation of machinery which is so located as to be inaccessible to the motor-driven lineshaft. When these conditions do not apply, the group drive is entirely satisfactory and ordinarily involves a smaller investment.

Selection of Motors for Electric Drive. The types of motors available as regards speed conditions are (*a*) constant speed, (*b*) multi-speed, (*c*) adjustable speed and (*d*) varying speed (see p. 1640). Torque conditions met with are either (*e*) constant or (*f*) varying; and load conditions are either those of (*g*) frequent overload or of (*h*) no overload. The following speed-torque-load combinations are frequently encountered: *aeg*, *aeh*, *beg*, *beh*, *bfg*, *bfh*, *cfg*, *cfh*, etc.

Thus, the machine to be driven may require a constant-speed, constant-torque motor capable of withstanding heavy overload (*aeg*); or it may require an adjustable-speed motor where the torque will vary in direct proportion to the speed and will never require any overload capacity (*cfh*); or it may require a motor that will exert a constant torque at only two definite speeds (*be*), etc.

Standard Practice. In general, the following statements may be considered as representative of standard practice:

1. Machines of present design for comparatively small work requiring constant-speed drive should be grouped in most instances and operated from motor-driven lineshafts.

2. For group driving both direct- and alternating-current motors give satisfactory results. In certain industries (textile mills, for example) the induction motor has decided advantages on account of close speed regulation with varying loads and lessened fire risk, but for machine shops these features are unimportant.

3. Mechanical means of speed control, by step cone pulleys, variable-speed countershafts or by gearing, is usually costly, if the machinery must be stopped to change from one speed to another and if it cannot be controlled from an independent point. It may also be inefficient.

4. For adjustable-speed work, direct-current motors of the field-weakening type are now used almost exclusively. It is hardly practicable to secure by this means a range greater than six to one, and in most cases the best economy is attained by limiting the range to three to one. In many instances it is necessary to resort to a combination of mechanical and electrical control, the disadvantages of each method being largely done away with by this means. Even where machines are handling a very general line of work, the greater part of it will be covered by a range of three to one, so that if this is obtained electrically, gear changes seldom will be necessary and at the same time comparatively inexpensive motors may be used.

5. The necessity of long-distance transmission lines may make alternating current desirable from the standpoint of line losses. When such conditions exist it is customary to use alternating-current motors for constant-speed requirements, and direct-current, adjustable-speed motors operated by current from a motor-generator or rotary converter for the adjustable-speed requirements. If but one kind of current is available, decision should be governed by the number of individual adjustable-speed drives required. In many instances, while group drives may be desirable at the start, new equipment should be purchased with individual motors for the sake of adjustable speed, ease of control, etc.

6. The most desirable voltage at which to transmit current through the various buildings and departments of an industrial plant is about 230.

7. If alternating current is to be used, 60-cycle, three-phase is recommended, as it meets satisfactorily both the light and power requirements and has been adopted as standard by a majority of the central station companies.

INDUSTRIAL MANAGEMENT

By

C. M. SAMES

REFERENCES: Diemer, "Factory Organization and Administration;" Emerson, "Efficiency as a Basis for Operation and Wages," and "Twelve Principles of Efficiency;" Ennis, "Works Management;" Evans, "Cost Keeping and Scientific Management;" Gantt, "Work, Wages and Profits;" Gilbreth, "Motion Study;" Going, "Principles of Industrial Engineering;" Hartness, "The Human Factor in Works Management;" Kimball, "Principles of Industrial Organization;" Lodge, "Rules of Management;" Parkhurst, "Applied Methods of Scientific Management;" Taylor, "Shop Management," and "Principles of Scientific Management;" files of *American Machinist*, *The Engineering Magazine* and *Industrial Engineering*.

Types of Organization. Under the **ordinary** or traditional **type** of organization groups of workers are in charge of foremen, who assign to them their tasks, supply whatever instructions are considered necessary, and exercise a general supervision of the output and of the methods employed in production. The foremen report to and receive orders from superintendents, who in turn are responsible to the general manager, the organization being **military in form** as regards the allocation of authority. Under this type of organization whatever economy in production has been effected has been largely that due to the introduction of labor-saving machinery and processes. Improvements are also possible in the methods employed in the management of industries, which should result in still further increase in economy of production. Dr. Frederick W. Taylor first formulated a system of management having this end in view, in a paper read before the American Society of Mechanical Engineers, in June, 1903. For the military type of organization he substituted a **functional type,** foremen and superintendents being replaced by eight functional officials, each of whom came into direct contact with and exercised authority over individual workmen within strictly defined limits. At a little later date Mr. Harrington Emerson put into practice a system in which the **military type** of organization was **supplemented by a staff** of counselors made up of **experts** in each department of the industry. Variants of these two systems have also been installed. In all of them each step in production is directed by an expert having special knowledge of his particular field, the activities of these specialists being co-ordinated by the system employed.

Planning Department. The important feature of the Taylor system of functional management (generally known as **"scientific management"**) is the **separation of the planning** of how production shall be accomplished **from the performance** of the work. The former is carried out by a planning department, the duties of which are to determine *how* and *when* work is to be done. Taking a machine shop as an example, this includes laying out the route each piece is to travel through the shop and specifying the machines upon which the work is to be done and the workmen who are to do it. With a knowledge of the course of work obtained by means of daily reports from the shop, the planning department, by proper changes in the **routing** of various jobs (standardization of equipment permitting this), is enabled to reduce the time that machines and men are idle to a minimum. All jobs are given out to workmen accompanied by **instruction cards** prepared by the planning department, which specify among other things the special tools or fixtures that must be used, the speeds, feeds, etc., to be employed, the time within which each operation should be completed, and the extra compensation to be received by the workmen if he performs his task within that time. The information embodied in these instruction cards is derived from data accumulated and classified by the department from the results of engineering investigations, experiments and time studies. For example, the determination of the speed, feed and depth of cut to be used in removing metal is not left to the judgment of the operator of the machine, but these are specified by the planning department at rates which their experiments or the records of experiments of others show will result in the metal being removed with maximum economy, wear and tear of machinery, cost of power, cost of regrinding tools, etc., all being taken into consideration. The various operations employed in production are subjected at one time or another to **time study,** by means of which each operation is resolved into a number of elementary operations, and a fair average time for performing each is determined. Such analyses make it nearly always possible to reduce the gross time required for an operation, by indicating where a given number of movements or elementary operations may be replaced by fewer, simpler, more quickly performed or less fatiguing movements, this often being accomplished by merely altering the relative positions of the man, the work and the machine (**motion study**). From the accumulated and classified records of elementary time requirements the department is generally able to predict the probable time required for the production of a given piece of new work, by synthesis of its data. From returns made by the workmen the department determines their compensation and also the cost of work. Records of stores are also kept by the planning department.

Following is an illustrative **time study** of a simple operation (drilling a hole 1 in. deep in an iron casting with a ⅜-in. high-speed drill). The drill press is assumed to be ready for use. The timing is done with a stop watch reading in hundredths of a minute.

	Time in minutes 1st trial	2d trial	3d trial	Average
*1. Place drill in spindle	0.40	....	....	....
*2. Place jig on table	0.40	....	....	....
*3. Center jig bushing with drill	0.45	....	....	....
*4. Bolt jig to table	1.20	....	....	....
*5. Adjust height of table	0.75	....	....	....
*6. Change speed and start machine	0.50	....	....	....
7. Pick up piece and place in jig	0.05	0.04	0.05	0.05
8. Clamp piece in jig	0.20	0.22	0.21	0.21
9. Drill hole at 1000 r.p.m.	0.20	0.21	0.22	0.21
10. Unclamp drilled piece and place in removal box	0.05	0.05	0.04	0.05
*11. Remove drill and jig from machine	1.50			0.52
Total machine time (items marked *) =	5.20 min.			
Average time for drilling each piece =	0.52 min.			

A study of the elementary machine times often indicates possible simplifications of procedure which will result in a decrease of the total machine time.

An instruction card for the preceding operation on a lot of 30 pieces would embody, in a printed heading, data as to the drawing number, the shop number of the machine, the order number, the material to be worked upon, the number of pieces in the lot, the time allowed for completing the work, the bonus to be paid for completing the lot in the given time, and the following detailed instructions:

	Time per piece, min.	Time for entire lot, min.
1. Obtain instruction card and learn what is to be done	....	4.00
2. Place drill in spindle	....	0.40
3. Place jig on table	....	0.40
4. Center jig bushing with drill	....	0.45
5. Bolt jig to table	....	1.20
6. Adjust height of table	....	0.75
7. Change speed of machine and start	....	0.50
8. Pick up piece and place in jig	0.05	....
9. Clamp piece in jig	0.21	....
10. Drill hole at 1000 r.p.m.	0.21	....
11. Unclamp drilled piece and place in removal box	0.05	....
12. Remove drill and jig from machine	....	1.50
Time allowances:		
Handling time, 50 per cent., of items 8, 9, and 11	0.16	....
Machine time, 10 per cent. of item 10	0.02	....
Totals	0.70	9.20

Time for lot = (30 pieces × 0.70) + 9.20 = 30.2 min.

The **tool list** furnished to the gang boss by the planning department would indicate the jig (by symbol-number) and drill to be delivered to the workman by the tool-room messenger, the former in good working order and provided with bolts having easy-running nuts and smooth threads, the latter properly sharpened.

Production Department. Under the Taylor system of management the orders issuing from the planning department are executed in the shops under the directions of four functional foremen (and their assistants), known respectively as the gang boss, the speed boss, the repair boss, and the inspector. The **gang boss** sees that all materials, tools, fixtures, special supplies, etc., are delivered to the workmen at exactly the time they are needed, and that finished pieces are promptly removed after they have been inspected. The information upon which he works is furnished to him by the planning department in the form of route sheets, tool lists, etc. The function of the **speed boss** is to see that work is performed exactly in accordance with the specifications of the instruction cards, and, in case of inability on the part of the workman to comprehend the instructions or to do the work in the allotted time, to teach him the proper procedure. The **repair boss** is required to keep all machinery and power-transmitting devices in first-class working order, seeing to it that they are well cleaned and properly lubricated, that belts run at proper tensions, etc. The **inspector** accepts or rejects finished work after examination and measurements made thereon. An additional member of the planning department staff is the **disciplinarian,** an official removed from all shop influences, to whom all disputes and differences between foremen and men are referred for adjustment. In Mr. **Emerson's system** the same general ends are sought as in the Taylor system, but through the activities of a line organisation supplied with information and counseled by a staff of experts guided by certain principles of efficiency which he has formulated.

Bonus Wage Systems. Where the co-operation of workmen can be secured, modern management methods make it possible greatly to increase the output of a given industry without increasing the number of its employees —in some cases to more than double it. Workmen, however, generally view the introduction of strange or novel methods with apprehension, and are reluctant to adopt them. To enlist their co-operation various methods of bonus wage payment have been devised, whereby a part of the money savings made possible by increased production is given to the workmen, who receive from 20 to 40 per cent. greater returns for their labor than they could obtain in competing establishments where efficient methods have not been installed. It is insisted upon by those advocating the new systems of management that the utmost good faith must always be maintained with the workmen, and that rates once set must not be lowered so long as the original method of working is followed, the management bearing all losses due to errors in calculations which may in isolated instances result in abnormally high wages.

In the **Taylor differential-piece-rate system** of compensation the workman receives a certain (low) rate per piece for production falling below the standard set, and a much higher rate provided his production attains or exceeds the standard. In the **Gantt task-and-bonus plan** a definite task for a given time is prescribed; if the workman accomplishes his task within the allotted time he is given a bonus in the form of an extra time allowance (25 to 50 per cent. usually); should he fail to accomplish his task as set, however, the management guarantees that he shall still receive his day rate. In the **Emerson plan** the workman is assured initially that he will receive his day wage, whatever the amount of his production. As soon, however, as he attains a production of 66⅔ per cent. of the standard set, he begins to receive a small bonus, which increases rapidly with an increase in the percentage of his efficiency, and substantially as follows:

Effy., per cent.	Bonus per \$1 of wages, cents	Effy., per cent.	Bonus per \$1 of wages, cents	Effy., per cent.	Bonus per \$1 of wages, cents	Effy., per cent.	Bonus per \$1 of wages, cents
67	0.01	75	1.31	87	7.56	100	20
68	0.04	77	1.99	90	9.91	105	25
69	0.11	80	3.27	92	11.62	110	30
70	0.22	82	4.33	95	14.53	120	40
72	0.55	85	6.17	97	16.62	140	60

The following table, arranged from three published in Kimball's "Principles of Industrial Organization," serves to illustrate the application of the bonus systems described; the rates and bonuses, however, are arbitrarily chosen, and no attempt is made to compare the systems. The task assumed is the machining of pieces of metal, bonus beginning at the standard output of 30 pieces a day. A machine rate of \$2.50 per day is also assumed. In the Taylor system the day wage is not assured to the workman; in the Gantt and Emerson systems he is assured (in the illustration) of a daily wage of \$3 regardless of his output. (It is to be understood of course that men would not be retained under any system on work where they proved to be hopelessly inefficient.)

		Taylor			Gantt			Emerson			
Number of pieces a day	Cost of material, \$	Piece rate, cents	Daily earnings, \$	Cost per piece, cents*	Bonus, \$	Daily earnings, \$	Cost per piece, cents*	Efficiency, per cent.	Bonus, \$	Daily earnings, \$	Cost per piece, cents*
10	1.00	10	1.00	45.0	0.00	3.00	65.0	33⅓	0.00	3.00	65.0
15	1.50	10	1.50	36.7	0.00	3.00	46.7	50	0.00	3.00	46.7
20	2.00	10	2.00	32.5	0.00	3.00	37.5	66⅔	0.03	3.03	37.5
30	3.00	15	4.50	33.3	1.00	4.00	31.7	100	0.60	3.60	30.3
40	4.00	15	6.00	31.3	1.33	5.33	29.5	133⅓	1.59	4.59	27.8
50	5.00	15	7.50	30.0	1.66	6.66	28.3	....	......	......	....

* Cost per piece = (daily earnings + machine rate + cost of material) ÷ number of pieces produced in a day.

Other Wage Systems. Where **day work** is employed, the time for performing a given task is not specified. It is the rule where the nature of the work varies from day to day to such an extent that it would be unprofitable to make time and motion studies of tasks that might never occur again. **Straight piece work** (wages = number of pieces × piece-work rate), disliked by workmen because of the tendency toward rate-cutting, is employed in repetition work where large quantities are dealt with. Where delays due to causes beyond the workman's control are liable to occur frequently, a **piece rate with guaranteed day rate** is fairer. In this case the hourly rate is fixed at a lower amount than the workman could ordinarily earn, to prevent recourse to the day rate except when absolutely necessary. A **differential piece rate** is advantageous where fixed charges are high. The workman is paid at a certain piece rate until his daily output reaches about 80 per cent. of the amount a good workman can regularly accomplish without injury to his health. Further output is paid at a higher piece rate.

In the **premium system** devised by F. A. Halsey the workman receives his hourly rate and in addition extra pay every time he performs the task in less than the standard time. The standard time is usually from 20 to 50 per cent. in excess of the time required by a skilled workman under correct conditions, and is established from the results of time and motion studies. Wages = (time taken × hourly rate) + (time saved × a fraction of the hourly rate), the fraction customarily taken being one-half. The field for a premium system would be in establishments where part of the work is repetitive, part interchangeable, and part that which is performed only once or at long intervals.

In the **bonus system on individual tasks** the workmen is paid an hourly rate and in addition a bonus on each task completed in the standard time. Its field is in industries in which the standards have been fairly well established under the original Gantt bonus system. A further development of this system is that of paying to the foreman a differential bonus varying with the number of workmen receiving bonus in his department. In a **combined bonus and premium system** devised by Hugo Diemer, the workman is paid a 10 per cent. increase in his hourly rate if he reduces the time for performing the task below past averages, and 20 per cent. increase if the task is performed in a specified standard time (based on time and motion studies). A further bonus on the Halsey premium system is allowed if the task is performed in less than standard time. In addition, a record is kept of the percentage of success of each man during each pay period, and this is made the basis of his promotion to a higher hourly rate.

It is impossible to realize to the fullest extent the economies attainable under modern management systems in industrial establishments working less than several hundred men. But a modification of the Taylor system, devised and described by F. A. Parkhurst in "Applied Methods of Scientific Management," shows excellent results in shops where as few as 100 men are employed.

It is stated by Dr. Taylor that an important fact to be noted in shops where an approved modern system of management has been installed, is the change in the mental attitude of both the men and the managerial staff, suspicion and open antagonism being replaced by cordial good-will and the earnest desire to co-operate; that the impartial justice of the code of laws upon which the system is based is recognized, and that its operation automatically does away with practically all of the subjects of dispute which under the old type of management were settled by argument or by collective bargaining.

COST AND OTHER FACTORY ACCOUNTS

By

HUGO DIEMER

The three fundamental cost accounts employed prior to the introduction of modern methods were designated as Material, Labor and Expense. The more modern accounts deal respectively with Raw Materials, Material Burden, Direct Labor, Expense Burden, Work in Process, and Finished Stock.

Raw Material Account. As material is received this account is **debited** with the amount of its cost as shown by the invoices, and is **credited** with the total charges to Work in Process for all material drawn for work in process through orders on the storeroom.

Material Burden is a general account which is **debited** with the monthly or periodic totals of all costs of carriage on materials received, cost of buying (including purchasing department salaries and expenses) and cost of storing and handling (including all storeroom salaries and expenses).

The Material Burden account is **credited** with the burden amount charged to the Work in Process account. These charges are usually on the basis of percentage-on-raw-material-cost, based on the ratio of the Material Burden account during the past period or several periods to the Raw Materials account during the same time.

Work in Process Account. This account is **debited** with all materials drawn for work in process per orders on the storeroom which have been credited to the Raw Materials account, as well as with all Material Burden items which have been credited to Material Burden. It is also debited with all Direct Labor charged to production orders during a given period, as well as with the Expense Burden. This Expense Burden may be determined by using one of the methods described below. If the Expense Burden includes in addition to Indirect Labor all other expense factors, there will be no further burden charges to Work in Process, but if the Expense Burden is divided into different kinds of expense factors, such as Indirect Labor Burden, Machine Burden and General Expense Burden, these will all have to be charged to Work in Process. Work in Process is **credited** with the total of all orders as soon as finished, or, in other words, just as soon as they become Finished Stock.

Finished Stock Account. This account is **debited** with the total of all work in process just as soon as an order is transformed from work in process into a finished order. The Work in Process account is credited with the same amount. Finished Stock is **credited** with the Manufacturer's Cost price as established for the various articles to be made, whenever any articles are shipped. This Manufacturer's Cost price is then made the basis of operations of the selling department. It may be higher than the sum of the Raw Material, Material Burden, Direct Labor, Indirect Labor, Machine Burden and General Expense Burden charges, in order to allow for fluctuations in cost. Any apparent profits accumulated in this way can be transferred to reserves for meeting depreciation of plant and equipment.

Methods of Allotting Expense Burden

Percentage on Wages. The oldest method and the one still in most general use is the percentage-on-wages method, established by finding the ratio in percentage which the sum total of Indirect Labor and all expense accounts in a given period bears to the sum total of Direct Labor in the same period. Its greatest weakness lies in the fact that it overcharges high-priced labor which may use shop and equipment and share running expenses only a short time, and undercharges low-priced labor which may use shop and equipment and share running expenses a long time, in creating a direct-labor cost of the same dollars-and-cents value.

Hourly Expense or Man-hour Rate. A more recent method, and the one which is in use by all machine-tool builders using the uniform cost-accounting methods recommended by the National Machine Tool Builders' Association, is the hourly expense rate obtained by dividing the sum total of all indirect labor and expenses during a given period by the sum total of direct-labor hours in the same period.

Separate Man-hour Departmental and General Rates and Hourly Machine Rates. A third method, probably in the least general use, is one which establishes (*a*) an hourly rate for each department, local to that department, (*b*) a general hourly shop overhead rate, and (*c*) an hourly rate for each machine or group of machines. Rates (*a*), (*b*) and (*c*) are mutually exclusive and the sum total of all expenses allotted from these three channels must approximate the total of all indirect labor and all other expenses in the same period. Inasmuch as the charges to Work in Process and corresponding credits to the various expense accounts during a given period are the results of calculations based on averages of preceding periods, the exact balancing in order to close the expense accounts must be left to an adjustment entry which may result in either a debit or credit to the expense account at the opening of the next period. If a considerable item, this adjustment entry may demand a modification of the rates for allotting expense burden during the next new period.

The establishment of local departmental burden rates affords the proper basis for comparing local expenses from month to month, as well as holding down to their true value costs on product which passes through departments having low local burdens.

Method of Establishing the Hourly Machine Rate. A number of different considerations enter into the establishment of the hourly machine rate. Among these are the following: (1) The interest and depreciation on the purchase price of the machine; (2) the annual cost of repairing the machine and keeping it supplied with lubricants, cutting tools, etc.; (3) the floor space occupied by the machine and the stock lying about it; (4) the power consumed by the machine.

With the previous year's expense accounts as a basis, an estimate is made of the total of the above-mentioned items. Out of this grand total, or budget, each machine tool is given a certain definite allowance or allotment for the coming year. A card is then written out for each separate machine tool, and after determining approximately the number of hours that the machine will run during the year, its hourly operating rate is established for the next year by dividing the total budget by the estimated hours that the machine is to be used. Every time that the machine is used it is credited with the amount it earns as its hourly rate, the amounts being posted on the card record for that machine tool from the cost department's records showing the hours which that machine was in operation. If at the end of an annual or semi-annual period it is found likely that the postings on any card will overrun or fall short of the amount allotted the given machine, changes must be made in the individual machine rate. The exact balancing at the close of a year will be left to adjustment entries, which may result in either a debit or credit to the machine expense account at the opening of the next period. With careful allotment of rates these adjustment entries will be relatively small and required only to make an exact balance at closing.

Segregation of Works Expenses from Selling Expenses. All distinctly selling expenses should be kept separate and the sales department made to show a profit on the basis of the difference between Manufacturer's Cost and Selling Price. Administrative expense which is neither a direct charge to Works Management nor Selling, should be equally apportioned against Manufacturer's Cost and Selling Cost.

Detailed Cost Statistics and Records. The nature of the business will determine whether these records are to be based on unit prices per quantity of output, per variety of output, per department, or per individual lot order or item, or whether each individual item is to have its cost figured regularly or at intervals.

In general, material charges on cost records are taken care of by posting on to the general cost records the various material withdrawals, from withdrawal slips which are exchanged for the goods designated at the time of withdrawal. In establishments having well-organized planning or production departments, these withdrawal slips are written out in advance so that no time is lost in writing them when the materials designated are needed.

Labor postings on cost records are transferred from time slips written out by time keepers or on job cards stamped with time stamps. With a well-organized planning department the job cards can be written out in advance.

In addition to the material and labor postings, there remain the postings covering expense burden. These postings are usually made in the cost department in accordance with whichever of the above-outlined systems of distributing expense burden is in use.

Cost Accounts a Part of Balance Sheets. If the fundamental principles above enunciated are observed, the totals of the money value of Material in Store Room, Work in Process, and Finished Stock can be obtained in a very short time, and the profit and loss account can be closed at as frequent financial intervals as may be desired.

PISTONLESS PUMPS

Pulsometers

Pulsometers (Fig. 1) are pistonless steam-operated displacement pumps with two chambers, *AA*. The steam enters these chambers alternately and is controlled by a ball or flap valve *C*. It enters one chamber and forces the water contained therein out through a check valve *F* to the discharge pipe *H* until the steam enters the discharge pipe where it is condensed and produces a suction effect which throws the valve *C* and draws up the water through the suction valves. *J* is an air chamber. Notwithstanding their low efficiency they are used extensively in mines, at railroad watering stations, for draining building pits, etc. Suction lift, up to 26 ft., max., preferably 7 to 14 ft.; discharge head, up to 150 ft. The steam pressure must be about 50 per cent. higher than the total water pressure. Low heads give a lower efficiency than high heads. The discharge water is heated 3.5 deg. fahr. for a head of 30 ft. For every additional 30 ft., add 1.5 deg. For water-temperatures in excess of 120 deg. fahr., no suction lift is obtainable. The steam consumption by volume is from 2 to 3 times the water displacement. Wood finds **duties** varying from 10.5 to 13.4 million ft.-lb., the higher figure corresponding to the higher head. This corresponds to a steam consumption of 190 to 150 lb. per h.p. per hour. A duty of 21,345,000 ft.-lb. has been found for total lifts of 102.6 ft.

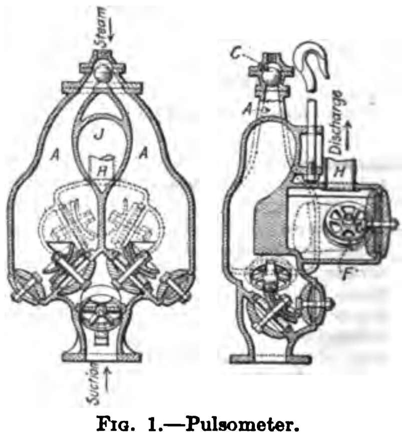

FIG. 1.—Pulsometer.

Jet Pumps

Water-jet Pumps are made in capacities up to 700 gal. per min., and may be driven by water entering under a head of 10 to 2500 ft. The efficiency is dependent upon the relation of supply head to pump head and ranges from 15 to 30 per cent. Suction lift up to 26 ft., preferably not more than 10 to 14 ft. They are used in mines for sinking purposes, in foundation work, for cellar drainage, etc. Because of the absence of moving parts, dirty and muddy water can be handled. Their special field is for high drive heads and low pump heads.

The Hydraulic Ram is used for the lifting of small quantities of water against high heads and where an abundance of drive water is available; capacities, 1 to 30 gal. per min. It works by a mild water-hammer action. (For theory of water hammer, see p. 277.) The clack valve closes at regular intervals, stopping the column of moving water in the drive pipe suddenly. This changes the kinetic energy of the water into pressure which is relieved by the forcing of part of the water through the check valve into the air chamber against the discharge head, and by the pressure wave traveling back up the drive pipe. The **drive pipe** should be unobstructed and nearly straight and have a length equal to $(h_d + 2)(h_d - h_s)/h_s$ and not less than $5h_s$, where h_d and h_s are respectively the delivery and supply heads, ft. The diam. of the drive pipe should be $d(\text{ft.}) = \sqrt{1.63 \times \text{cu. ft. of water supplied per sec.}}$ The volume of the **air chamber** should equal that of the delivery pipe. Hydraulic rams are generally used only under low supply heads, as the maximum pressure due to the water-hammer action increases directly with the velocity of the water in the supply pipe, or as the square root of the supply head. Their **efficiency** as pumps is dependent upon the relation of pump head to supply head or the ratio of lift to fall, as follows:

Ratio of lift to fall	4	6	8	12	16	20	24	26
Efficiency, per cent	72	61	52	37	25	14	4	0

A large ram designed by Prof. D. W. Mead for the village of West Dundee, Ill., delivers water into a stand pipe 115 ft. above the ram. The 10-in. drive pipe is 2200 ft. long and under a head of 55 ft. The duration of one cycle of this ram is 4⅓ sec. and the maximum resistance of the check valve is less than 2½ lb. According to indicator cards taken the maximum pressure in the drive pipe lasts only about 1 sec., which is equal to the time required for the wave of compression, or sound wave, to make a "round trip" from the valve to the reservoir and back.

According to Joukovsky's experiments on water hammer, the velocity, C, of the compression wave is about 4670 ft. per sec. and the time for the "round trip" would equal $t_r = 2l/C = 4400/4670 = 0.95$ sec., neglecting the distension of the pipe.

Tests of a Rumsey hydraulic ram (Prof. R. C. Carpenter, *Eng. Mechanics*, 1894) with a discharge head of 19.75 ft. of water through a ½-in. pipe, an average supply head of 5.67 ft. of water through a 1½-in. pipe having an equivalent length of 65 ft., and with full travel of the clack valve = $^{15}/_{16}$ in., gave the following results:

Length of stroke, per cent	100	80	50	46
Number of strokes per min	52	56	61	66
Efficiency, per cent	64.9	66	74.9	70

At maximum efficiency the travel of the clack valve was $^{9}/_{16}$ in. The weight of water pumped was practically constant throughout these tests.

Tests of a Rife hydraulic ram (*Stevens Indicator*, April, 1898) give the highest efficiency as 75.6 per cent.

Steam-jet Pumps

Injectors. An injector consists of a **steam nozzle** a (Fig. 2), in which the steam acquires kinetic energy; a **combining tube** b, at the entrance to which the steam impinges on the feed water entering at c; and a **delivery tube** d, in which the velocity head of the feed water is reduced and its static pressure increased.

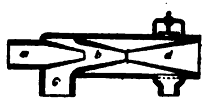

Fig. 2.—Injector.

The velocity acquired by the steam in the steam nozzle can be calculated as indicated on p. 355. The pressure at the entrance to the combining tube is found to be 3 to 4 lb. per sq. in. abs. for usual feed temperatures. The quantity of feed water that can be handled is obtainable from the equation

$$(W + 1)v_m = C(v_s + Wv_w)$$

where W = weight of water discharged per lb. of steam, lb.; v_s = velocity of steam before impact, ft. per sec.; v_w = velocity of feed water before impact, ft. per sec.; v_m = velocity of mixture after impact, ft. per sec.; and C = coefficient of impact. The value of v_w is calculable when the head and lift of the feed water, the vacuum at the entrance to the combining tube and the frictional resistances are known. Its amount is generally negligible, so that the equation becomes $(W + 1)v_m = Cv_s$. The value of C averages about 0.5.

The **actual weight of feed water handled per lb. of steam,** W, is easily determined in an injector from a heat balance. The heat given up by the steam is equal to the heat given to the feed water plus the external work done. The external work is usually about 2 per cent. of the heat given up by the steam. The heat-balance equation becomes

$$0.98(H - h_2) = W(h_2 - h_1)$$

where H, h_1 and h_2 are respectively the total heats (in B.t.u.) of 1 lb. of steam, 1 lb. of feed water, and 1 lb. of the mixture. Table 1 gives results of tests of an injector and shows its general characteristics. The weight of feed water handled per lb. of steam is generally found to diminish as the steam pressure increases, and usually varies from about 21 lb. at 20 lb. gage pressure to 10 lb. at 100 lb. pressure; the maximum temperature of feed water which can be handled does not vary much with the steam pressure, and averages from 120 to 140 deg. fahr. The pressure against which the injector will deliver water is usually from 50 to 80 lb. above the steam pressure.

Table 1. Test of Sellers Injector

(From "Theory and Practice of the Injector," by S. L. Kneass)

Mean steam pressure, lb. per sq. in.	30	60	121	150	200
Temperature of supply water, deg. fahr.	67	67	54	54	50
Maximum capacity:

Temp. of delivered water, deg. fahr.	113	125	134	135	154
Weight of delivered water per lb. of steam used, lb.	25.9	19.1	13.6	12.6	10.3
Minimum capacity:					
Gal. water handled per hour	765	937	1290	1432	1732
Temp. of delivered water, deg. fahr.	171	212	238	250	263
Ratio of min. to max. capacity	0.4	0.37	0.37	0.38	0.43
Limiting restarting temp., deg. fahr	130	135	122	120	......
Limiting operating temp., deg. fahr	139	144	137	133	......

The **efficiency** of an injector considered merely as a pump is very low, about 1 to 2 per cent.; as a boiler feed pump, where the heat of the steam is utilized in the boiler, the efficiency is nearly 100 per cent. It is commonly not the most economical means for feeding a boiler, since it can handle only cold or moderately warm water, and the effect is equivalent to heating the feed water by live steam, while a pump can handle water which has been heated by exhaust steam from the main and auxiliary engines, which would otherwise be wasted. Steam consumption about 400 lb. per water h.p. per hour; a small direct-acting steam pump consumes from 100 to 200 lb.

The Ejector is a modified type of injector for handling large volumes. Discharge heads with usual steam pressures range up to about 120 ft. for suction lift of less than 5 ft., and up to 75 ft. for suction lift of 22 ft. With no suction lift the discharge pressure for cold water may rise to twice the steam pressure; water as hot as 175 deg. fahr. may be raised 6 to 10 ft. Ejectors are used as well pumps, bilge pumps, as fire pumps in factories, and for the lifting of muddy liquids, acids, alkaline solutions, and other liquids where admixture with the condensing steam is unobjectionable.

The Air Lift

The air lift consists of a drop pipe placed in a well with its lower end submerged. The depth of submergence measured from the level at which the water stands during operation to the air entrance is called the **submergence.** An air pipe delivers air at the bottom of the drop pipe and forms a mixture of air and water which is lighter than the column of solid water in the well; consequently the mixture rises above the surrounding water. The necessary **percentage of submergence** (the percentage of the total length of pipe which is submerged in "solid" water when pumping) decreases as the lift increases, ranging from 66 per cent. for a lift of 20 ft. to 41 per cent. for a lift of 500 ft. The average will usually lie between 50 and 60 per cent. A submergence of 60 per cent. would require a submergence of 60 ft. for a lift of 40 ft. and a total height of discharge pipe of 100 ft. from air inlet to water discharge. The **efficiency** (ratio of the water h.p. to the indicated air h.p. of the compressor) varies between 20 and 50 per cent. The low efficiency is offset by the advantage of having the whole operating mechanism above ground and by the capacity for handling dirty, gritty or acidulous mine water, slimes from reduction plants, sewage, etc. The theoretical consumption (v) of free air in cu. ft. per gal. of water pumped is given by Goodman's formula:

$v = l/585 \log [1 + (s/34)]$, where l = total lift, ft.; s = submergence, ft. The displacement of the air compressor = $[3 + (l/700)]v$.

The air pressure required for starting is higher than that for operating and is equivalent to the height of the water level at rest above the end of the air pipe. The actual pumping level and yield of a well are seldom known in advance. After the piping is installed the submergence is altered to suit by raising or lowering the pipe in the well. The quantity of water a well will yield depends upon its diameter. The water pipe should have a cross-sectional area (sq. in.) equal to discharge in gal. per min. ÷ 12 to 15. Too large a pipe lets the air slip by, and too small a pipe means excessive friction and inefficient expansion of the air bubbles.

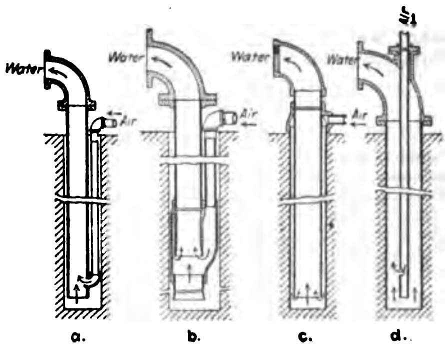

FIG. 3.—Arrangements of Air Lifts.

The arrangements most generally used, where conditions permit, are shown at *a* and *b*, Fig. 3. This is the **Pohlé** or "side-inlet" **method,** where the discharge and air pipes are placed side by side in the well and joined by a suitable foot-piece. In *b*, compressed air fills the annular space or ring surrounding the uptake pipe and is free to enter the rising column at all points of its periphery, at the same time acting without obstructing or contracting the discharge pipe anywhere. The **Saunders system** is shown at *c*. A central discharge pipe is suspended in the well, the air passing down between it and the well casing. If the well is not cased a second pipe must be used outside of the main discharge pipe, the air as before filling the annular space between the two pipes. The **central air pipe system** is shown at *d*. This method is generally used where the lift is low. The air pipe is suspended in the well without the usual discharge pipe, thereby making the well its own discharge pipe. Data on air-lift pumps are given in Table 2.

Table 2. Pipe Sizes and Capacities of Air Lifts

Side air inlet (Pohlé)				Concentric air pipe (Saunders)		Central air pipe		
Air pipe diam., in.	Water pipe diam., in.	Well diam., in.	Max. economical capacity (moderate lift), gal. per min.	Height of lift, ft.	Gal. per min. per sq. in. of water pipe cross-section	Diam. of casing, in.	Air pipe diam., in.	Capacity, gal. per min.
½	1	3	7	25	15–20	3½	1¼	80– 100
¾	1½	4	20	50–125	12–15	4	1½	100– 150
1	2	4½	35			5	2	150– 250
1	2½	5	60			6	2	275– 375
1¼	3	6	90			8	2½	500– 665
1½	3½	7	120			10	2½	775–1000
1½	4	8	160					
1½	5	9	250					
2	6	10	350					

Tests of Air Lifts operating in oil wells (Ivens, *Trans. A. S. M. E.*, 1909) give the following results (Weight of 1 gal. of fluid pumped, at 116.3 deg. fahr., 8.67 lb. Pipe diameters: Casing, 6 in.; discharge, 4 in.; air, 1¼ in. Total length of vertical discharge line, 1500 ft.; air line, 12 ft. shorter):

Tests of eleven wells at Atlantic City, N. J. (*Eng. News*, June 18, 1908) showed the following results: At capacity (3,544,900 gal. per 24 hr. through a mean lift of 26.88 ft. with air pressure of 31 lb.), duty of whole plant, 19,900,000 ft.-lb. per 1000 lb. of steam used by compressors; at ¾ capacity (2,642,900 gal. through mean lift of 25.43 ft. with 26 lb. air pressure), duty, 24,207,000 ft.-lb. The wells were 10 in. in diam., water pipes 4 to 5¼ in. and air pipes ¾ to 1¼ in. Maximum lift of the several wells ranged from 26 to 40 ft.; submergence 37 to 49 ft.; ratio of submergence to lift, 0.9 to 1.8; submergence in percentage of length of pipe, 53 to 64.

RECIPROCATING PUMPS

Efficiencies, Suction Lift, Dimensions, Speeds

Reciprocating vs. Centrifugal Pumps. The advantages of reciprocating pumps over centrifugal pumps are their flexibility in regard to capacity, head and speed, and their nearly uniform efficiency under a wide range of conditions. The advantages of centrifugal pumps over reciprocating pumps lie in their lower initial cost, smaller floor-space requirements, less need for attendance, quiet operation, absence of excessive stresses in the pipe line owing to the uniform discharge, and adaptability for being driven by motors of high rotative speed.

Pump Diagram. In Fig. 4, h = head pumped against; h_i = indicated head; h_s = static suction lift; h_d = static discharge head; s = losses through suction pipe and valves; d = losses through discharge valves and force chamber. $h_i = h + s + d$, and $h = h_s + h_d$.

Efficiencies

Volumetric Efficiency = $E_v = Q_e/Q$, where Q_e = actual volume discharged, and Q = plunger displacement. This efficiency gives information as to the loss of capacity due to defective piston packing, leaky stuffing boxes or valves and the delayed closing of the valves. It is generally stated as loss in percentage of the displacement and is then called **slip** ($= 1 - E_v$). The slip is very little in a new pump, actual tests having demonstrated that it rarely exceeds 2 per cent. in a plunger-and-ring pump. In packed pumps where there is no leakage past the piston or plunger, it is less. Pumps handling large amounts of water have shown slips of ½ per cent., no slip or even negative slip, which latter is a result of the tendency of the water to continue to flow after the plunger has stopped. The average slip for good pumps is probably from 3 to 5 per cent.; under unfavorable conditions it may amount to as much as 10 or 15 per cent. Small pumps are tested for tightness by closing the discharge valve and admitting sufficient steam to produce the required water pressure. The pump will then make a certain number of strokes per min., called **lost actions.** If the lost actions are about 1 per cent. of the normal speed, the pump is passed as satisfactory. At normal speed the leakage will be less than this amount.

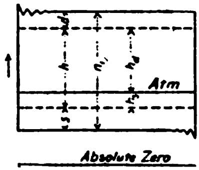

Fig. 4.—Pump Diagram.

Hydraulic Efficiency = $E_h = h/h_i$, where h = total head pumped against and $h_i = h$ + hydraulic losses. These losses consist of (1) the losses in passing from the well to the pump chamber, and (2) the losses in passing from the pump chamber to the point where the discharge gage is attached. The losses under (1) are usually small. They comprise: (*a*) The velocity head, (*b*) entrance head, (*c*) friction in the suction pipe, (*d*) losses in the bends, and (*e*) loss in passing through the suction valves. The losses under (2) comprise: (*a*) The loss in passing through the discharge valves, which consists of the head set up by the spring pressure and the friction through the valves. The former should be ½ per cent. of the discharge pressure and the whole loss may be assumed to be equal to 1 per cent. of this pressure. (*b*) The velocity head, the friction in the passages, etc. At the low velocity used these losses are insignificant. The friction in the main discharge pipe is part of the useful work of the pump and is not included in the hydraulic efficiency. The pressure indicated by a gage at the discharge nozzle plus the height of this gage above the level in the suction well constitutes the total head h. The hydraulic efficiency is greater in a high-service pump than in a low-service pump. It is very difficult to measure this efficiency owing to the impossibility of obtaining reliable indicator cards from the pump end (due to the disturbing influence of the inertia of the water), and it is therefore generally included in the expression for the mechanical efficiency.

Indicated Efficiency = $E_{pi} = N_w/N_i$, where N_w = the water horse power calculated from the amount of water actually pumped ($= Q_e$) and the total head h, and N_i = the h.p. calculated from the pump indicator diagram.

$$E_{pi} = Q_e h/Q h_i = E_v \times E_h.$$

This efficiency comprises all losses in the pump end.

Mechanical Efficiency $= E_m = N_i/N_b$, where N_b = the brake horse power or the indicated steam horse power. This efficiency gives information as to the mechanical friction in the mechanism transmitting the power to the pump. It can only be determined by actual experiments with the different types of pumps, and depends upon the size of the pump and the service. In Table 3 the pumps are therefore classified according to stroke and type. The figures are conservative.

Table 3. Mechanical Efficiencies of Direct-acting Pumps
(Efficiencies in per cent.)

Stroke, in.	Plunger pumps	Piston pumps	Outside-packed pumps	Pressure pumps	Stroke, in.	Plunger pumps	Piston pumps	Outside-packed pumps	Pressure pumps
3	50	50	47	45	12	77.5	77.5	74	70
4	55	55	52	50	15	80	80	76	72
5	60	60	57	54	18	82.5	82.5	78	74
6	65	65	61	58	24	85	85	81	77
8	70	70	66	63	36	87.5	87.5	83	79
10	75	75	71	67	48-60	90	90	85	81

Total Efficiency $= E = E_v \times E_h \times E_m$. This efficiency comprises all losses in the driving mechanism and the pump and indicates the economy of the whole installation.

Suction Lift. The velocity of the water in the suction pipe is usually about 3 ft. per sec., making the losses enumerated under "hydraulic efficiency" as follows:

(*a*) Velocity head $= h = v^2/2g = 0.14$ ft. water column.

(*b*) Entrance head $= h/2 = 0.07$ ft.

(*c*) and (*d*) Friction in suction pipe and loss in bends: small at the low velocity, usually not over 1 ft.

(*e*) Loss through suction valves: this may be assumed as equal to 1.5 ft., so that the total loss will rarely exceed 3 ft.

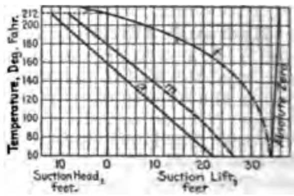

Fig. 5.—Suction Lifts for Various Water Temperatures.

The inertia of the water in the suction passages may assume serious proportions in a single single-acting pump. It can, however, be disregarded in a pump with vacuum chamber, and especially in a duplex pump.

The temperature of the water determines the theoretical suction lift from which all the suction losses should be deducted. The theoretical suction lift = atmospheric pressure minus the vapor pressure of the water. The air contained in the water is the main cause for the difference between the theoretical and the actually attainable suction lift. Fig. 5 gives the theoretical suction lift *t*, the attainable suction lift *a*, and the maximum *m* possible under favorable conditions. This diagram is based on a velocity of 3 ft. per sec. and a short suction pipe with one bend. The suction lift is the vertical distance from the water in the well to the top of the discharge valve deck. A head of 12 ft. is sufficient for any temperature, because water cannot exist at a temperature above 212 deg. fahr., except under pressure, the effect of which is added to the static head.

Air Chamber. To take up irregularities and induce a uniform flow in the discharge pipe, an air chamber is generally used. This is a necessity in single pumps and also in crank and flywheel pumps of any type, but may be dispensed with in duplex direct-acting low-service pumps (75 lb. pressure). In duplex pumps its volume should be 4 times the displacement of one plunger per stroke; in the other types, 8 times.

Plunger Diameters—Piston Speeds. The diameter d (in.) of one double-acting plunger for a given displacement G (U. S. gal. per min.) may be obtained from the formula $d^2P = 24.51G$, where P = piston speed, ft. per min. For the diameter d of each of two double-acting plungers for a given displacement, substitute $\frac{1}{2}G$ for G; for that of each of three single-acting plungers, substitute $\frac{2}{3}G$ for G, etc. The displacement of the piston rod must be deducted from G and the proper allowance made for slip. The proper **speeds** for different types of pumps are given in Table 4.

Table 4. Normal Speeds of Different Types of Pumps

Arrangements of Pumps

1. **Single Single-acting Pumps** are seldom used; they cannot run without large air chambers. Exception: Deep well pumps.

2. **Single Double-acting Pumps,** either of the direct-acting or crank-and-flywheel type, are used extensively for boiler feeding, elevator service and in waterworks. They must be equipped with large air chambers and especial attention must be paid to keeping the water free from air.

3. **Duplex Double-acting Pumps,** either direct-acting or with crank and flywheel, deliver a very steady flow of water, and are used for all services. Only small air chambers required.

4. **Triplex Single-acting Pumps** deliver an almost uniform flow of water. This arrangement is used in power pumps and triple-expansion crank-and-flywheel pumps.

5. **Triplex Double-acting Pumps.** The triplex double-acting arrangement is preferred for horizontal pumps because the load on the frame and shaft is only one-half of that of a single-acting pump.

Fig. 6 shows the irregularity in discharge of types (2), (3) and (4) when driven by a crank motion.

Methods of Driving

Belt-driven Pumps are built as horizontal or vertical, duplex, triplex or quintuplex pumps; very small house pumps as single single-acting. The shaft carries one or two gear wheels driven by a pinion on a countershaft carrying a pulley.

Steam-driven Pumps are either direct-acting or operated by crank and flywheel. **Direct-acting pumps** are used extensively for all purposes, especially as duplex pumps with simple cylinders (so-called high-pressure pumps), compound, or triple-expansion steam-ends. Advantages: Low initial cost, small attendance, few repairs, reliability, safety of operation, flexibility and inexpensive foundations. Disadvantages: High steam consumption, difficulty in regulating the length of stroke, slow speed. Regulation is effected either by hand, by a pressure regulator or by a Mason speed

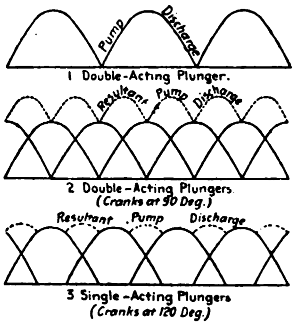

Fig. 6.—Discharge of Crank Pumps.

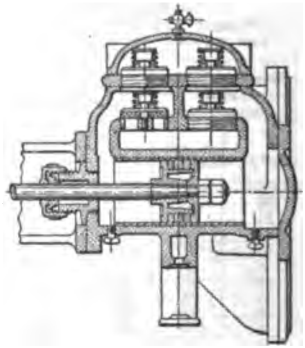

Fig. 7.—Submerged Piston Pump.

governor. An automatic stop valve is necessary to stop the pump if the discharge main breaks.

Crank-and-flywheel Pumps are power pumps driven from the cross head of a steam engine. The governor should not be very sensitive. Watt's slow-speed governor with heavy balls is considered the best, since extreme uniformity is not desired and the load is constant. For the same reason, engines with hand-operated cut-off and a throttling governor give excellent satisfaction. Advantages: High economy, high speed. Disadvantages: High initial cost, expensive foundations, high cost of attendance and repairs.

Pump Ends

Submerged Piston Pumps (Fig. 7) are pumps with both valve decks located above the piston. Small pumps, such as boiler feed and tank pumps, also wet vacuum pumps, small or large, are of this type.

General Service and Boiler Feed Pumps have a ratio of piston areas of about 2¼ to 1, and are either fitted with packed pistons and driven linings, packed pistons and removable linings, or plunger and ring. The plungers are usually cast iron and the rings bronze. Pumps are designed for 150 lb. water

pressure. Sizes and capacities of boiler feed pumps are given in Table 5. To find the size of pump to supply a given boiler, multiply the boiler horse power by 45, which will give the pounds of water required per hour.

Table 5. Boiler Feed Pumps

Size, in.	Rev. per min.	Gal. per min.	Lb. per hour	Size, in.	Rev. per min.	Gal. per min.	Lb. per hour
2 × 1¼ × 2¾	40.0	2.2	1,075	8 × 5 × 10	24.0	76	38,000
3 × 2 × 3	40.0	6.0	3,000	9 × 5¼ × 10	24.0	84	42,000
3½ × 2¼ × 4	37.5	9.6	4,800	10 × 6 × 10	24.0	110	55,000
4½ × 2¾ × 4	37.5	14.4	7,200	12 × 7 × 12	22.5	170	85,000
5¼ × 3½ × 5	36.0	28.0	14,000	14 × 8½ × 12	22.5	250	125,000
6 × 4 × 6	32.5	39.6	19,800	16 × 10¼ × 12	22.5	360	180,000
7½ × 4½ × 6	32.5	50.6	25,300	18 × 12 × 12	22.5	500	250,000
7½ × 4½ × 10	24.0	60.0	30,000	20 × 14 × 12	22.5	690	345,000

Tank Pumps are fitted with packed pistons, either with driven or removable linings. Ratio of piston areas, 1½ to 1. **Wet vacuum pumps** are used for removing air and water from jet or surface condensers, and operate at moderate speeds (see Table 4). They are of the submerged piston type and are very effective on account of the absence of clearance. Deaerated water fills the pump barrel and ports and acts as a water piston. They are suitable for 27 in. vacuum.

Straightway Pumps (Fig. 8) are pumps with the suction valve deck below and the discharge valve deck above the plunger or piston. They are fitted with piston and removable sleeve or with plunger and ring, the latter type being used only with clean water. For **general service** they are designed for 150 lb. pressure, and for **low service**, for 75 lb. On account of the large clearance spaces this type is not suitable for wet vacuum pumps.

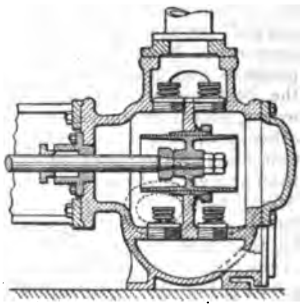

FIG. 8.—Straightway Pump.

Table 6. Sizes and Capacities of National Standard Fire Pumps

Pump sizes, in.			Approximate ratio of piston areas	Capacity at 100 lb. pressure at pump			Boiler power required		Full speed	
Steam cyl.	Water cyl.	Stroke		Number of 1⅛-in. streams	Nominal gal. per min.	Actual gal. per min.	Horse power	Steam pressure at pump, lb. per sq. in.	R.p.m.	Piston speed, ft. per min.
14 ×	7 ×	12	4:1	2	500	483	100	40	70	140
14 ×	7¼ ×	12				520				
16 ×	9 ×	12	3:1	3	750	806	115	45	70	140
18 ×	10 ×	12	3:1	4	1000	999	150	45	70	140
18½ ×	10¼ ×	12				1050				
20 ×	12 ×	16	2:1	6	1500	1655	200	50	60	160

Data on National Standard pumps for **fire service, as developed by John R. Freeman in 1890, are given in Table 6. These pumps are designed to be** rust-proof, reliable and durable; they have extra-large valve areas and are fitted with hose nozzles. (See Specifications published by National Board of Fire Underwriters.)

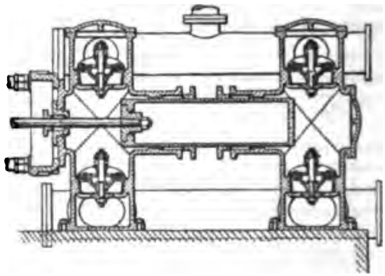

FIG. 9.—Outside Center-packed Pump.

The plunger-and-ring type is suitable for **elevator service** if water is circulating in the system. Elevator pumps operate non-condensing because no cooling water is available, and must be provided with a pressure regulator to adjust the speed to the varying demand for water. There are two methods of regulation: (1) Regulation between minimum and maximum speed, and (2) automatic stop and start.

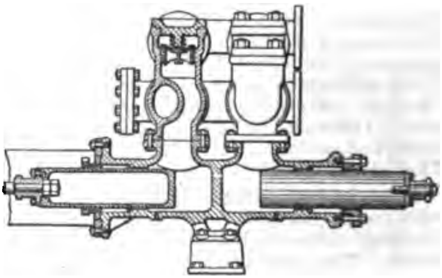

FIG. 10.—Outside End-packed Pump.

Outside Center-packed Pumps (Fig. 9) may be of the straightway or the submerged plunger type. The former are built for 300 lb. pressure and are considered the best pumps for waterworks, elevators, mines, and other general service. They cost about 50 per cent. more than plunger-and-ring pumps. Advantages: The plunger packing is accessible and can be tightened while pump is in operation; plungers can be watched and cutting can be detected; no leakage past the plunger is possible. Disadvantages: Greater friction in the large stuffing boxes. The mechanical efficiency is in consequence about 5 per cent. lower than in plunger-and-ring pumps.

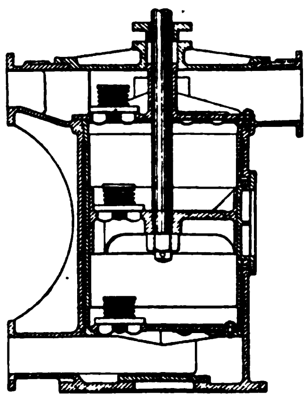

FIG. 11.—Bucket Pump.

Outside End-packed Pumps (Fig. 10) are used for pressures over 300 lb. per sq. in., and are subdivided into small parts. Cast iron is used for 1000 lb. pump pressure, cast steel for 3000 lb. and forged steel for pressures over 3000 lb. These pumps are used for mine service, accumulators, hydraulic presses, etc. The pump barrels are plain cylinders, and the valves (usually of the conical wing type) are located in separate pots containing either one valve, one pair of valves, or two pairs of valves. For moderate pressures large pots may be used containing a greater number of valves. The water should come to the pump under a head, as a slight amount of air

compressed to such high pressures would, in expanding, destroy the suction action.

Bucket Pumps are always vertical. A bucket is a piston containing valves. Bucket pumps are excellent **for condenser service** (Fig. 11), and for such work should be provided with three sets of valves, viz., foot valves, bucket valves and discharge valves. The bucket may be packed and is accessible through a hand hole in the cylinder wall. They are generally arranged duplex and the two sides are connected by a beam, giving the effect of a double-acting pump. They may be driven by a single double-acting steam cylinder, a duplex steam end or a compound steam end. The displacement of bucket should be from 0.5 to 0.7 cu. ft. per lb. of steam coming from the (surface) condenser.

In the **Edwards air pump** (Fig. 12) the piston has a conical undersurface that exactly fits the lower cylinder cover. There are no bucket or foot valves. On the up stroke the condensate flows into the space below the piston while the water of the previous stroke is lifted and delivered through head valves into an upper chamber. On the down stroke the piston almost reaches the bottom cover and forces the condensate through ports into the barrel and above the piston. These pumps may be run at higher speeds than older forms. An Edwards pump with three 14-in. barrels (stroke, 12 in.), single-acting, at 150 r.p.m. will handle 45,000 lb. of steam per hour from a surface condenser, which is equivalent to a cylinder volume of 0.64 cu. ft. per lb. of boiler feed water.

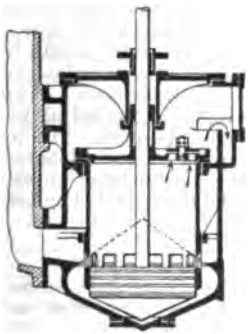

FIG. 12.—Edwards Air Pump.

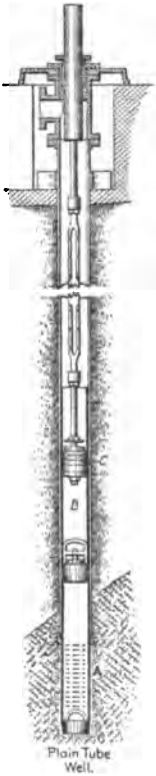

FIG. 13.

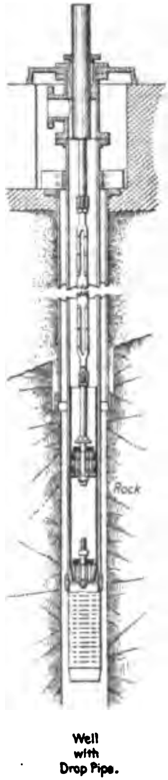

FIG. 14.

Deep-well Pumps.

Deep-well Pumps of the bucket type are designed for use on non-flowing wells where the water does not stand within suction distance. Two methods are employed: In the **plain tube well** (Fig. 13) the well pipe with open ends is sunk to the proper depth where a sufficient water-bearing stratum is penetrated. The strainer *A* is then lowered to bottom of the well and the well pipe drawn back far enough to expose the slotted portion. The working barrel *B* is then lowered into the gum packer on top of strainer and tapped firmly into place. The top of the well pipe is provided with a tee for discharge connection. The bucket *C* is driven by means of wooden rods of convenient length (18 ft.), coupled together. The top of the well pipe is provided with a stuffing box through which a brass plunger works. If the well discharges at the surface this plunger is made one-half the area of the bucket, resulting in a uniform discharge. If the pump discharges into an elevated tank the top plunger is made larger so as to throw the effect of the additional head upon the plunger and thereby assist in the up stroke. The **well with drop pipe** (Fig. 14) differs from the plain tube well in that the brass working barrel is attached to a pipe and is lowered into the well pipe. This is a better arrangement in case of a small supply, as it allows a head of water to collect above the bucket during the down stroke. It is used in wells that are either wholly or partly drilled into rock and in wells where the casing does not extend low enough to reach the water supply; also in old wells with defective or bent casing.

Vertical End-packed Plunger Pumps are only used as multiplex power pumps or with triple-expansion crank-and-flywheel engines. In the latter case the plunger is weighted to counterbalance one-half of the water pressure so as to equalize the loads on the up and down strokes.

Vertical Double-acting Pumps are used with duplex direct-acting steam ends and cross-compound crank-and-flywheel engines, or are power-driven. They may be fitted with either piston, plunger-and-ring or outside center-packed plungers. A design in which the **valves** are **arranged around** the **plunger** is excellent for moderate sizes. For large capacities and heavy pressures the castings become too large, and must be subdivided into several chambers which are connected together by pipes. When the **pump barrels and valve chambers** are **separate,** one valve chamber is placed in each corner for moderate pressures, and one or more for higher pressures. Either piston or outside center-packed plungers may be used. **Differential plunger pumps** have a large piston and a small single-acting plunger. The pump is single-acting on the suction side and double-acting on the discharge side. Plunger area = ½ piston area, so as to give uniform discharge. Irregularity in load resulting from single-acting suction can be counteracted by balancing weights.

Pump Valves

Disk Valves (Fig. 15). The valves generally used are plain rubber disks 1½ to 9 in. in diam. The 4½-in. size is considered the most suitable, considering quiet working and initial cost. The valve seat is screwed or driven into the valve deck (see Fig. 20). In the latter case the seat should be expanded below the deck to withstand the hammering of the valve against the guard. The stem is screwed into the hub of the seat on a fine taper. A number of ribs connect the hub and rim and form a support for the rubber disk. The valve disks are made of **rubber** of a **composition** suitable for the service. For wet vacuum pumps, soft rubber

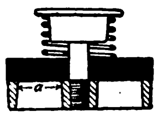

Fig. 15. Disk Valve.

Fig. 16.—Metal Valve Disk.

is used; for low service pumps (75 lb.), medium soft; for general service pumps (150 lb.), medium hard; and for pressure of 300 lb., hard rubber. Where hot water is handled a special composition is employed. For pressures over 125 lb., **metal valve disks** (Fig. 16) are preferable to those of rubber.

The **thickness of the valve disk** (in.) $= t = 0.05\,a\sqrt{p}$, where a = span, in. (see Fig. 15), and p = pressure, lb. per sq. in.

The **area of the valve seat** of a plain disk valve $= F = pA/b$, in which F = area of seat, sq. in.; p = pressure on the back of valve, lb. per sq. in.; A = area of valve on which p is acting, sq. in.; and b = bearing pressure of valve on seat, lb. per sq. in. = 10,000 for steel, 2000 for red brass, bronze and gun metal, 2500–3000 for phosphor bronze, 1000 for cast iron, 750 for leather and 375 for rubber. For high-speed pumps these values should be reduced to allow for shock. The **valve area** is the free area through the valve seat, and equals the area at the inner circle minus the areas of ribs and hub. The water velocity through this valve area should not be over 222 ft. per min., which requires a valve area of 45 per cent. of the plunger area at 100 ft. piston speed. Frequently areas of 50 per cent. and 60 per cent. are demanded by water-works' specifications, corresponding to velocities of 200 and 167 ft. per min., respectively.

The **number of valves** N of a given size required in a pumping engine, according to Nagle (*Trans. A. S. M. E.*, vol. 31, p. 974) and Bach, is $N = QV_m/CLv_mk$, where Q = area of pump plunger, sq. in.; V_m = maximum velocity of plunger, ft. per sec. (= 1.6 × mean plunger velocity for flywheel pumps); C = net circumference of valve seat (subtracting parts occupied by ribs), in.; L = lift of valve (= 0.1 to 0.2 × outside diam. D of valve seat), in.; v_m = maximum velocity of water at lift L, ft. per sec.; k = coefficient of contraction at the point of discharge with a given lift.

The **spring pressure** per sq. in. of inside seat area usually runs from 0.3 to 0.6 lb. at the beginning of the lift, and is about 40 per cent. of the pressure when the valve is at full lift. This final pressure, plus the weight of the valve in water, is designated by p in Table 7. This quantity is the determining factor for the velocity of the issuing stream. The relation of v_m to p and the ratio of lift to valve diam., according to Bach's experiments, are given in Table 7. The **discharge area** of the valve = CLk.

Table 7. Pump Valve Ratios

$\frac{L}{D}$	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.50
k	0.65	0.60	0.56	0.53	0.50	0.47	0.44	0.41	0.37
$\frac{100p}{v_m^2}$	0.69	0.72	0.74	0.77	0.80	0.83	0.86	0.89	0.92

Approximate Rules for Spring Pressures on Disk Valves. For discharge valves make p = 0.005 to 0.01 × water pressure, with a maximum of 5 lb. per sq. in. For a suction valve under suction lift, p = 0.25 to 0.5 lb. per sq. in. For a suction valve under suction head, p = 0.5 to 1 lb. per sq. in.

Leather-faced Valves have the form shown in Fig. 17. **Conical wing valves** (Fig. 18) are used for high pressures because they can be ground in more tightly than flat valves. As regards operation they are inferior to flat disk valves because they must lift higher to give the same opening. Lift $h_1 = h/\cos a$ (see Fig. 18). For a = 45 deg., $h_1 = 1.41h$, or the conical valve must lift 41 per cent. higher than the flat disk and therefore close with a greater shock. **Leather-faced wing valves** are made as shown in Fig. 19.

FIG. 17. Leather-faced Valve.

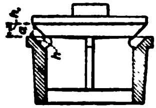

FIG. 18. Conical Wing Valve.

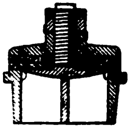

FIG. 19. Leather-faced Wing Valve.

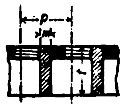

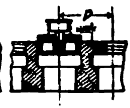

FIG. 20. FIG. 21 Valve Decks.

Valve Decks are perforated plates, and can be calculated by the formula, $t = cd\sqrt{Pp/m}$, where t = thickness, in.; d = diam. of round plate or smallest dimension of rectangular plate, in.; P = pressure, lb. per sq. in.; p = pitch = distance between centers of valves, in.; m = thickness of metal between the valves, in.

	Rectangular	Square	Round
For a plain valve deck (Fig. 20) c = ...	0.013	0.009	0.008
For reinforced valve deck (Fig. 21) c = ...	0.010	0.007	0.006

Mechanically Operated Valves. In a crank-and-flywheel pump the valve lags behind the plunger so that the valve is open a certain amount at the end of the stroke. Attempts to close the valve by mechanical means have not met with success, resulting in breakages. To overcome this difficulty springs are inserted which produce an extra-heavy spring pressure at the end of the stroke, thus reducing the shock greatly without throwing too heavy a load on the valve during the period of opening. Pumps with mechanically operated valves were developed by Prof. A Riedler and are successfully used abroad, especially for pumping water carrying large impurities, such as sewerage, where a high valve lift is desired.

Valves for High-speed or Express Pumps. The attempts at producing pumps with high piston speeds have not led to very satisfactory results. The valve area remains the same for a given capacity. The reduction in the size of the plunger reduces the plunger load without cheapening the frame, which, owing to the high speed, must be made extra strong and rigid. Fig. 22 shows a design of valve for a high-speed pump. Rubber rings are used in place of springs, giving a very strong spring pressure and a very low lift with high velocity through the discharge area. Table 8 (due to Hæder) gives the possible speeds in relation to the suction lift.

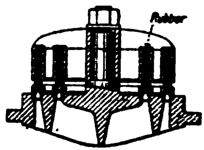

FIG. 22.—Valve for High-speed Pumps.

Table 8. Possible Rev. per Min. of High-speed Pumps
(Temperature, 70 deg. fahr.)

24	255	215	185	160	135	110	100	85

Ball Valves for pumps operating in impure liquids, paper pulp, etc., are made to the form shown in Fig. 23. The balls are made of bronze, and when large, of rubber with lead or iron cores. The diam. d_k of the ball should be from 1.2 to 1.6 times the diam. d of the outlet. The angle a should be equal to or less than 45 deg. The lift of the valve should be from 0.10d to 0.25d, while the mean velocity of the liquid through the valve should be from 3 ft. per sec. for suction valves to 8 ft. per sec. for discharge valves, determined by the equation $QV_m = Lv_mC$, in which the symbols have the meanings given on p. 1491. **Annular valves** are shown in Fig. 9.

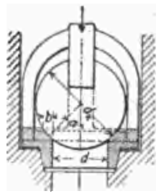

FIG. 23.—Ball Valve.

Clack or Flap Valves. Figs. 24 and 25 show leather-faced flap valves provided with strainers, for pump suction pipes. The hinge shown in Fig. 24 is of metal, while that in Fig. 25 is of leather. When the leather forms its own hinge, it is liable to rupture. The **size** of clack or flap valves depends on the shape of the seat opening, which is determined for a stated velocity of flow of the liquids by taking into consideration the narrowing of the opening by ribs, wings and screws, and by contraction. In the case of rubber clacks or flaps the grid bars will take up from 0.3 to 0.5 the total area of the opening. The coefficient of contraction is about 0.9 for circular, and 0.8 for rectangular, openings. The **lift** h is dependent on the method of hinging and on the shape of the opening. If the passage is **rectangular,** with a width a and a length c, and the hinge is parallel to c, then the **cross-section** through which the liquid can escape when the clack is open (at an angle b with the seat) is approximately equal to $h(c + a \cos b)$, where $h = a \sin b$.

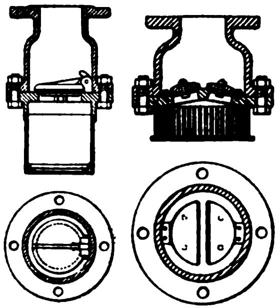

FIG. 24. FIG. 25.
Leather-faced Flap Valves.

The volume of liquid Q (cu. ft. per sec.) flowing through the valve with a velocity v (ft. per sec.) is expressed by the equation

$$Q = kvh(c + a \cos b)/144,$$

where h, c, and a are in in. and k = 0.85 to 0.90. For practical purposes, assume that v is equal to the velocity through the unobstructed cross-section ac.

For a passage of **circular cross-section** (diam. = d), with the valve hinged as in Fig. 24,

$$Q = \frac{\pi d}{4 \times 12}(1 + \cos b)\frac{hv}{12} = \frac{\pi d^2 v}{4 \times 144} \text{ approximately.}$$

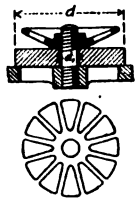

FIG. 26.—Rubber Flap Valve.

Fig. 26 shows a circular rubber flap valve, a type which can only be made with a thin and very soft rubber disk. Such valves will generally be found to bend on one diameter.

The **Gutermuth flap valve** for pumps consists of a thin sheet of tempered steel or bronze, one end of which is coiled to form a spiral spring hinge. Fig.

27 shows such valves mounted in a laterally removable cylindrical casing of and inserted between the suction and compression air chambers *C* and *D A* the pump.

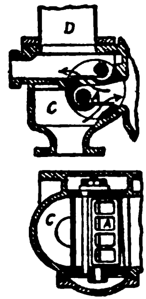

Fig. 27. Gutermuth Flap Valve.

Materials for Pumps. The **allowable stresses** (lb. per sq. in.) in pumps are lower than in most machinery owing to the shocks and water hammer, and the tensile stress may be taken as follows: Cast iron, 1500 to 1800; malleable iron, 3000; steel castings, plain, 8000; complicated, 5000; bronze (government metal), 3000; Tobin bronze, 5000; steel, 7000; forged steel, 10,000. The materials to be used for pump parts vary with the liquids handled, and are specified in Table 9.

Steam Ends

Direct-acting Pumps have the steam piston connected to the pump piston by means of a rod without the intervention of a crank motion. Here the steam end forms an important part of the machine and must be given especial care in the design. As there is no moving mass to store up energy, no early cut-off is possible.

Table 9. Materials for Pump Parts for Handling Various Liquids

Liquid pumped	Material for pump parts	Liquid pumped	Material for pump parts
Ammonia	All iron*	Magma	Brass fitted, large openings‡
Beer	Brass fitted†	Milk	All bronze
Bichloride of mercury	All iron	Milk of lime	All iron
Brine	Brass fitted	Molasses	Brass fitted, large openings
Calcium brine	Brass fitted	Naphtha	Regular fitted[1]
Calcium chloride	All iron	Oil	Brass fitted
Cane juice	Brass fitted	Salt water	Brass fitted
Caustic soda	All iron	Sewage	Brass fitted, large openings
Chlorate of lime	Regular fitted[1]	Soap	All iron
Citric acid	Regular fitted[1]	Sulphuric acid	All bronze or wood-lined cast iron, no zinc
Copper liquors	Brass fitted		
Glue (hot)	Brass fitted	Syrup	Brass fitted
Glycerine	Brass fitted	Tan liquor	All bronze
Hydrochloric acid	Lead lined, no zinc	Tar	All iron, large openings
Hyposulphite of soda	Lead lined, no zinc	Vinegar	All bronze
Lard (hot)	Brass fitted	Whiskey	All bronze

[1] Regular fitted: cast-iron plunger or piston in bronze sleeve, steel rods, rubber or bronze valves.
* Cast iron, steel or malleable cast iron only, bronze not to be used.
† Rods and pistons to be of bronze; stuffing-box throats and glands to be bronze-lined.
‡ Valve seats must not be obstructed by ribs; ball valves or clapper valves are suitable.

Single Steam Pumps. The steam end of a single steam pump consists of four elements: the main piston, the main valve, the auxiliary piston and the auxiliary valve. They may be combined in various ways or split up into several units. The pumps may be fitted with external or internal valve motions and the valves may be of the "D" or the "B" type. Fig. 28 shows a plain D-valve with neither inside nor outside lap, to avoid the danger of stoppage. The B-valve, Fig. 29, takes steam at the opposite end from that of the D-valve. With the D-valve the piston follows its valve; with the B-valve the piston travels in the opposite direction; in other words, the B-valve reverses the mo-

Fig. 28.—D-Valve.

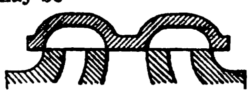

Fig. 29.—B-Valve.

tion, while with a D-valve this must be accomplished by a special reversing mechanism. Figs. 30–32 show the three combinations diagrammatically.

Duplex Steam Pumps. In a duplex pump the same four elements are found as in a single pump, but they appear as two main pistons and two main valves. The piston of one side is mechanically connected to the valve of the opposite side. As it is desirable to have both cylinders alike, D-valves are used, and the reversal of the motion is accomplished by a reversing mechanism. Fig. 33 shows a common design of the steam end of a duplex pump. The valve is not rigidly connected to the crank pin but a certain clearance or lost motion is allowed in order to retard the movement of the valve. This gives the desired pause at the end of the stroke. Figs. 33 and 34 show common types of lost-motion devices, inside for small and outside for large pumps. The following formulæ for valve motion (see Fig. 34) are based on the width of the port A. The port areas (= width × length) are calculated for a velocity of steam through the steam port of 6000 ft. per min., and 5000 ft. through the exhaust port; travel of crank pin $= L = 3.3A$; lost motion $= 2J = A = 0.3\,L$; clearance in chest to avoid danger by improper adjustment $= I = \frac{1}{2}L + J$; to avoid danger of reopening, make $\frac{1}{2}L + \frac{1}{8}$ in. $< (A + D)$; width of inner bridge $= B = (9A + 4)/16$; width of outer bridge $= D = B + \frac{1}{8}$ in.; width of main exhaust port $= C = 2A$. The sectional areas of the pipes are made equal to

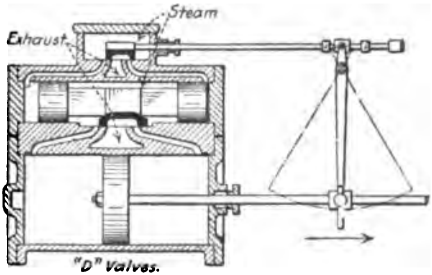

FIG. 30.

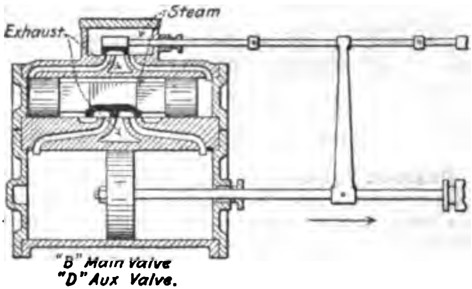

FIG. 31.

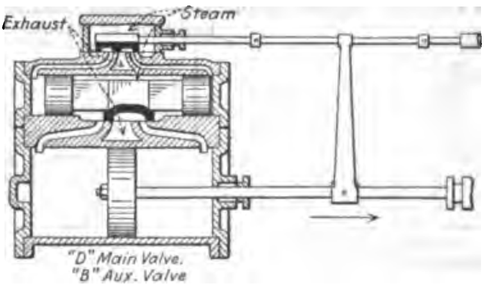

FIG. 32.

FIGS. 30–32.—Valve Combinations in Steam Ends of Single Steam Pumps.

the areas of the ports, using the next larger commercial size. The area of the main pipe is 1½ times that of the side pipe; the exhaust pipe is taken one size larger than the steam pipe.

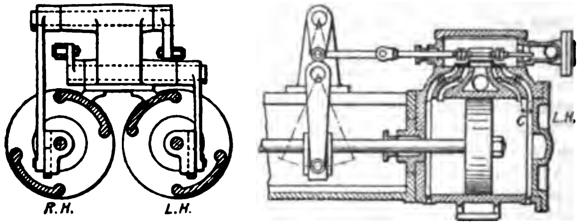

Fig. 33.—Steam End of a Duplex Pump.

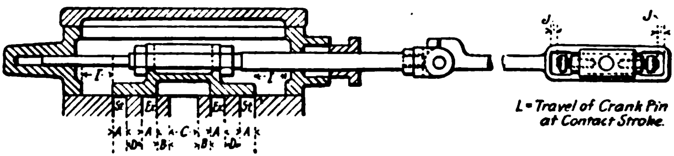

Fig. 34.—Dimensions for Duplex Valve Motions.

Cushion Valves. To stop the motion of the piston the cylinder is made with five ports (see Fig. 33), the outer ones being used for steam admission, the inner ones for exhaust. A communicating port between the two, provided with a regulating valve called the cushion valve or **dash relief valve,** offers a means for regulating the cushion. The cushion is the distance *c* (Fig. 33) from the cylinder head to the outer edge of the exhaust port. The cushion valve opening should be 0.5 per cent. of the area of the piston.

Table 10. Proper Amount of Steam Cushion for Pumps of Various Lengths of Stroke

Nominal stroke, in.	Contact stroke, in.*	Cushion, in.	Nominal stroke, in.	Contact stroke, in.*	Cushion, in.	Nominal stroke, in.	Contact stroke, in.*	Cushion, in.
3	3.5	0.625	8	8.75	1.25	18	19.5	2.25
4	4.5	0.750	10	11	1.50	24	26	2.75
5	5.75	0.875	12	13	1.75	30	32	3.125
6	6.75	1.125	15	16	2.00	36	38	3.5

* Extreme length of stroke possible = internal length of cylinder (from head to head) minus width of piston.

Compound Direct-acting Steam Ends. Single pumps and duplex pumps may be compounded by arranging a high- and a low-pressure cylinder tandem with each pump cylinder. No cross-compound arrangement is possible in a duplex pump, because there is no mechanical connection between the two sides, which must therefore be symmetrical and duplicates. No early cut-off is possible. On non-condensing engines the low-pressure cylinders are fitted with cushion valves; on condensing engines both cylinders should be so fitted on account of the poor cushioning effect of the low-pressure exhaust steam. The two high-pressure exhaust pipes are connected by a communicating port with valve for the purpose of straightening out the back-pressure line. This is called the **cross exhaust.**

Triple-expansion Direct-acting Steam Ends. In this arrangement the three steam cylinders are arranged tandem on each side. The high-pressure cylinders are equipped with cut-off valves for the purpose of regulating the length of stroke. Cushion valves are inserted in one of the larger cylinders and cross exhausts on the h.-p. and i.-p. exhaust pipes. A live-steam connection is made to the intermediate-pressure cylinder for starting.

The above-mentioned pumps all belong to the class of **low-duty** pumps, the term **high duty** being applied to pumps using an early cut-off in the steam cylinders.

Calculation of the Steam Ends of Direct-acting Pumps. Let a_s = area of steam piston, sq. in.; p = absolute initial pressure in cylinder, lb. per sq. in.; b = absolute back pressure in cylinder, lb. per sq. in.; L = plunger load, lb.; S = total pressure exerted by the steam, lb. $= a_s p_{si}$. Then $E_m S = L$, where E_m is the mechanical efficiency of the pump. Since no cut-off is possible in a direct-acting pump, the steam diagram is composed of plain rectangles. In **simple steam cylinder pumps** (so-called high-pressure pumps) $p_{si} = p - b$. In **compound pumps** $p_{si} = 2p - (p/R) - bR$, where R = ratio of the cylinder areas, the best value of this ratio being $R = \sqrt{p/b} \leq 4$. In **triple-expansion pumps** $p_{si} = 3p - (2p/\sqrt{R_1}) - bR_1$, where R_1 = area of low-pressure cylinder + area of high-pressure cylinder. The best values of these ratios are $R_1 = R^2 = \sqrt[3]{(p/b)^2} \leq 9$, where R = area of intermediate-pressure cylinder + area of high-pressure cylinder. In compound and triple-expansion pumps p is the absolute initial pressure in the high-pressure cylinder, and p_{si} is the mean effective pressure referred to the area of the high-pressure cylinder.

PERFORMANCE

Duty. Pumps are tested for economy by determining the duty in foot-pounds of work done by 1000 lb. of dry steam, or per 1,000,000 B.t.u. furnished by the boiler. Although the latter unit is more rational, it has not found favor among the manufacturers because it gives a slightly lower duty.

The work is found by measuring the amount of water pumped, and the height through which it is lifted. The former may be done either by direct measurement or, as recommended by the Committee, by calculating the plunger displacement, deducting a certain amount for slip.

The data and results should be reported in accordance with the form given herewith, adding lines for data not provided for, or omitting those not required, as may conform to the object in view. In the case of a pumping engine of the reciprocating class for which a record of the complete performance is desired, the additional engine data and results given in the Steam Engine Code may supplement those here given. In trials for maximum duty, air should be prevented from snifting into the pump cylinders. In all cases where air is thus admitted, the results should be corrected accordingly. For duration, starting and stopping, and records, see Steam Engine Code, p. 1756.

Data and Results of Duty Trial of Steam Pumping Machinery
(A. S. M. E. CODE OF 1915)

(For a short report the items designated by letters of the alphabet may be omitted.)

(1) Test of..........pump located at..........

(a) Total head expressed in ft..ft.

Quality of Steam

(18) Percentage of moisture in steam near throttle, or number of degrees of superheating..............................per cent. or deg.

Total Quantities

(19) Total water fed to boilers..lb.
(20) Total condensed steam from surface condenser (corrected for condenser leakage)..lb.
(21) Total dry steam consumed (Item 19 or 20 less moisture in steam)............lb.
(22) Total gal. of water discharged, by measurement..gal.
(a) Total gal. of water discharged, by plunger displacement, uncorrected....gal.
(b) Percentage of slip [100(Item 22a–Item 22)/Item 22a.]..........per cent.
(c) Leakage of pump*..gal.
(d) Total gal. of water discharged, by calculation from plunger displacement, corrected for leakage..gal.
(e) Total weight of water discharged, as measured..lb.
(f) Total weight of water discharged, by calculation from plunger displacement, corrected for leakage..lb.

*Leakage of an inside plunger may best be determined by removing the cylinder head and bolting a wide board over the lower part of cylinder end to form a dam, in which an overflow pipe is inserted. The plunger is then blocked (preferably at some intermediate point of the stroke), and water admitted behind it from the force main, at full pressure. The leakage is caught from the overflow pipe in barrels and measured. If possible, tests should be made with the plunger in various positions. If the cylinder head is difficult to remove, the leakage may be measured through one of the openings provided for inspecting the suction valves. Any leakage of valves should be remedied

HOURLY QUANTITIES

(23) Total water fed to boilers or drawn from surface condenser per hour............lb.
(24) Total dry steam consumed for all purposes per hour (Item 21 ÷ Item 8).......lb.
(25) Steam consumed per hour for all purposes foreign to main engine ....lb.
(26) Dry steam consumed by engine or turbine per hour (Item 24 − Item 25)......lb.
(*a*) Circulating water supplied to condenser per hour..................lb.
(27) Weight of water discharged per hour, by measurement.....................lb.
(*a*) Weight of water discharged per hour, calculated from plunger displacement, corrected..lb.

HOURLY HEAT DATA

(28) Heat units consumed by engine or turbine per hour [Item 26 × (total heat of 1 lb. of steam at pressure of Item 9, less heat in 1 lb. of water at temperature of Item 14)]..B.t.u.

EFFICIENCY RESULTS

(38) Thermal efficiency referred to i.h.p. [(2546.5 ÷ Item 36) × 100]........per cent.
(*a*) Thermal efficiency referred to water h.p. [(2546.5 ÷ Item 37) × 100].per cent.
(*b*) Mechanical efficiency [(100 × Item 32)/Item 31]................ per cent.
(*c*) Pump efficiency [(100 × Item 32)/Item 31*a*]..................per cent.

---

before making the plunger test. Leakage of discharge valves will be shown by water passing down into the empty cylinder at either end when they are under pressure; and of suction valves by the disappearance of water which covers them. If valve leakage is found which cannot be remedied, the water thus lost should also be measured. One method consists in measuring the amount of water required to maintain a certain pressure in the pump cylinder when this is introduced through a pipe temporarily erected, no water being allowed to enter through the discharge valves of the pump.

† Water h.p. = ft.-lb. of work per min. ÷ 33,000. Work done per min., ft.-lb. = net area of plunger A (sq. in.) × total head H, lb. per sq. in. (= pressure on force main + pressure on suction main + pressure equivalent to the head or vertical distance between the centers of the two gages) × length of stroke S, ft. × number of single strokes per min., N; corrected for leakage.

‡ Capacity in gal. per 24 hr. = 74.8 ASN, corrected for leakage; in direct-connected engines, S = average length of stroke.

Duty

(39) Duty per 1,000,000 heat units..ft.-lb.

Work Done per Heat Unit

(40) Ft.-lb. of work per B.t.u. (1,980,000 ÷ Item 37).....................ft.-lb.

Sample Diagrams

(41) Sample indicator diagrams from each steam and pump cylinder................

Note. The items relating to indicator diagrams and indicated horse power are to be used only in the case of reciprocating machines. The i.h.p. on which the economy results are based is that of the main engine, given by Item 31.

Table 11. Probable Duty of High-pressure Direct-acting Steam Pumps

(Duty in millions of foot-pounds per 1000 lb. of steam. Steam cylinders lagged; 4.7 lb. wire-drawing)

Stroke, in.	Simple non-condensing, not jacketed, 16-lb. back press				Compound non-condensing, not jacketed, 16-lb. back press				Compound condensing, jacketed, 6-lb. back press				Triple-expansion condensing, jacketed, 4-lb. back press			
	Boiler pressure, lb. per sq. in.															
	50	80	120	150	50	80	120	150	50	100	150	180	70	120	160	200
10	15	18	20	20	21	25	29	30	35	40	43	44	64	76	80	82
15	18	21	23	24	24	30	34	36	41	47	50	51	73	87	92	95
18	20	23	25	25	26	32	36	38	44	51	54	56	78	93	98	101
24	21	25	27	28	28	35	40	42	46	54	58	59	83	99	104	108
36	23	26	29	29	30	37	42	45	50	58	62	63	88	105	111	114
48	25	28	31	32	33	40	46	48	53	62	66	68	93	111	117	121

Triple-expansion non-condensing pumps give approximately the same duty as compound condensing pumps.

Card Duty. The duty can be calculated approximately from the indicator diagram (either actual or theoretical):

$$\text{Card Duty} = 144{,}000pv, \text{ and Duty} = \text{Card Duty} \times E_sE_m$$

where p = mean effective pressure of whole steam end referred to the area of any one cylinder; v = specific volume of steam at the terminal pressure in this same cylinder, E_m = mechanical efficiency, and E_s = steam efficiency. Table 12 gives practical values for the steam efficiencies when the card duty is calculated from a theoretical diagram and is based on the high-pressure p and v. If the card duty is calculated from actual diagram, the steam efficiency must be divided by the diagram factor.

Cost of Pumping Engines, complete with foundations, piping and appurtenances per million gallons per 24 hr. capacity: Compound condensing, low duty, $2300; triple-expansion condensing, low duty, $2800; triple-expansion vertical, high duty, $4800.

Cost of Complete Pumping Stations (triple-expansion high-duty engines and high-pressure boilers) per million gallons per 24 hr., including a reserve:

Total water pressure, lb. per sq. in.	30	40	60	80	100	120	130
Cost	$6750	7000	7500	8000	8500	9000	10,000

These costs include building of a good quality of brick or stone, steel-trussed and slated roofs and adequate chimneys. Cost of land not included. With cheaper types of engines more boiler capacity is required, which should be taken into account.

Table 12. Steam Efficiencies of Direct-acting Pumps

Stroke, in.	Simple cylinders	Compound pumps			Triple-expansion pumps	
	Non-condensing	Non-cond.	Condensing		Non-cond.	Condensing
			Non-jacketed	Jacketed		
	Steam efficiency, per cent.					
4	37.5

8	42.5	42.5	47.5			
10	45.0	45.0	50.0	55.0	55.0	67.5
12	47.5	47.5	52.5	57.5	57.5	70.0
15	50.0	50.0	55.0	60.0	60.0	72.5
18	52.5	52.5	57.5	62.5	62.5	75.0
24	55.0	55.0	60.0	65.0	65.0	77.5
36	57.5	57.5	62.5	67.5	67.5	80.0
48	60.0	60.0	65.0	70.0	70.0	82.5

For mechanical efficiencies, see Table 3, p. 1484.

Rotary Pumps

Various types of rotary pumps may be distinguished:

1. Pumps with two rotating elements, called pistons, impellers or lobes. These impellers are designed with one, two or more teeth shaped for continuous contact at uniform velocity. In the Roots rotary pump (Fig. 35) two teeth are used. The revolution of the shafts and impellers traps the water between the lobes and the case and delivers it to the discharge side; the rolling together of the impellers prevents the return of the water. These pumps handle any liquid not containing grit under any head from 10 to 200 ft., with an efficiency which is claimed to range from 75 per cent. to 85 per cent. Pumps of this type give a continuous but not a uniform discharge and therefore require air chambers. (See *Trans. A. S. M. E.*, 1930, p. 387.)

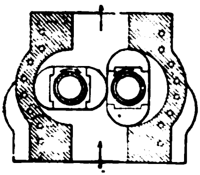

FIG. 35.—Roots Rotary Pump.

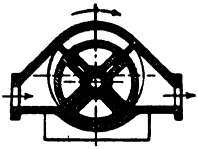

Fig. 36.

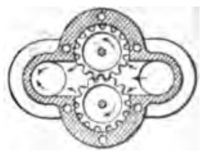

FIG. 37.—Gear-wheel Pump.

Rotary Pumps.

2. Pumps with one rotating element eccentrically located in the casing and provided with a number of packing blades which are free to slide radially in the rotor (Fig. 36). The blades can never wear down to a tight fit owing to the variation of the curvature. Either 3 or 4 blades may be used and they must be arranged so as to avoid short-circuit losses. Packing strips cannot be used at the ends of the rotor and blades, and, consequently, there is considerable slip. These pumps have a uniform discharge, but the speed is limited by the effect of the reciprocating blades.

3. Gear-wheel pumps for high rotative speeds (Fig. 37). Volumetric efficiencise range from 90 to 95 per cent. (less for thin liquids); overall efficiencies 50 to 60 per cent. for small and up to 70 per cent. for large pumps. Can be built for pressures up to 350 lb. per sq. in.; capacities from ⅛ to 60 gal. per min.

CENTRIFUGAL PUMPS

BY

L. C. LOEWENSTEIN

REFERENCES: Loewenstein and Crissey, "Centrifugal Pumps," Van Nostrand. Greene, "Pumping Machinery," Wiley. Lorenz, "Neue Theorie und Berechnung der Kreiselräder," Oldenbourg, Berlin.

A centrifugal pump consists of one or more impellers (wheels carrying blades) mounted on a shaft. These impellers are surrounded by sets of discharge vanes (stationary reversed nozzles) or by a spiral casing. The rotating impellers generate centrifugal force, which is utilized for the compression of liquids and for transmitting them against resistance. The discharge vanes, or the spiral casing, serve to convert the high velocity of the liquids as they leave the impeller into additional pressure.

The centrifugal pump and the centrifugal compressor differ only in the kind of fluid that each handles. Consequently, much of the subject matter under centrifugal pumps applies to centrifugal compressors as well, and *vice versa*.

Classification. Centrifugal pumps are classified

1. According to the magnitude of pressure developed: (*a*) Low-pressure pumps for heads of 50 ft. or less. (*b*) High-pressure pumps for heads above 50 ft.

2. According to position of shaft: (*a*) Vertical pumps, having their shafts vertical. (*b*) Horizontal pumps, having their shafts horizontal.

3. According to the number of inlets per impeller: (*a*) Single-inlet, in which the liquid enters each impeller on one side or face only. (*b*) Double-inlet, in which the liquid enters each impeller on both sides in opposite directions.

4. According to the direction of the impeller tips at impeller exit: (*a*) Radial discharge, (*b*) backward discharge and (*c*) forward discharge, according as the impeller tips at exit are radial, bent backward or bent forward, respectively, with reference to the direction of rotation.

5. According to the number of stages in the pump: (*a*) Single-stage pumps, in which the required head or pressure rise is generated by a single impeller. (*b*) Multi-stage pumps in which the required head or pressure rise is generated by two or more impellers in series.

Low-pressure pumps are usually built without a suction pipe, being placed below the level of the water supply. They are also generally built without discharge vanes, and are designated as **volute pumps.** Vertical pumps are chiefly used in mine shafts, and for small heads are built without a casing. Single-inlet impellers are easier to construct, but they are subject to an axial thrust in the direction of the liquid flow. Double-inlet impellers are practically free from axial thrust, but the leading of the liquid from stage to stage in multi-stage pumps is somewhat complicated. The backward-discharge impeller is the one most commonly used, especially where the pump is liable to be suddenly overloaded. The radial-discharge impeller also finds wide application, particularly in high-pressure pumps.

THEORY

Fundamental Equation. Referring to Fig. 1, the water enters the impeller inlet with an absolute velocity (in space) w_e, and leaves the impeller with an absolute velocity w_a. The inner peripheral velocity of the impeller is u_e, and the outer peripheral velocity u_a. All velocities are in ft. per sec.

Let H_b be the theoretical head (in ft.) against which the pump would deliver if there were no losses. Then $H_b = (1/g)(u_a w_a \cos d_a - u_e w_e \cos d_e) = (1/2g) \times (u_a^2 - u_e^2 + w_a^2 - w_e^2 + v_e^2 - v_a^2)$, where v_e and v_a are the inlet and exit relative velocities, respectively.

Axial Impeller Inlet. Unless special inlet guide vanes are provided to introduce the water into the impeller at a certain angle (sometimes done in high-pressure pumps to reduce inlet friction losses), the water approaches the impeller in an axial direction. In that case $d_e = 90°$; $v_e^2 = w_e^2 + u_e^2$, and $H_b = (1/g)(u_a w_a \cos d_a) = (1/2g) \times (u_a^2 - v_a^2 + w_a^2)$. Of this, $w_a^2/2g$ is available for the discharge vanes or the volute casing.

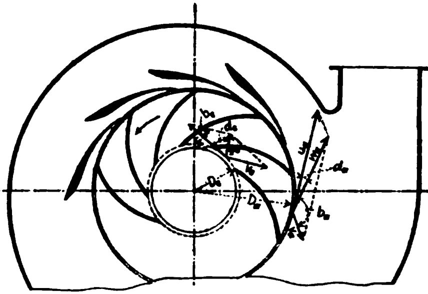

FIG. 1.

Radial Impeller Exit. For radial impeller exit, or $b_a = 90°$, $w_a^2 = u_a^2 + v_a^2$. If, in addition to this, $d_e = 90°$, as is usually the case, the theoretical head is $H_b = u_a^2/g$, while $(u_a^2 + v_a^2)/2g$ is available for the discharge vanes or the casing.

Pressure, Quantity, and Impeller Exit Angle. For radial impeller discharge ($b_a = 90°$) the pressure head H_b is independent of the quantity Q of liquid passing through the pump. For forward discharge, $b_a < 90°$, H_b increases with Q. For backward discharge, $b_a > 90°$, H_b decreases as Q increases. A backward-discharge pump is thus in a way self-regulating, being unlikely to overload its driver under circumstances where Q is liable to vary.

Hydraulic Losses. The theoretical head H_b is never realized on account of the hydraulic losses in the pump. A certain part is always wasted in friction losses, in losses due to sudden changes in velocity or direction of flow and, finally, in the discarded velocity head at the pump exit. These losses may be subdivided as follows: The **suction-pipe losses** due to friction may be computed from formula on p. 269. The liquid velocity in the suction pipe w_s (ft. per sec.), is so chosen that $w_s^2/2g = mH_b$, where m varies from 0.01 for high-pressure and small-quantity pumps to 0.08 (and sometimes greater) for low-pressure and large-quantity pumps. The clear area in the strainer at the suction-pipe inlet should be about two or three times the pipe area. The **impeller losses** can be subdivided into three parts: (1) Impeller inlet loss, caused by the sudden reduction of clear passage area by the thicknesses of the impeller blades. This can be reduced by sharpening the blades at inlet for a length equal to about twice their thickness, and by having the number of blades as small as possible, consistent with the proper guiding of the liquid. (2) Friction and shock losses along the blades. These can be reduced by having the impeller castings very smooth, the passages between blades of ample area, and the blades so shaped that the reduction of liquid velocity is gradual and constant. (3) Impeller exit loss, caused by the sudden emerging of the liquid from the impeller into a clear space. This can also be reduced by sharpening the blade exit tips. The **discharge-vane losses** (at the inlet, along the vanes, and at their exit) and their remedies are of the same nature as those in the impeller. With long, scroll-shaped vanes, the number of vanes can be made very small. The **casing loss**, due to the fact that the jet issuing from every discharge vane has to be carried around a part of a circumference till all the jets are brought to the pump outlet, and resulting in shocks and eddy currents, is best minimized by employing a spiral casing. To carry the liquid away from the pump, an unutilizable velocity head $w_d^2/2g$ is necessary. This **discarded velocity head** varies from 0.005 H_b for high heads, to 0.10 H_b for low heads and large quantities of liquid.

Hydraulic Efficiency. The hydraulic losses enumerated above reduce the theoretical head H_b to a smaller head H_n; the hydraulic efficiency $e_h = H_n/H_b$. Unless the number of impeller blades is very large, the angle d_a in Fig. 1 is frequently greater than would be computed from the *apparent* impeller exit angle b_a. Consequently, the hydraulic efficiency as computed from tests on actual pumps at about or above full load is slightly *below* its true value, since the theoretical head H_b is not really as high as it is supposed to be.

The **theoretical horse power** necessary to raise Q cu. ft. per sec. of a liquid of density d lb. per cu. ft. through a height of H_n ft. $= QdH_n/550 = Qde_hH_b/550$.

Power Losses. The power losses in a centrifugal pump consist mainly of bearing and stuffing-box losses, of rotation loss, and of short-circuit losses. The **bearing loss** for ring-oiled bearings with proper lubrication $= F = 0.002 \times dNW$, where F = work lost in bearing friction, ft.-lb. per min.; d = shaft diam., in.; N = r.p.m., and W = weight of shaft and impeller plus belt pull (if any), lb. For a properly designed and well-lubricated thrust bearing, $F = 0.005P_a(d + d_1)N$, where P_a = axial thrust, lb., and d_1 = outer diam. of collar, in. With proper design and arrangement for water-cooling, the **stuffing-box losses** can be made negligibly small. The friction loss caused by the rotation of the impeller in the liquid can be expressed by the formula: **Rotation loss** (in h p.) $= 1.25\ (u_a/100)^3D^2Ss$, where u_a = wheel speed (ft. per sec.), D = outer diam. of impeller (ft.), S = number of stages, and s = specific gravity of the liquid, referred to water as unity. This loss is seen to be proportional to the number of stages and to the 5th power of the impeller diameter. (In numerous tests worked up by the writer, nearly the entire power loss at full load and beyond has been accounted for by the rotation loss alone.) The problem, therefore, of building a small centrifugal pump for high pressure and of good efficiency at a low cost is frequently perplexing. **Short-circuit losses** result from the return of part of the liquid raised through the impeller to the impeller inlet instead of proceeding to the pump exit. Part of this short-circuiting takes place through the axial clearance between the impeller and the casing under the impeller pressure head $(u_a^2 - v_a^2)/2g$, and evidently decreases as v_a, which is a measure of the quantity of liquid passed by the pump, increases. Another part passes up the backs of the vanes, where the static pressure is lowest and the relative velocity is highest, and, at very light loads, passes down the front or driving faces of the vanes, where the static pressure is highest and the relative velocity is very low and may be even negative. At no load the short-circuit loss is usually about 25 or 30 per cent. of the rated power of the pump, while at full load it is fairly negligible.

Shaft Efficiency. The shaft efficiency of a pump is the ratio of the theoretical power to the power delivered to the shaft of the pump. In the best modern pumps it is between 70 and 80 per cent. In a few cases even higher efficiencies have been reported.

Efficiencies of Centrifugal Pumps. In general, the efficiency of a centrifugal pump will depend on its brake horse power, or on the product of its rated gallons per minute into the head in feet. The table below gives a fair idea of current practice, but it must be remembered that first cost and efficiency are very closely related, and that in smaller machines efficiency is very likely to be sacrificed to first cost, while larger machines have been designed with shaft efficiency as high as 88 per cent.

In the table the shaft efficiencies are for rated head, volume and r.p.m. Fig. 2, shows typical interrelations of head, volume, r.p.m. and efficiency for good commercial pumps. There is no sharp division line between high head and low head; low head is assumed to mean less than 50 ft.; high head above 50 ft. Low speed is up to 600 r.p.m.; moderate speeds from 600 to 1800 r.p.m.; high speeds above 1800 r.p.m.

The most general drive for low-speed centrifugal pumps is the reciprocating

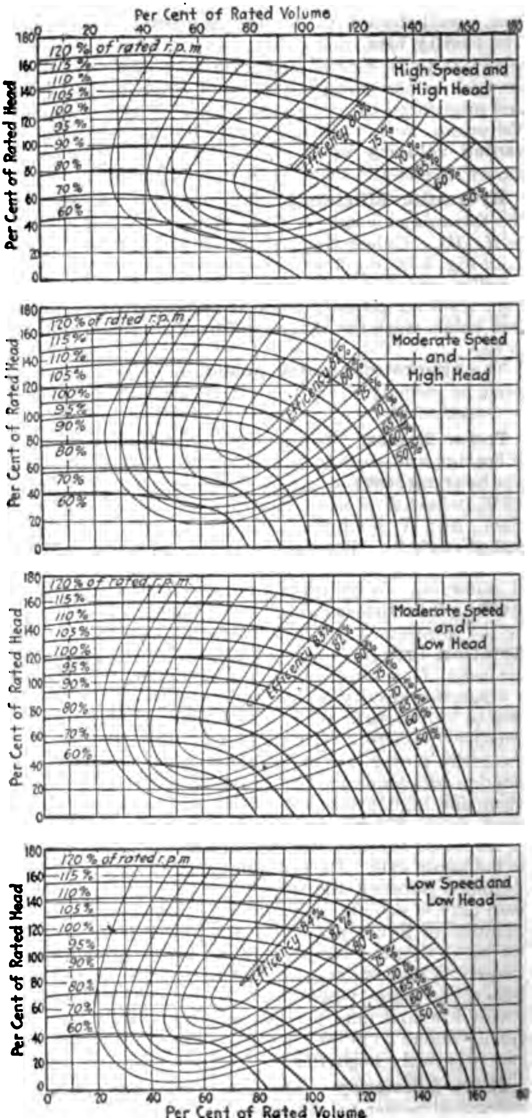

Fig. 2.—Typical Interrelations of Head, Volume, R.P.M., and Efficiency for Good Commercial Centrifugal Pumps.

steam engine, although low-speed motors are sometimes used. The most general drive for moderate-speed pumps is the electric motor, although high-speed engines and low-speed steam turbines are also occasionally used. For high-speed pumps, steam turbines are generally best, although high-speed motors are occasionally used. The curves represent general practice with commercial machines; that is, units that are built in quantity. In most cases special machines can be designed to give better economies than those quoted in the curves, but the cost of such units is proportionately higher.

CENTRIFUGAL-PUMP CONSTANTS AND CHARACTERISTICS

Constant-head Characteristics (Fig. 1). Let D_e and D_a be respectively the inlet and exit diameters of the impeller, ft.; F_e and F_a the inlet and exit areas, sq. ft.; w_r the radial component of the impeller inlet velocity, ft. per sec., $= w_e \sin d_e = Q/F_e$ where Q is in cu. ft. per sec.; other quantities as previously defined. Then, if

$$C_1 = \left(\frac{F_e}{F_a \tan b_a} + \frac{D_e}{D_a \tan b_e}\right) \Big/ 2\left[1 - \left(\frac{D_e}{D_a}\right)^2\right], \text{and } C_2 = 1 \Big/ \left[1 - \left(\frac{D_e}{D_a}\right)^2\right],$$

the pump characteristic for constant head will be

$$u_a = -w_r C_1 - \sqrt{w_r^2 C_1^2 + gH_b C_2}.$$

This equation gives for a pump of given dimensions the variation of u_a (r.p.m.) against w_r (discharge quantity) for a fixed total head H_b if the inlets into the impeller and into the discharge vanes are to be shockless.

Constant-speed Characteristics. Letting $C_3 = (u_a^2 - u_e^2)/g$ and $C_4 = [(u_a/\tan b_a) + (u_e/\tan b_e)(F_a/F_e)]/g$, the pump characteristic for constant speed will be $H_b = C_3 + v_r C_4$, where $v_r = w_a \sin d_a = Q/F_a$. The total head H_b will therefore for a constant r.p.m. increase with increasing values of Q if C_4 is positive (forward discharge), and will decrease with increasing values of Q if C_4 is negative (backward discharge).

Constant-efficiency Characteristics. A pump has its best hydraulic efficiency when the sizes and shapes of its passages have been correctly designed for the particular head and quantity desired. If the characteristic of the satisfactory pump design be written as $C_5 = Q/\sqrt{H_b}$, then the same pump patterns can be used for various values of Q with the same hydraulic efficiency if H_b is so varied that C_5 remains constant. The relation between H_b and H_n, or the hydraulic efficiency for the particular model, is, of course, supposed to be known.

The expression $C_5 = Q/\sqrt{H_b}$ may also be written nearly enough as $C_5 = Q/N$, where N = r.p.m., so that if the r.p.m. are not prescribed, the same model can be used for various heads by changing the r.p.m. to correspond.

Speed and Shock vs. Efficiency. The various hydraulic losses are directly proportional to the total head, so that changing the speed and the head will have no effect on the hydraulic efficiency. Of the power losses, all, except the rotation loss, are fairly constant for various heads, and (especially at full load) their variations may be quite neglected. The rotation loss however, varying with the cube of the r.p.m. and with the fifth power of the outer impeller diameter, must always be very carefully considered. The foregoing discussion of characteristics and efficiencies assumes shockless entrance into the impeller and into the discharge vanes, in other words, that the angles b_e and d_e are adjusted to suit the varying quantity of liquid. Adjustable discharge vanes have actually been built for single-stage, large-quantity pumps; but for multi-stage or small-quantity pumps they are impracticable. Shock losses are therefore usually present, but, as they can not be evaluated mathematically, the exact characteristic curves for any particular pump can be determined only by experiment.

Behavior of Centrifugal Pumps with Changes in Quantity, Speed and Head Regulation. From the fundamental equation the theoretical pressure head for zero quantity ($Q = 0$) is u^2/g. With increase in quantity, the head remains constant with radial blades, increases with forward-discharge blades and decreases with backward-discharge blades (see Fig. 3). The actual pressure lines pursue a materially different course; because even with very reduced quantities, and especially for zero quantity, the fundamental equation is no longer applicable. For zero quantity, when practically the centrifugal force alone is effective, the generated head is $u^2/2g$; or, since even with the blast gate closed there are water currents within the pump, it is slightly larger, on account of the conversion of velocity into pressure. With increase in quantity, the pressure rises, with forward-discharge blades faster than with backward-discharge blades; and then drops again, as the pressure drop within the pump is increasing. (See lower lines in Fig. 3.)

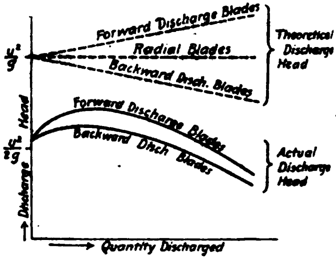

FIG. 3.

If the head to be overcome is plotted against the quantity Q, the intersection of the line of generated head with the line of head operated against

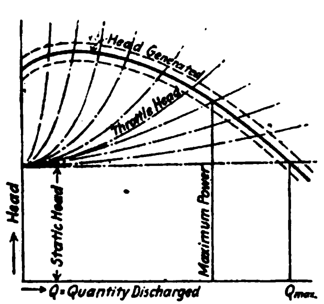

FIG. 4.

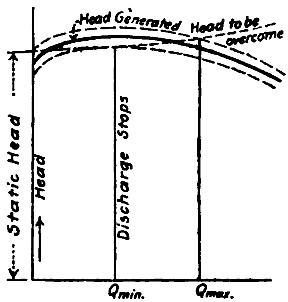

FIG. 5.

forms the point at which the pump is working at the time. Such a diagram also shows how the quantity varies with the r.p.m. In Figs. 4 and 5 the heavy line shows the head generated at normal speed with different rates of discharge. The two neighboring dotted lines give the heads for speeds 2 per cent. above and below, respectively. The curves marked "throttle head" in Fig. 4 show the variations in the total head to be overcome (static head + throttle head) with different amounts of throttling and with different rates of discharge. If the throttled head of the pump is large in comparison with the geometric or static head, as in the case of a mine-shaft pump when the head corresponding to the r.p.m. of the pump is greater than the depth of the shaft and the excess head has to be throttled down (see Fig. 4), or in the case of a condenser circulating pump with a small static head but with very long piping, the pump is not so sensitive to variations in the r.p.m. But in a pump where there is mainly a static head to be overcome, as in drainage work, the quantity of discharge varies considerably with variation in the r.p.m., and it decreases even with a moderate drop in the r.p.m.; that is, when the generated head becomes too small, the check valve of the pump closes and the discharge of water stops (see Fig. 5). If a drainage pump is to work with normal r.p.m. against the full discharge head and not have its discharge vary unduly with variations in r.p.m., it should work on the drooping part of the pressure curve, as indicated in Fig. 5. In actual drainage pumps, a change of 1 per cent. in speed involves a change of about 5 per cent. in discharge.

Regulation of Quantity or Output. In centrifugal pumps the quantity Q is proportioned to the r.p.m. only when flow resistances alone are to be overcome (zero static head). But if a static head is also to be overcome, the quantity changes faster than the r.p.m. If the head operated against is also variable, as in the case of water-works installations, the quantity of discharge no longer bears a definite relation to the r.p.m. To regulate for constant quantity while maintaining the r.p.m. constant, it is necessary to regulate for constant velocity of flow in the discharge pipe or in the suction pipe; for instance, by arranging that a change in velocity should cause a valve in the piping to open to a greater or lesser extent. In certain cases, as in water-works pumps, which operate against a gradually increasing head, so that the r.p.m. must be gradually increased, it is sufficient to admit a constant supply of steam; then the pump automatically maintains a speed and a quantity corresponding to the steam supply. Governors which hold the speed are a hindrance in this respect. In pumps where flow resistances alone are to be overcome, the quantity may be regulated down to zero. But where static pressure is mainly to be overcome, the quantity can be reduced only down to a certain limit, because if the pump works before the pressure-curve peak, the check valve closes.

DESIGN DATA

Suction Pipe. If A = atmospheric pressure, H_s = suction head, h_s = friction head, and $w_s^2/2g$ = velocity head in the suction pipe, in general $A - [H_s + h_s + (w_s^2/2g)] = 0$. In practice, it is advisable to take $H_s + h_s + (w_s^2/2g) = 23$ ft. In low-pressure pumps the loss of head in the suction pipe may affect materially the efficiency of the pump.

Impeller. After determining the shaft and the impeller hub diameters from mechanical considerations, the impeller inlet diameter is taken to allow an annulus inlet velocity of from 6 to 12 ft. per sec. The number of impeller blades is made from 6 to 12, with an equal number of half-blades extending inward from the outer periphery. Backward-discharge blades are more easily bent to the proper involute shapes, and render the pump proof against overloading. The tips, however, are subject to centrifugal forces normal to their axial surfaces, and they must be reinforced by shrouds. These shrouds, as well as the impeller web and blades, must be carefully computed for centrifugal stresses. The angle between blade and wheel tangent is usually about 30 deg. The impeller inlet is frequently provided with a labyrinth packing or some similar arrangement to reduce the short-circuit loss.

Discharge Vanes. The number of discharge vanes is somewhat smaller than that of the impeller blades. They are usually of the involute shape, with a gradual divergency of passage. Their inlet angle should be small so as to keep down the short-circuit losses and also the shock losses with varying quantities of liquid.

TYPES OF CENTRIFUGAL PUMPS

The methods usually employed for overcoming axial thrust with single-inlet impellers and other features of modern centrifugal pumps are shown below. Fig. 6 illustrates diagrammatically the **Sulzer type** (Sulzer Bros., Winterthur, Switzerland), in which the impellers are mounted alternately in a reverse position so that the directions of thrust of any two adjacent impellers are opposed. The projected areas at 1 and 4, taken in a plane perpendicular to the shaft axis, are equal; similarly, the projected areas at 2 and 3 are equal. By making the pressure heads of all impellers equal, substantially $p_2 - p_1 = p_4 - p_3$. Any small resulting axial thrust is taken care of by a rigid collar thrust bearing. R. D. Wood & Co. (Philadelphia) and the Buffalo Steam Pump Co. (Buffalo, N. Y.) make pumps of this type.

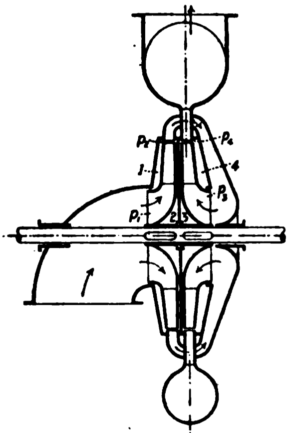

Fig. 6.—Sulzer Type of Pump.

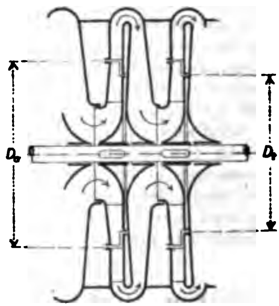

Fig. 7.—Rateau Type of Pump.

Fig. 7 illustrates diagrammatically the **Rateau type,** in which the end thrust is largely neutralised by shrouding the two sides of each impeller to different diameters D_a and D_t. The higher pressure corresponding to the larger diameter D_a acting on a smaller surface is fairly balanced by the lower pressure corresponding to the smaller diameter D_t acting on a larger surface. Complete balance is finally obtained by means of a balancing piston keyed to the shaft beyond the last impeller on the high-pressure side, and rotating in a cylindrical casing with very small clearances. On one side of the piston full water pressure exists, while the other side can be connected to any pressure stage or to the suction end of the pump.

Fig. 8 illustrates diagrammatically the **Jaeger type** (J. H. Jaeger & Co., Leipsig). In this design—the one most generally adopted—each impeller is balanced individually by means of holes in the impeller web which equalize the pressure in spaces 3 and 4. By making the clearance at the outer rim of the impeller sufficiently large, equal pressure will exist in spaces 1 and 2. By using an inner and an outer packing as indicated at *R*, the short-circuit

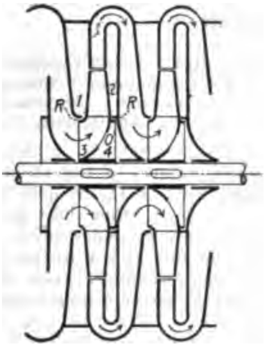

FIG. 8.—Jaeger Type of Pump.

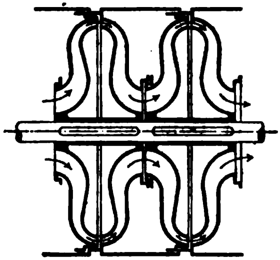

FIG. 9.—Kugel-Gelpke Type of Pump.

loss is greatly reduced and the maintenance of equal pressures in spaces 1 and 2 is made possible. Any remaining axial thrust is taken up by a marine-type thrust bearing on the suction side of the pump. Henry R. Worthington, of New York, the Byron Jackson Iron Works, of San Francisco, the Alberger Pump Co., of New York, and the De Laval Steam Turbine Co., of Trenton, N. J., build pumps embodying the basic Jaeger principle.

Fig. 9 illustrates diagrammatically the **Kugel-Gelpke type** (Escher, Wyss & Co., Zurich, Switzerland). As seen, both impeller and discharge vanes are S-shaped, the water entering and leaving both the impeller and the discharge vanes in an axial direction. The axial thrust is balanced by the admission of water under pressure in the spaces between the guide vanes and impellers, the water pressure being regulated by means of a valve. Balancing pistons and thrust bearings are also used to balance the axial thrust. The Allis-Chalmers Co., of Milwaukee, Wis., builds pumps of this type.

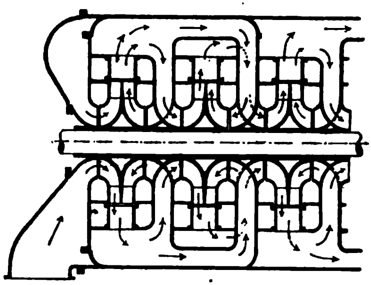

FIG. 10.—Double-inlet Pump without End Thrust.

Fig. 10 illustrates a double-inlet pump which has no end thrust and needs no special balancing arrangement excepting an ordinary thrust bearing for simply locating the rotating part.

AIR COMPRESSORS

BY

H. J. THORKELSON

REFERENCES: Simons, "Compressed Air," McGraw-Hill. Peele, "Compressed Air Plants," Wiley. Harris, "Compressed Air Theory and Computation," McGraw-Hill. Innes, "Air Compressors and Blowing Engines," Van Nostrand. Thorkelson, "Air Compression and Transmission," McGraw-Hill. Von Ihering, "Die Gebläse," Springer, Berlin. Hirsch, "Die Luftpumpen," Jänecke, Hanover.

Types of Compressors. For pressures below that of the atmosphere many types of compressors are available. **Fans** (see p. 1541) are usually used for exhaust systems for handling foul air, shavings or other light material. **Jet blowers** (p. 1516) are also used, and for the low pressures occurring in condensers, piston and special centrifugal or impeller types are employed.

For pressures varying from ⅛ oz. to 16 oz., various types of **fans** are used. For pressures from 1 to 5 or even 10 lb. above atmospheric pressure, **rotary blowers** (p. 1515) are available.

For compressing air to pressures of 5 or 10 lb., and in some cases pressures as high as 100 lb. and over, **centrifugal compressors** (turbo-blowers—p. 1530) have been recently introduced.

Piston Compressors are built for pressures as low as 1 lb. above atmospheric, and single cylinders are used with "single-stage" compression to pressures of 80 or 100 lb. per sq. in. gage. When **higher pressures** are desired, the compression is divided into stages, with intercoolers between the cylinders. Two-stage compressors are used for pressures from 80 or 100 to 500 lb., three-stage for pressures up to 1200 lb. (in small units up to 2000 or 2500 lb.), and four-stage for pressures of 2500 to 3000 lb. per sq. in. or even higher. All these types of piston compressors may be driven by steam or gas engines, electric motors or water wheels.

Several types of **compressors** have been designed to utilise water powers directly **without** the use of any mechanical **moving parts.** These are particularly adaptable when such natural resources are available near mines or other industries using large quantities of compressed air. An installation of this type is described on p. 1517.

DATA ON AIR

Specific Weight. Table 1 will be found useful in determining the specific weight of air at various temperatures, pressures and degrees of humidity.

Table 2 gives the specific weight of saturated air at various temperatures and pressures.

Table 2. Weight of Saturated Air in Lb. per Cu. Ft. at Different Barometric Pressures

Specific Heat. The instantaneous specific heat of **dry air** is given by F. G. Swann as $0.24112 + 0.000009\,t$, and the specific heat of **water vapor** as $0.4423 + 0.00018\,t$, where t is the temperature in deg. fahr. The **mean specific heat** of air with any degree of saturation may then be found by multiplying the weight of air by its specific heat and adding to this the product of the weight of water vapor and its specific heat and dividing the sum by the weight of the mixture. Table 3 is calculated on that basis.

For dry air at high temperatures see p. 366.

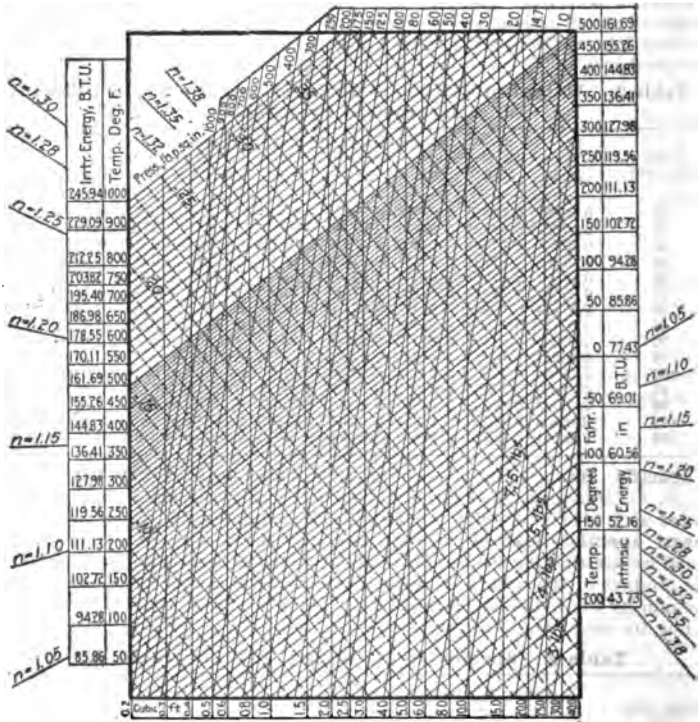
Table 3. Specific Heats of Dry and Saturated Air

Temp., deg. fahr.	Specific heat of		Temp., deg. fahr.	Specific heat of	
	Dry air	Saturated air		Dry air	Saturated air
60	0.2417	0.244	85	0.2419	0.2474
65	0.2417	0.2447	90	0.2419	0.2486
70	0.2417	0.2452	95	0.2420	0.2498
75	0.2418	0.2458	100	0.2420	0.2512
80	0.2418	0.2466			

The mean specific heat of air having any relative humidity may be found from Table 3 by interpolation. *E.g.*, for air of 40 per cent. relative humidity and at 80 deg. fahr. the mean specific heat will be $0.2418 + 0.40 \times (0.2466 - 0.2418)$, or 0.2437.

The variation of the specific heat of air with pressure has been investigated by Holborn and Jakob (*Z. V. D. I.*, vol. 58, p. 1436). The mean specific heat at constant pressure for the temperature range 20–100 deg. cent. (68–212 deg. fahr.) is given by the equation $10^4c_p = 2413 + 286p + 0.0005\,p^2 - 0.00001\,p^3$, where p is the pressure in kg. per sq. cm. The experimental values are given below:

Pressure, lb. per sq. in. abs.	14.2	356	711	1422	2133	2844
c_p	.2415	.2490	.2554	.2690	.2821	.2925



Adapted from Prof. C. R. Richards, Entropy-Log. Temp. Diagram, Univ. of Ill. Eng. Experiment Station Bulletin No. 63.

FIG. 1.—Diagram for Determining the Amount of Energy Stored in Compressed Air.

Calculations of the work done by the expansion of air are greatly facilitated by the diagram Fig. 1, adapted from the "Entropy-Log. Temperature Diagram for Air" by Prof. C. R. Richards (*Bulletin* No. 63, University of Illinois Experiment Station).

In Fig. 1 the vertical lines represent the volume in cu. ft. occupied by 1 lb. of air. The lines slightly inclined to the vertical represent the absolute pressure in lb. per sq. in. The lines at an angle of 45 deg. represent temperature in deg. fahr. and intrinsic (internal) energy in B.t.u., and the dotted inclined lines represent entropy. These last lines are paralleled in finding the results of an adiabatic change, while if the change follows a $p_1V_1^n = p_2V_2^n$ path, the effects are studied by paralleling lines indicated at the margin for various values of n. For example, an inspection of Fig. 1 shows that 1 lb. weight of air at a pressure of 125 lb. abs. per sq. in. and occupying a volume of 1.5 cu. ft. will have a temperature of 50 deg. fahr. and contain 85.86 B.t.u. or 66,800 ft.-lb. of internal energy.

Furthermore, the **adiabatic expansion** of 1 lb. of air from a pressure of 125 lb. abs. per sq. in. and a temperature of 70 deg. fahr to a pressure of 14.7 lb. abs. will result in a final temperature of -170 deg. fahr., and the work done during the expansion would be $(89.22 - 48.79 =)$ 40.43 B.t.u. or 31,454 ft.-lb. per lb. of air. This expansion follows the dotted line of the diagram, but if the expansion followed the equation $p_1V_1^{1.2} = p_2V_2^{1.2}$, the available intrinsic energy per lb. for any pressure range would be found by following a line parallel to the marginal line of the chart marked $n = 1.20$ from the upper to the lower pressure. *E.g.*, if such an expansion occurred between 125 lb. abs. per sq. in. and 70 deg. fahr. and 14.7 lb. abs., the resulting temperature would be -87 deg. fahr. and the work done would be $(89.22 - 62.76 =)$ 27.46 B.t.u. or 21,346 ft.-lb. per lb. of air.

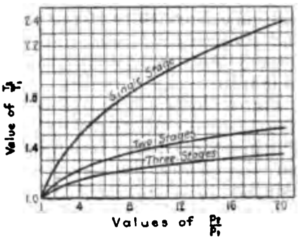


FIG. 2.—Compression Temperatures.

With **adiabatic compression**, the **final temperature** T_2 (deg. fahr. abs.) is given by the formula $T_2 = T_1\,(p_2/p_1)^{0.29}$ for single-stage compression; by $T_2 = T_1\,\sqrt{(p_2/p_1)^{0.29}}$ for two-stage compression, and by $T_2 = T_1\,\sqrt[3]{(p_2/p_1)^{0.29}}$ for three-stage. Values of T_2 may be obtained readily from the chart devised by F. W. O'Neill and shown in Fig. 2, in which the ordinates give the factors by which the initial absolute temperature T_1 (deg. fahr.) is to be multiplied to obtain the final absolute temperature T_2 for various ratios of p_2 to p_1.

BLOWERS AND COMPRESSORS

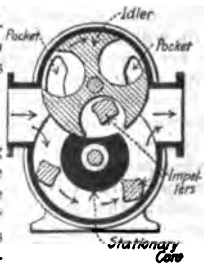

FIG. 3.—Sturtevant Rotary Blower.

Rotary Blowers are built for air pressures varying from 6 oz. to 10 lb. or even 12 lb. per sq. in. The best efficiencies of this type of blower, however, are usually secured below 5 lb. pressure, but the simplicity of the machine gives it an advantage over compressors of the piston type and frequently warrants its installation for the higher pressures indicated when designed for this purpose. As the machine operates by displacement, it is usually preferred for cupola practice because its positive action will not permit a reduction in air supply if the cupola tends to clog. For other uses of air at pressures below 8 oz. the fan is ordinarily more economical.

Blowers of this type may be arranged to give either **constant volume or constant pressure,** and to handle either liquids or gases. They consist of a casing containing one or more revolving impellers of various forms of design.

Fig. 3 represents a cross-section of the **Sturtevant high-pressure blower,** which is built in capacities ranging from 5 to 15,000 cu. ft. per min. at 8 oz. pressure (speeds, from 375 to 800 r.p.m. for the smallest size down to 160 to 220 r.p.m. for the largest; weights with sub-base range from 200 to 39,000 lb.). The smaller machines have a vertical arrangement of shafts, while the larger types usually have their shafts in the same horizontal plane. Two impeller blades are always in action, and leakage by one is caught by the other. The proper **size of blower for a cupola** may be calculated on the basis of 30,000 cu. ft. of air per ton of iron melted. Sturtevant machines are also used for handling gases. The capacities for the various sizes of **gas exhausters** range from 7500 to 900,000 cu. ft. per hour at 8 oz. pressure, making no allowance for shrinkage, which will vary from 10 to 20 per cent., depending on the gas and its pressure. The inlet and outlet diameters run from 3 in. in the smallest size to 30 in. in the largest; weights, from 400 to 33,000 lb.

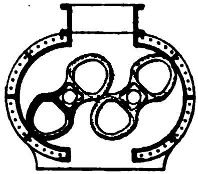

FIG. 4.—Roots Blower.

Fig. 4 illustrates a cross-section of a **Roots blower**. The two impellers are symmetrical and are driven in opposite directions by gears outside the casing. The impellers do not touch each other nor the casing, but the clearance is reduced to a minimum in order to reduce slip or leakage. The amount of this **slip or leakage** may be determined by operating the machine with a closed discharge, at a speed sufficient to maintain the required discharge pressure. The amount is usually largest in machines of smallest capacity, *i.e.*, a machine displacing 0.75 cu. ft. per rev. at a pressure of 1 lb. will have a slip of from 60 to 70 rev., while a machine having a capacity of 300 cu. ft. per rev. will have a slip of from 3 to 5 rev. For intermediate capacities the slip will vary proportionally and increase with higher pressures as the square root of the discharge pressure, *i.e.*, at 4 lb. pressure the slip will be approximately twice that at 1 lb.

In most blower work the so-called hydraulic formula for **horse power** will be found satisfactory: h.p. = $Q(p_2 - p_1)/33{,}000$, where Q is the cu. ft. of air compressed per min., p_1 the initial pressure and p_2 the final pressure, lb. per sq. ft. To get the actual horse power at the shaft, the horse power should be divided by the efficiency, which will vary from 0.80 to 0.90.

FIG. 5.

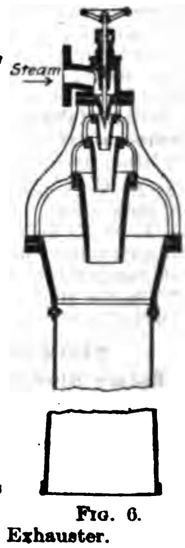

FIG. 6.

FIG. 5.—Körting Exhauster.

FIG. 6.—Körting Steam-jet Air Compressor.

Steam-jet Blowers. Steam jets have long been used for "blowing" or exhausting in order to maintain combustion in locomotive boilers, usually employing the exhaust from the engines through properly shaped "nozzles." This type of air compressor or exhauster also finds extended application for emergency use and at times in permanent installations for removing foul air from mines, factories, ship holds, and for gas exhausters, for securing forced draft, and for handling gases under low pressures in certain chemical industries. Among its **advantages** are simplicity, ease of operation, small space, minimum of repairs and ease of regulation.

Fig. 5 shows a **Körting exhauster** for removing air, and Fig. 6 a Körting compressor of the steam-jet type. These machines are built in **capacities** of from 10 to over 20,000 cu. ft. per min., and usually operate with steam at from 60 to 100 lb. gage pressure. In some cases they are operated by water under pressures from 1 to 45 lb. gage. A. von Ihering ("Die Gebläse") reports some tests as to **steam consumption** which indicate from 1.3 to 3.4 lb. of steam required per 1000 cu. ft. of air handled, the larger sizes being the more economical.

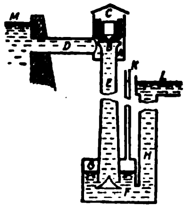

FIG. 7.—Taylor Hydraulic Air Compressor.

Hydraulic Compressors. Several devices have been made for utilizing falling water for the purpose of compressing air without the use of any mechanical moving parts. The most successful of these is the **Taylor compressor,** shown diagrammatically in Fig. 7. In the figure, air tubes are represented at *C*, all terminating at the conical entrance *B* to the down-flow pipe *E*. The water supply is furnished through the flume *D*. As the water falls it draws air through the small tubes, carrying it down to the separating tank *G*, where it is liberated at a pressure depending on the weight of water in the vertical pipe *H*. The compressed air is then conducted through the pipe *K* to the place where it is to be used. The distance from *M* to the tail race *L* represents the height or fall of water that is available.

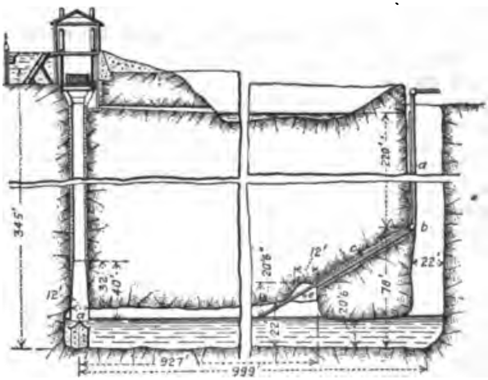

FIG. 8.—Taylor Hydraulic Compressor Installation near Cobalt, Ont.

In this system the compression is isothermal and the compressed air is saturated with moisture. The oxygen content of the air is reduced, which renders the air less beneficial for purposes of mine ventilation if the exhaust from the air tools is planned to assist ventilation. The system offers a very simple solution for

Air Measurements				Water Measurements			
	Absolute Pressures (lb. per sq. in.)						
Free Air, cu. ft. per min.	Free Air	Compressed Air	Horse power	Cu. ft. per min.	Head, ft.	Horse power	Efficiency, per cent.
10,580	14	128	1,430	13,057	70.5	1,741	82.17
11,930	14	128	1,623	14,820	70.0	1,961	82.27
9,238	14	128	1,248	12,710	70.6	1,700	73.50

utilising water powers when the market for compressed air justifies its installation. It has the advantage of simplicity with a minimum of operating expense, and very high efficiencies are secured. The first cost of the installation is likely to be high.

In 1906 a large plant of this type was installed at the Victoria Copper Mine, near Rockland, Mich., consisting of three units with a total capacity of from 34,000 to 36,000 cu. ft. of free air per min. A series of tests made on a single intake head by Prof. F. W. Sperr, gave the results shown on p. 1517.

Fig. 8 illustrates some of the dimensions of a Taylor hydraulic compressor installed near Cobalt, Ontario, Canada. This was designed for a capacity of 40,000 cu. ft. of free air per min. to be compressed to a gage pressure of 120 lb. The compressed air is conducted to mines through 9 miles of 20-in. pipe leading to two 12-in. lines with a total distributing line of 21 miles in length. The water is admitted through suitable gates to two "heads" each 16 ft. in diam. and containing 66 pipes 14 in. in diam. The size of the heads is reduced in diameter to about 8 ft. and the whole apparatus can be raised or lowered as required by operating conditions. A cone *a* assists in separating the air and water, and the long horizontal tunnel permits quite complete separation. The compressed air is removed through the pipe *c* and the water freed from the entrained air escapes through the vertical shaft *b*. Pipe *e* acts as a relief for a surplus of compressed air. Its end is normally below the surface of the water in the tunnel, but if the amount of air should accumulate it would be exposed and permit the escape of the surplus air without seriously affecting the normal air pressure of the distribution system.

Piston Compressors and Blowers

The large quantities of air required for blast-furnaces and Bessemer converters are usually supplied by piston compressors of large capacity, driven either by steam or gas engines. Turbo-blowers directly driven by steam turbines, however, have been recently developed for this work.

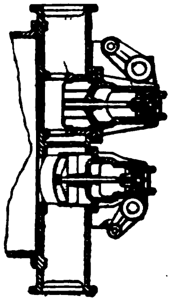

Fig. 9.—Valves of Allis-Chalmers Blower.

Piston compressors used as blowers for blast furnaces and Bessemer converters usually operate at **discharge pressures** of 15 or 20 lb. gage. The tendency in blower design is to secure increased capacity by higher speeds than formerly. The Allis-Chalmers Company now uses a maximum speed of 90 r.p.m. for 48-in. stroke and 85 r.p.m. for 60-in. stroke, giving **piston speeds** of from 720 to 850 ft. per min. With piston speeds approximating 750 ft. per min. the inlet area is approximately 13 per cent. and the outlet area 11 per cent. of the piston area. With increased speeds the tendency is to increase clearance, which will usually vary from 9½ to 11½ per cent.

Fig. 9 shows the **valves** of an Allis-Chalmers blower, in which the upper valve is for inlet and is mechanically operated. The lower discharge valve opens automatically but is closed mechanically. It is made of sheet steel so as to diminish inertia effect.

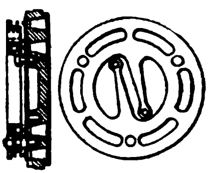

Fig. 10.—Borsig Valve.

The Slick blowing tub consists of a reciprocating cylinder on the outside of the compressing cylinder, arranged so as to open ports at the ends of the cylinders for inlet. This gives unobstructed inlet areas of from 18 to 20 per cent. with very small clearance.

Fig. 10 illustrates a European design of valve (the Borsig) which has been used quite successfully in this country. It is guided without friction by elastic deformation of part of the valve. To get enough valve area the cylinder heads must be extended to permit the insertion of a number of these valves in cages. The **Gutermuth flap valve** (Fig. 11) is also used in compressors. It consists of a thin sheet of tempered steel or bronze, formed at one end into a spring hinge.

FIG. 11.—Gutermuth Valve.

Figs. 12–14 show types of inlet and discharge valves made by the Ingersoll-Rand Co. Fig. 12 is a "Hurricane-Inlet" valve placed in the piston and communicating with the intake through a tube. These valves are made from a continuous ring of oil-treated high-carbon steel forged from the solid and turned to a T-section. No springs, pins or rods are used, and the valve is entirely automatic in its action. Fig. 13 shows a direct-lift inlet valve and Fig. 14 an automatic discharge valve.

The **ratio of inlet valve area to piston area** varies from 0.05 to 0.14. For ordinary types of valves, the inlet area should, as a rule, be not less than 8 or 10 per cent. of the piston area. Automatically operated inlet valves are apt to be irregular in their action and reduce the volumetric efficiency of the compressor. This disadvantage is overcome by using mechanically operated inlet valves, usually of a Corliss type, but on account of the variation of discharge pressure they are not used as often for discharge or for inlet on the high-pressure stages of a multi-stage compressor. The **area of the discharge valves** will usually vary from 10 to 15 per cent. of the piston area, the larger percentage being required for the higher piston speeds.

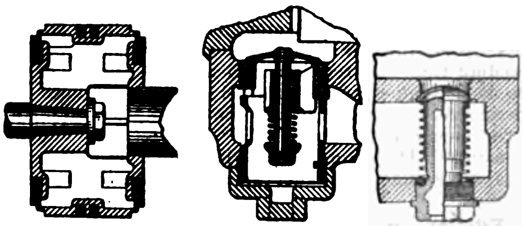

FIG. 12. FIG. 13. FIG. 14.
Ingersoll-Rand Inlet and Discharge Valves.

In the Laidlaw-Dunn-Gordon compressors a valve gear is used that mechanically controls the opening and closing of the suction and the closing of the discharge. The opening of the discharge is effected by means of vertically placed poppet valves. At the end of each stroke, however, the discharge is mechanically closed by means of a Corliss semi-rotary valve directly under the poppet valves, thus retaining under the latter a cushion of air under discharge pressure, enabling them to seat without violent and noisy impact. The construction is such that very small clearances are possible. In a 28 × 30-in. cylinder, for example, it is but 0.7 per cent. This type of gear has proved very successful on dry air pumps when very high vacuum is required.

AIR COMPRESSION

For the **theory of air compression**, see p. 321.

Mean Effective Pressure in Multi-stage Compression. The mean effective pressure, lb. per sq. in., with complete intercooling, referred to the l.-p. piston, is expressed by the formula

$$p_m = p_1\left\{\frac{Sn}{n-1}\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{Sn}} - 1\right]\right\}$$

where S represents the number of stages and n is the exponent of the compression curve. Fig. 15, from a chart plotted by F. W. O'Neill, shows the relation between the mean effective pressure and the initial pressure for various pressure ratios, p_2/p_1, with adiabatic compression and complete intercooling.

Wet vs. Dry Compression. The ideal method of compressing air when it is to be stored or allowed to cool before being used is the isothermal, and in the earlier types of compressors this was attempted by so-called wet compressors, by means of which it was possible to secure compressions approximating $p_1V_1^{1.2} = p_2V_2^{1.2}$. The mechanical difficulties involved and the necessary low speeds with consequent small capacity have led to the use of modern "dry compressors," which in small sizes have cylinders with cast-iron ribs for radiating heat, and in large sizes have water jackets surrounding the cylinder. The cooling thus secured is sufficient to keep temperatures from being excessive, but as a rule the compression curves are above $pV^{1.35}$ = constant. Dry compression has the advantage of higher speeds and larger capacities.

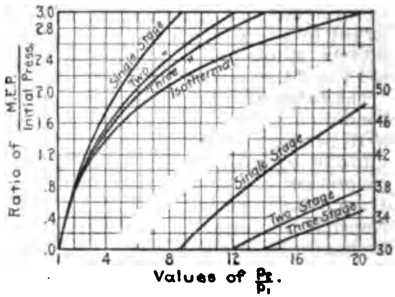

FIG. 15.—Mean Effective Pressures in Air Compression.

Efficiencies. The effect of clearance upon capacity is usually expressed in terms of **volumetric efficiency.**

The **apparent volumetric efficiency** is the apparent volume of free air drawn in (as shown by the indicator card) divided by the volume of the piston displacement. This is the term that is commonly used in speaking of volumetric efficiency, and in Fig. 16 it is GK/L. If the clearance expansion line follows the equation $p_JV_J^n = p_KV_K^n$, where the clearance $C = V_J/L$,

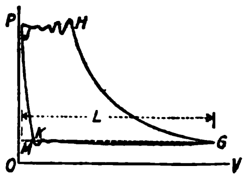

FIG. 16.—Air Compressor Card.

ıen $V_K/L = (p_J/p_K)^{\frac{1}{n}}C$. The volumetric efficiency may also be written:

$$1 - \frac{V_K - V_J}{L} = 1 - C\left[\left(\frac{p_J}{p_K}\right)^{\frac{1}{n}} - 1\right].$$

Example. If p_J is 94.7 lb. per sq. in. abs. and C is 2 per cent., the volumetric efficiency will be $1 - 0.02\left[\left(\frac{94.7}{14.7}\right)^{\frac{1}{1.4}} - 1\right] = 0.9444$.

The loss in capacity for stage compression will be represented by the following formulæ, in which p_1 is the initial and p_2 the final pressure:

Two-stage: $1 - C\left[\left(\frac{p_2}{p_1}\right)^{\frac{1}{2\times 1.4}} - 1\right]$; Three-stage: $1 - C\left[\left(\frac{p_2}{p_1}\right)^{\frac{1}{3\times 1.4}} - 1\right]$

Fig. 17 represents graphically the part within the brackets of the above equations. Knowing the actual clearance and the pressure range, the **effect of this clearance on capacity** can be found. For example, with a pressure ratio of $p_2/p_1 = 8$, the chart shows this value for single-stage compression to be 3.3. The capacity for these conditions and a 4-per cent. clearance will be $1 - (0.04 \times 3.3) = 1 - 0.132$, or 86.8 per cent. of the piston displacement. **Clearances** in the larger sizes of compressors approximate 1 per cent.; in smaller machines they are greater, being in some cases as high as 3 per cent.

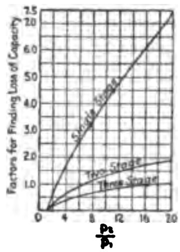

Fig. 17.

The indicator card would be a true method of measuring the volumetric efficiency if the temperature of the air after being drawn into the cylinder were the same as that of the atmosphere, and if the pressure at the end of the suction stroke were the same as that of the atmosphere. This is never the case.

The **true volumetric efficiency** is the ratio of the free air actually drawn in to the piston displacement.

The **cylinder efficiency** of an air compressor may be defined as the ratio of the work done in a complete cycle to compress isothermally a volume of of air at atmospheric pressure equal to the intake piston displacement, divided by the actual work done in the air cylinder. This would be the area *AKCG* (Fig. 18) divided by the shaded area or the actual work done in the air cylinder.

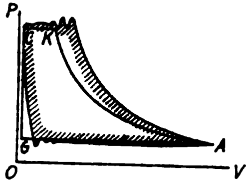

Fig. 18.

The **efficiency of compression** may be defined as the product of the cylinder efficiency and the true volumetric efficiency, or it is the work done in a complete cycle to compress isothermally (without clearance) a given volume of free air, divided by the work actually expended in compressing the same volume of free air.

The **mechanical efficiency** of an air compressor is the work done in the air cylinders divided by the work done in the engine cylinders if driven direct by steam or gas engine, or by the work delivered at the belt if the compressor is belt-driven.

Actual Values of Efficiencies. Tests of piston compressors show extreme variations of mechanical efficiency from 76 to 97 per cent., with approximate averages for the more common sizes of 85 per cent.

The true volumetric efficiency of piston air compressors will vary from 80 to 97 per cent., and the cylinder efficiency for water-jacketed compressors from 80 to 85 per cent. This will result in efficiencies of compression varying from 64 to 82 per cent.

Multiplying the mechanical efficiency by the efficiency of compression will show variations from 48 to 79 per cent. That is, the energy required to compress a certain amount of air isothermally is only from 48 to 79 per cent. of that actually expended in the steam cylinder. Tests show that with the great majority of compressors this product ranges from 50 to 60 per cent., while with some of the best compressors under test conditions it will reach as high as 78 per cent.

Horse Power Required to Compress Air. Disregarding clearance, the horse power required to compress air in a single-stage compressor is:

$$\text{h.p.} = \frac{144}{33{,}000}\,\frac{n}{n-1}\,p_1V_1\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}} - 1\right]$$

where V_1 represents the volume (cu. ft.) of free air compressed per min. and p_1 and p_2 the pressures in lb. per sq. in. abs.

Representing the intercooler pressure by p_i, the work done in both cylinders of a two-stage compressor will be

$$\text{h.p.} = \frac{144}{33{,}000}\,\frac{n}{n-1}\,p_1V_1\left[\left(\frac{p_i}{p_1}\right)^{\frac{n-1}{n}} + \left(\frac{p_2}{p_i}\right)^{\frac{n-1}{n}} - 2\right]$$

With perfect intercooling, $p_1V_1 = p_iV_i$. The above expression for the total work will be a minimum when $p_i = \sqrt{p_1p_2}$.

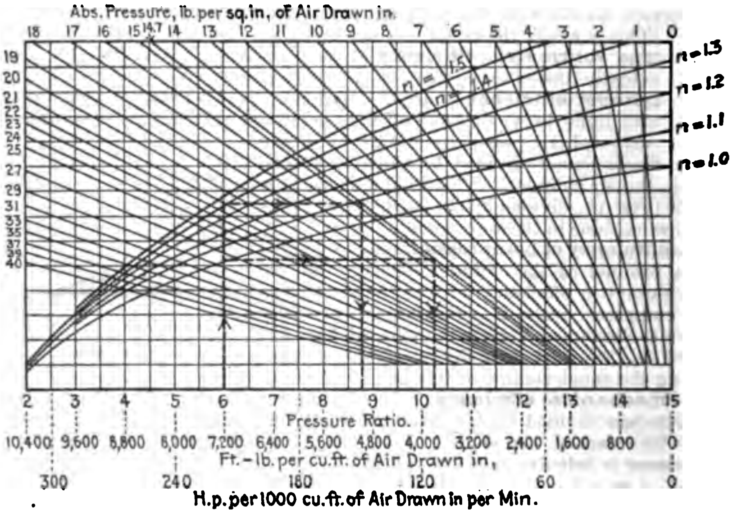

FIG. 19.—Chart for Determining the Work Done in Single-stage Air Compression (Lucke).

The proper intercooler pressures for three-stage compression are:

First intercooler, $p = \sqrt[3]{p_1^2p_2}$; second intercooler, $p = \sqrt[3]{p_1p_2^2}$

The minimum work done in compressing air is given by

$$\text{h.p.} = 2 \times \frac{144}{33{,}000}\,\frac{n}{n-1}\cdot p_1V_1\cdot\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{2n}} - 1\right] \text{ for two-stage compressors.}$$

$$\text{and h.p.} = 3 \times \frac{144}{33{,}000}\,\frac{n}{n-1}\cdot p_1V_1\left[\left(\frac{p_2}{p_1}\right)^{\frac{n-1}{3n}} - 1\right] \text{ for three-stage compressors.}$$

With perfect intercooling the volumes of the cylinders should be inversely as the pressures of the air admitted to them.

Professor Lucke ("Engineering Thermodynamics") gives a number of charts for solving graphically many of the problems of air compression, of which Fig. 19 is a very convenient one for determining the work per cu. ft. and the horse power per 1000 cu. ft. of free air compressed in a single stage to any pressure up to 15 times its initial pressure and for various kinds of compression curves from the isothermal to the adiabatic.

In Fig. 19 the diagonal lines represent various absolute pressures for the free air drawn in and the curved lines apply to various kinds of compression curves. The lower horizontal scale gives pressure ratios, work and horse power. In using the curves follow vertically from the pressure ratio to the n curve, horizontally to the inlet pressure line and vertically downward to the horizontal axis where the work and horse power may be read. For example, if the compression ratio is 6, the compression curve follows the equation $p_1V_1^{1.4} = p_2V_2^{1.4}$, and the free air is at 14.7 lb. per sq. in. abs., there will be required 4960 ft.-lb. of work per cu. ft. of free air compressed, or 152 h.p. per 1000 cu. ft. of free air per min.

If the compression for the same pressure range (or to 88.2 lb. per sq. in. abs.) had followed the isothermal compression curve it would have required 3880 ft.-lb. of work per cu. ft., or 120 h.p. per 1000 cu. ft. per min.

Fig. 20 enables calculations to be made for work and horse power for two- and three-stage compression, when used in connection with Fig. 19. The dotted lines represent two-stage and the full lines three-stage compression, and are marked according to the character of the compression curve. The horizontal scale shows pressure ratios and the vertical scale ratio of work or horse power for two- or three-stage compression to the work that would be required for single-stage compression as determined from Fig. 19. For example, for a pressure ratio of 8, or a discharge of 117.6 lb. per sq. in. abs. on a suction pressure of 14.7 lb., the work for a compression following the equation $p_1V_1^{1.4} = p_2V_2^{1.4}$ would be 85.2 per cent. of the work for the same conditions single-stage if two-stage were used, and 81 per cent. of it if three-stage compression were used.

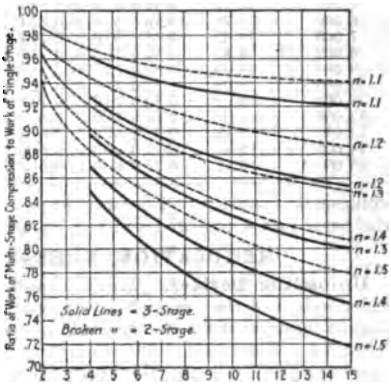

Fig. 20.—Chart for Determining the Work Done in Two- and Three-stage Air Compression (Lucke).

Effect of Altitude. As the density of the atmosphere decreases with the altitude, a compressor located at a high altitude will take in a smaller weight of air at each stroke. The reduction of pressure at the inlet affects the power expended in compressing the air, but the decrease in power required does not vary in the same ratio as the decrease in capacity. For this reason compressors to be used at high altitudes should have the steam and air cylinders properly proportioned to meet the varying conditions at different levels. Table 4, published by the Sullivan Machinery Co., of Chicago, Ill., shows the variation in capacity and horse power for various altitudes. The altitudes given are heights above mean sea level and are subject to correction for temperature and latitude. From the table it can be seen that for a two-stage compressor discharging at 100 lb. pressure when operating at an altitude of 8000 ft. the

volumetric capacity will be only 76 per cent. of that at mean sea level, while the horse power required will be 85 per cent. of that at mean sea level.

REGULATION, REHEATING, LUBRICATION

Unloading Devices. Many compressors operate at **constant speed,** independent of the demands for compressed air; and, in order to secure economy of operation for this condition, various types of "unloaders" have been designed. For small single-stage compressors the Sullivan Machinery Co. provides an unloading valve connected by piping to the inlet valves. When the predetermined pressure is exceeded, the unloader raises the inlet valves from their seats and prevents further compression of air until the pressure falls a few pounds, when the unloader allows the valves to resume their seats and the work of compression is again taken up. Other manufacturers use a similar device to keep the inlet closed when the predetermined pressure is reached. For larger compressors a double-beat valve is used, which is placed on the air inlet duct and controlled by air pressure from the air receiver. This valve is set to shut off all or part of the incoming air from the compressor when the receiver pressure rises above a predetermined point.

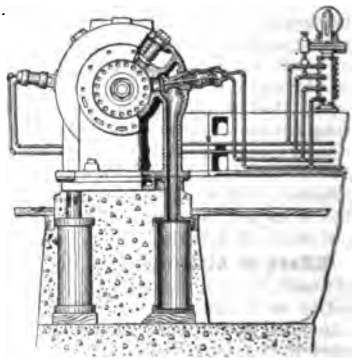

Fig. 21.—Ingersoll-Rand Automatic Clearance Unloader.

The Ingersoll-Rand automatic "clearance unloader" (Fig. 21) consists of a number of clearance pockets which are thrown automatically into communication with the ends of each air cylinder in proper succession, the process being controlled by predetermined variation in receiver pressure. Regulation is obtained in five stages, *viz.*, full load, three-quarter, half, quarter and no load. The effect of thus changing the clearance space is to change the volumetric efficiency without changing the suction or discharge pressures. Cards for the high-pressure cylinder of a two-stage compressor, showing the operation of this device, are reproduced in Fig. 22. The device is applied simultaneously

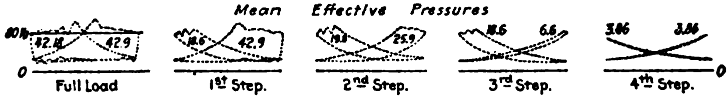

FIG. 22.—Cards from High-pressure Cylinder of a Two-stage Compressor with Clearance Unloader.

to all the cylinders of a multi-stage compressor. The performance of a 20¼-in. and 12¼-in. × 18-in. direct-connected motor-driven compressor (piston displacement 1087 cu. ft.) operating at sea level with this type of unloader is given by F. D. Longacre as follows (r.p.m., 175; discharge pressure, 100 lb.):

	Full load	¾ load	½ load
Actual capacity, cu. ft. free air per min.	940.0	698.0	458.0
Compression effy., isothermal base, per cent	80.0	76.5	73.0
Indicated horse power of air cylinder	164.5	129.0	91.0
Mechanical efficiency, per cent	92.0	89.0	86.0
Brake horse power of motor	179.0	145.0	105.8
Motor efficiency, per cent	92.5	91.5	90.0
Elec. horse-power input per 100 cu. ft. actual	20.53	22.6	25.78

He gives a comparison of the action of clearance and choking control between zero and full load for a 1000-cu. ft. compressor, as shown in Fig. 23.

Regulators. When the **speed is not constant**, other types of regulating devices are available. For simple belt-driven compressors a belt shifter can be designed to shift the belt from the tight to the loose pulley when the predetermined air pressure is reached, but for steam-driven compressors the device is usually one for governing the speed of the compressor to suit the demands for compressed air.

A combined air and speed governor manufactured by the Nordberg Mfg. Co. is shown in Fig. 24. In this type of governor the speed of the engine is controlled not only by the centrifugal action of the governor, but also by any variation of the air pressure. The arm *A* controls the point of cut-off for the steam cylinder and is operated by the movement of the bell-crank *C* about the fulcrum *D*. The rod *E* controls the bell-crank and is connected to a "floating lever" *B*. This is con-

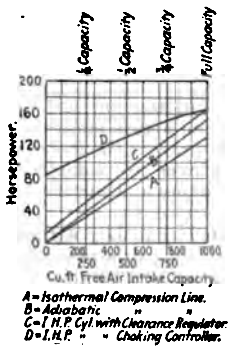

FIG. 23.

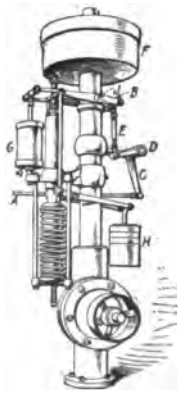

FIG. 24.

FIG. 23.—Comparison of Clearance and Choking Control.

FIG. 24.—Nordberg Combined Air and Speed Governor.

nected with the centrifugal governor F at J, and with a piston which is in communication with the air pressure at G and is held up by the weight H. With this arrangement, if the air pressure should rise above normal, the engine will have its supply of steam per stroke reduced, and if the air pressure should fall, the supply of steam will be increased; or, if the pressure of air remains constant, the governor will have the same control over the speed of the engine that the ordinary centrifugal governor has.

Water Jackets, Intercoolers, Receivers and Aftercoolers. The cooling surface in an intercooler is generally designed from the formula $S = Q/0.25(t_a - t_w)$, where S is the cooling surface in sq. ft., Q is the number of cu. ft. of free air per min., and t_a and t_w are the temperatures, in deg. fahr., of the air leaving and the water entering the intercooler, respectively.

The amount of cooling water required is given by Longacre as $G = 75 + 2.5t$ when the intercooler and jacket are in series; $G = 20 + 2t$ for a separate intercooler; and $G = 2t$ for l.-p. and h.-p. jackets only. In these formulæ G is in gallons of water per hour per 100 cu. ft. of free air per min. and t is the entering temperature, deg. fahr., of the cooling water.

Receivers are used to supply a reservoir of air; to equalize the pulsations in the air coming from the compressor; to collect the water and grease held in suspension by the compressed air as it leaves the compressor; to reduce the friction of air in the pipe system; and to cool the air as thoroughly as possible before entering the transmission system. To facilitate the removal of water from the compressed air, a receiver is frequently equipped with a coil of pipes through which cooling water flows; in this way it serves as an **aftercooler**, and by precipitating the water from the air reduces difficulties in transmission lines and tools. The Ingersoll-Rand Co. states the amount of cooling water required for aftercoolers for air at 80 to 100 lb. pressure to be as follows:

Temp. of cooling water, deg. fahr.	50	60	70	80	90
Gal. per min. per 1000 cu. ft. of free air per min.	120	140	160	180	200

When the transmission pipe line is long, receivers should be placed at both ends of the pipe.

Reheaters. Heating the air just before expansion may increase the efficiency of the system, and in addition will increase the temperature at the end of expansion and prevent the freezing up of the motor.

In quarry work **stoves** are sometimes used for preheating the air. In locomotive work for mines and surface use, hot water is frequently employed for this purpose.

Reheaters are usually capable of raising the **temperature** of the air to from 300 to 500 deg. fahr., although common practice shows temperatures of from 250 to 350. In figuring on reheaters it is usual to assume that 1 lb. of coal will give from 8000 to 10,000 B.t.u. to the air. As the specific heat of air is approximately 0.24, 1 lb. of coal will raise the temperature of approximately 100 lb. (or 1200 cu. ft.) of free air 300 deg.

The **increase in efficiency resulting from reheating** is greater with tools that use air expansively than with machines taking in air for full stroke. Sometimes it is not desirable to have the air entering a tool at a temperature above 300 deg., because of the effect of this high temperature on the lubrication. For these conditions small portable hot-water stove-type reheaters are available in capacities of from 62 to 800 cu. ft. of air per min.

Lubrication. If oil is fed too rapidly in the air cylinders there is a gradual accumulation of carbon, which interferes with the free movement of the valves and may actually choke the passages and produce high temperatures sufficient to produce ignition or **explosion.**

Explosions have taken place from the introduction of kerosene or naphtha into the air cylinder for the purpose of cleaning the valves and cutting away the carbon deposits. This is a very effective way of **cleaning valves and pipes,** but is a source of danger and should be absolutely prohibited. Soft soap and water is the best cleanser for the air cylinder and is recommended even when the best grades of cylinder oil are used, feeding once or twice a week in order to prevent any gumming of the valves.

In order to reduce the danger of excessive temperatures, fusible **safety alarm plugs** may be inserted in the discharge line. These are usually set for a temperature of 350 deg. for a single-stage compressor working at 40 lb. gage pressure, for a two-stage compressor at 100 lb. gage, and for a three- or four-stage compressor delivering at 1000 lb. gage. A 500-deg. plug is furnished for use with a single-stage compressor discharging at 100 lb. gage pressure.

AIR CONSUMPTION OF VARIOUS TOOLS

Air Consumption of Rock Drills. Table 5 gives the free-air consumption per min. of rock drills of various cylinder diameters for fair conditions in

Table 5. Cubic Feet of Free Air Required per Minute by One Rock Drill

(Ingersoll-Rand Co.)

Gage pressure, lb. per sq. in.	Cylinder diameter of drill, inches												
	2	2¼	2½	2¾	3	3⅛	3³⁄₁₆	3¼	3½	3⅝	4¼	5	5½
60	50	60	68	82	90	95	97	100	108	113	130	150	164
70	56	68	77	93	102	108	110	113	124	129	147	170	181
80	63	76	86	104	114	120	123	127	131	143	164	190	207
90	70	84	95	115	126	133	136	141	152	159	182	210	230
100	77	92	104	126	138	146	149	154	166	174	199	240	252

rock of ordinary hardness. To find the amount of free **air required by a number of drills** supplied from the same compressor, multiply the air required by one drill, as given in Table 5, by one of the following factors:

Number of drills..........	2	3	4	5	6	7	8	9	10
Factor (*a*)................	1.8	2.7	3.4	4.1	4.8	5.4	6	6.5	7.1
Number of drills..........	12	15	20	25	30	40	50	60	70
Factor (*a*)................	8.1	9.5	11.7	13.7	15.8	21.4	25.5	29.4	33.2

To find the **free air consumption at any altitude** above sea level, multiply the consumption at sea level as obtained above by the one of following factors:

Altitude, ft.......	1,000	2,000	3,000	4,000	5,000	6,000
Factor (*b*)........	1.03	1.07	1.10	1.14	1.17	1.20
Altitude, ft.......	7,000	8,000	9,000	10,000	12,000	15,000
Factor (*b*)........	1.23	1.26	1.29	1.32	1.37	1.43

Example. Required the amount of free air to operate thirty 5-in. drills at an altitude of 9000 ft., air being furnished at a gage pressure of 80 lb. per sq. in.

From Table 5, cu. ft. per min. for one 5-in. drill at 80 lb. gage pressure = 190. For 30 drills, factor (*a*) = 15.8, and for 9000 ft. altitude, factor (*b*) = 1.29. Whence, cu. ft. of free air per min. for thirty 5-in. drills at 9000 ft. altitude = $190 \times 15.8 \times 1.29 = 3872$. The capacity of the compressor should be larger than this, to provide for leakage and friction in the pipe lines.

Air Consumption of Pneumatic Tools. The Sullivan Machinery Co. gives the following data on the consumption of free air (cu. ft. per min.) of various industrial tools and machines with air pressures from 70 to 90 lb. gage. Small hand paint sprays, 2–3 cu. ft.; foundry jolting machines, platform type, 30–40 cu. ft. per ton lifting capacity; hand grinders, 20 lb. size, 20 cu. ft; molding machines and squeezers, ½ to 1½ cu. ft. per mold; riveting machines, reach 12 to 30 (36 to 45) in., 5 (6½) cu. ft. per rivet; surfacers, small size (35 lb. approx.), 30 to 40 cu. ft., large size (65 lb. approx.), 60–70 cu. ft.

Chipping hammers	Weight, lb	5	7	8	9	10	11	12	13	14	18

	Cu. ft. per min	15	20	25								

Compressor Dimensions. The Ingersoll-Rand Co. manufactures small single-acting compressors of the following sizes: 2½ × 3 in., running at from 450 to 700 r.p.m.; 3½ × 4 in., at from 350 to 550 r.p.m., and 4½ × 5 in., at from 325 to 500 r.p.m. Its double-acting compressors vary in speed from 100 to 225 r.p.m., direct-electric-driven compressors from 110 to 225 r.p.m., steam-driven compressors with simple or Meyer type of slide-valve gears from 150 to 225 r.p.m., and Corliss-valve-gear steam-driven compressors of from 1450 to 8000 cu. ft. per min. capacity at speeds of from 80 to 150 r.p.m.

The average **piston speeds** of commercial air compressors will vary approximately from 300 ft. per min. for the smaller sizes to 500 ft. per min. for the larger sizes.

Compressed-air Hoisting Engines. Compressed air can be used in any engine that will operate with steam and finds considerable application for hoisting engines for mining, or for work of a temporary or intermittent character. R. L. Streeter (*Eng. Mag.*) gives the following table of free-air consumptions for single-cylinder hoisting engines, the air being compressed to 60 lb. gage:

Cyl. diam., in.	Stroke, in.	R.p.m.	Nominal h.p.	Actual h.p.	Weight lifted by single rope	Free air per min., cu. ft.
5	6	200	3	5.9	600	75
5	8	160	4	6.3	1,000	80
6¼	8	160	6	9.9	1,500	125
8¼	10	125	15	12.1	2,000	151
7	10	125	10	16.8	3,000	170
8½	12	110	20	18.9	5,000	238
10	12	110	25	26.2	6,000	330

Compressed-air Locomotives are used in mines and quarries for handling excavated material, and are particularly adapted to the handling of explosives or other material where it is necessary to reduce the fire hazard to a minimum. Such locomotives are usually supplied with compressed air at a pressure of approximately 800 lb. per sq. in. The air is admitted to the cylinders at a reduced pressure varying from 150 to 250 lb. per sq. in., and in some cases is exhausted after a single expansion. In the more economical types of locomotives, the air after expansion in the first cylinder with consequent reduction of temperature passes to a second cylinder, and in doing so is reheated by the surrounding atmosphere before its final expansion and discharge. This reheating effects an increase of from 40 to 60 per cent. in the work done by the locomotive.

For the A. S. M. E. Code for testing steam-driven air-compressing machinery, see p. 1776.

CENTRIFUGAL COMPRESSORS

BY

L. C. LOEWENSTEIN

REFERENCES: Ostertag, "Kolben und Turbo-Compressoren," Springer, Berlin. Zerkowitz, "Thermodynamik der Turbomaschinen," Oldenbourg, Berlin.

Classification. Centrifugal compressors differ from centrifugal pumps (see p. 1503) only in handling gases instead of liquids, and are similarly classified as regards the number of inlets per impeller, the direction of the impeller tips at impeller exit, and the number of stages employed. They are further classified into low-pressure (1 to 5 lb. per sq. in.) and high-pressure (above 5 lb.) compressors, and also into the radial-inlet type and the axial-inlet type according as the gas enters at right angles to the shaft or in a direction parallel to the shaft.

Centrifugal compressors for pressures below 1 lb. per sq. in. are generally known as blowers or centrifugal fans (see p. 1541); in these the kinetic energy of the gas at the impeller exit is usually allowed to dissipate itself in eddies. For air pressures of 5 lb. per sq. in. and under, a single impeller is generally sufficient. For comparatively light gases, however, a pressure of 5 lb. may require two or more impellers in series, or a multi-stage compressor. Such a compressor is also frequently spoken of as a high-pressure gas compressor. For quantities of gas of 10,000 cu. ft. per min. and over, compressors of the radial-inlet type require shrouds or reinforcing rings at the inner ends of the impeller blades to prevent the wide blades from crumpling at the inlet under the action of centrifugal stresses. Impellers of the axial-inlet type are not subject to such crumpling, and are therefore generally used when large volumes are handled. As to single-inlet and double-inlet impellers, see remarks on p. 1503. The radial-discharge impeller is the one best adapted for high peripheral speeds, and is the type most commonly used. Both the backward-discharge and the forward-discharge impellers require shrouds at their outer peripheries. The former are frequently resorted to when large gas quantities (requiring a large impeller inlet) are to be raised to a comparatively low pressure with a direct-connected high-r.p.m. driver; the latter are but rarely used. Multi-stage compressors are usually provided with special means for cooling the gas during its passage through each impeller and from stage to stage, and also for preventing leakage from stage to stage and to the atmosphere.

Advantages and Applications. The centrifugal compressor occupies comparatively little room for its output; direct-connected to an electric motor or to a steam turbine, it forms a very compact unit. Besides its bearings it has no rubbing or wearing parts; it contains no moving valves or springs; and it requires a minimum of attendance and oiling. It is also fairly free from vibrations and requires comparatively light foundations. At constant r.p.m. it will maintain approximately constant pressure for widely varying quantities of gas, which makes it very desirable for general power transmission. If no gas is required temporarily the discharge pipe may be shut off without stopping the compressor or wasting the gas into the atmosphere. Its steadiness of blast makes it also very valuable for oil burning and for general forge work.

For blast furnaces, where the resistance to the flow of the air is likely to vary from time to time, while a uniform supply of oxygen or air regardless of such variation in resistance is important, the centrifugal compressor may be supplied with a constant-volume governor. This governor, actuated by the variation of air velocity in the compressor inlet, causes the speed of the driver to vary in accordance with the needs of the furnace, and thus maintains a constant volume (referred to atmospheric conditions) of air against widely varying pressures with fairly constant efficiency. The centrifugal compressor also finds wide application as an exhauster in ash conveying, sawdust conveying, and in the general pneumatic conveying of coal, cement, rice, starch, etc. For intermittent work, such as pneumatic cash and mail conveying, its prompt response to overloads allows the use of a comparatively small driver. In coke-oven-gas manufacture the centrifugal compressor maintains constant suction on the gas main, and then compresses the gas so that it will flow through the condensers, purifiers, and into the gas holders. It is frequently used as a booster to a high-pressure reciprocating compressor, the two compressors forming together a very compact and efficient set. By compressing the air, say, to 30 lb. per sq. in. gage in the centrifugal compressor, the volume of the air to be handled by the reciprocating compressor is only about one-third of what it would otherwise be, making it possible to employ a much smaller unit.

Limitations. While a centrifugal compressor will maintain a fairly constant pressure over a wide range of quantities, there is for every speed a certain range of quantity at which the discharge vanes cease to co-operate, causing a sudden drop in pressure. This "break-down" region can be pushed back toward lighter loads, and the drop in pressure made less abrupt by making the discharge vanes very few and their inlet angle small. Also, when working on that part of the pressure curve where the pressure increases with the quantity or remains constant, there are usually pressure surges or pulsations which, while slight in themselves, may be greatly intensified by a sort of resonance effect if the volume of the inlet and of the discharge piping happens to have a certain critical value. A slight throttling of the inlet will always stop these pulsations by making the pressure curve slightly drooping.

Theory

Notation. Referring to Fig. 1, let

$D_e(D_a)$ = impeller inlet (exit) diameter, ft.
$u_e(u_a)$ = impeller inlet (exit) peripheral velocity, ft. per sec.
$w_e(w_a)$ = absolute inlet (exit) velocity of gas, ft. per sec.
$v_e(v_a)$ = relative inlet (exit) velocity of gas, ft. per sec.
$b_e(b_a)$ = impeller inlet (exit) angle, deg.
d_e = angle between w_e and u_e, deg.
d_a = angle between w_a and u_a, deg., or inlet angle of discharge vanes, if any.

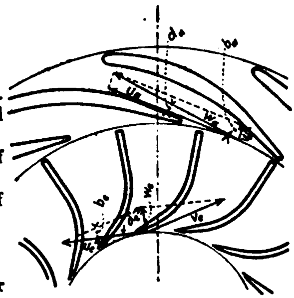

FIG. 1.

p_1 = initial pressure of the gas, including the velocity energy (if any), lb. per sq. in.
T_1 = temperature of gas corresponding to p_1, deg. fahr. abs.
d_1 = density of gas corresponding to p_1, lb. per cu. ft.
p_2, T_2, d_2 = corresponding values for the final conditions of the gas as it leaves the compressor.
K = ratio of specific heats of gas, taken as 1.41.

$A = (T_2/T_1) - 1 = (p_2/p_1)^{(K-1)/K} - 1 = (p_2/p_1)^{0.289} - 1.$

s = specific gravity of gas at inlet conditions, referred to that of "free air" as unity.

Q = quantity of inlet gas, cu. ft. per sec.

e_h = hydraulic efficiency, referred to adiabatic compression.

H = the theoretical (or total) head, or height against which the gas is raised, ft., including all hydraulic losses.

N = r.p.m.

Total Pressure Rise. The fundamental equation giving the value of H is the same as that for H_b (see Centrifugal Pumps, p. 1504). For single-stage compression,

$$A = \left(\frac{p_2}{p_1}\right)^{(K-1)/K} - 1 = \frac{e_h d_1 (K-1) H}{144 p_1 K} = \frac{e_h d_1 (K-1) u_a^2}{4631 p_1 K}$$

when $d_e = 90$ deg. (no inlet guide vanes) and $b_a = 90$ deg. (radial discharge). Assuming $p_1 = 14.7$, $T_1 = 520$, $K = 1.41$, $e_h = 0.72$, and substituting, $p_2 = 14.7[1 + (u_a^2 s/4{,}300{,}000)]^{3.44}$. For small pressure rise, with $d_e = 90$ deg., $p_2 - p_1 = 0.0000165 e_h u_a^2 s[1 + (v_a/u_a) \cos b_a]$.

Fluid Input Horse Power is the horse power applied to the gas and is independent of the actual pressure rise obtained. Fluid input h.p. = $Q d_1 H/550$. For $d_e = 90$ deg., this becomes $0.00000432\, Q s u_a^2 [1 + (v_a/u_a) \times \cos b_a]$.

Theoretical Horse Power. This is the horse power necessary to compress (and deliver) Q cu. ft. of gas per sec. from p_1 to p_2.

Theoretical horse power $= 0.901\, Q p_1 (p_2/p_1)^{0.289} - 1$; or, for small pressure rise $= 0.2618 Q p_e$, where $p_e = p_2 - p_1$. This formula may also be used for higher pressures if $p_1 = 14.7$ lb. per sq. in. and p_e ($= 50.6A$) is regarded as the mean effective pressure for adiabatic compression from p_1 to p_2. Table 1 gives values of the mean effective pressure p_e against values of $p_2 - p_1$, for the usual case of $p_1 = 14.7$.

Table 1

(p_2 − 14.7), lb. per sq. in.	5	10	15	20	25	30	35	40	45	50
p_e, lb. per sq. in.	4.5	8.2	11.4	14.3	16.9	19.3	21.5	23.5	25.4	27.2

Table 2 gives the theoretical horse power necessary to compress adiabatically (and deliver) 100 cu. ft. of air per min. from 14.7 lb. abs. to various gage pressures.

Table 2

Final gage pressure, lb. per sq. in.	5	10	15	20	25	30	35	40	45	50
Theoretical horse power per 100 cu. ft.	1.95	3.58	4.99	6.25	7.37	8.39	9.35	10.23	11.06	11.84

Hydraulic Losses. The hydraulic losses are the losses in pressure caused by the gas friction and by the sudden changes in the gas velocity or direction of flow. On the basis of Mr. D. W. Taylor's experiments on the flow of air in pipes, the pressure drop in the suction and in the discharge pipes (lb. per sq. in.) $= L = l v^2 s/400{,}000D$, where l is the length of pipe, ft., v the velocity of gas, ft. per sec., s the specific gravity of gas referred to free air (0.0764) as unity, and D the diameter of pipe, in. For pipes of first-class workmanship and in very best condition, this loss may be reduced by about 20 per cent. (See also p. 357 for further data on friction losses in pipes.) The other hydraulic losses are of the same nature and can be reduced in the same way as explained under Centrifugal Pumps, p. 1504.

Hydraulic Efficiency. The hydraulic efficiency is the ratio of the theoretical horse power to the fluid input horse power, or $e_h = 184.8AT_1/H$. For $d_e = 90$ deg.,

$$e_h = \frac{5955\ A\ T_1}{u_a^2[1 + (v_a^2/u_a^2)\cos b_a]}. \quad \text{Also, } e_h = \frac{60{,}600(p_2 - p_1)}{s\ u_a^2[1 + (v_a^2/u_a^2)\cos b_a]}$$

for small pressure rise, with $d_e = 90$ deg.

Other Losses. The **rotation loss,** or friction loss of the impeller considered as a flat disk of negligible axial width, as it rotates in the compressed gas, may be obtained from the formula: Rotation loss (h.p.) $= 0.0737 \times (u_a/1000)^3 D_a^2 d_m$, where d_m is the mean density of the gas (between p_1 and p_2), lb. per cu. ft. At full load this is practically the only loss to be considered, and it is this loss, more frequently than the centrifugal stresses, that determines the pressure rise that may be developed by a single impeller. The nature of the **short-circuit loss** has been explained under Centrifugal Pumps, p. 1505. It is highest when v_a, the relative velocity of the gas, is lowest, that is, at light loads. For the same reason, it is roughly proportional to the impeller outer diameter, the impeller exit width, and the passage height at the discharge-vane inlet. At no load the short-circuit loss is between two and four times the rotation loss, while at full load it is fairly negligible.

Centrifugal Compressor Constants and Characteristic Curves

Quantity Constant. The quantity of gas delivered by a centrifugal compressor is proportional to $u_a D_a b_a$, or, quantity constant $= u_a D_a b_a$.

Compressor Constant. A compressor model can be used with practically the same efficiency for various combinations of quantity and pressure such that $K = Q/\sqrt{p_e}$, where K is the compressor constant, Q and p_e are the desired quantity and mean effective pressure, respectively. The compressor constant can be more conveniently written as $K = QN^2/p_e^{3/2}$.

Similar Compressors. Two compressors are similar when they have the same compressor constant. In similar compressors all impeller and discharge-vane linear dimensions are in the same ratio as their impeller diameters, while their impeller and discharge vane angles are respectively equal. For the same r.p.m. the quantities delivered by similar compressors will vary as the cubes of their diameters; the pressures will vary as the squares of their diameters, and the shaft powers will vary as the fifth powers of their diameters. For the same wheel speed the quantity and the power will vary as the square of the diameter, while the pressure will remain constant.

Compressor Coefficients. In order to make the tests on different compressors, or on the same compressor under different circumstances, comparable on a common basis, various coefficients are computed corresponding to the given observations and these coefficients are plotted as **characteristic curves.** From these curves the pressure, power, and the hydraulic and shaft efficiencies can readily be computed for any quantity of gas and any r.p.m. The departure of the ratio v_a/u_a from that value for which the compressor was designed determines largely the efficiency of operation. Therefore, v_a/u_a, or its equivalent, Q/u_a, is generally used as the abscissa for the characteristic curves of a compressor, and it is designated as the **load coefficient,** C_q. It is also frequently represented by Q/N. The **fluid input coefficient** (C_i) represents the horse power corresponding to any given observation divided by the cube of the wheel speed. For the case of axial impeller inlet and radial impeller exit, $C_i = 0.00000432Q_s/u_a = 0.00000432C_s s$. Evidently the characteristic curve of C_i against C_s is a straight line making an angle with C_s whose tangent is $0.00000432s$; it may be drawn independently of the actual observations. In general, $C_i = 0.00000216s\,QV^2/u_a^3$, where $V^2 = 2gH = u_a^2 + w_a^2 - v_a^2 - u_e^2 - w_e^2 + v_e^2$. The **pressure coefficient** corresponding to the observed pressure rise $(p_2 - p_1)$, is $C_p = AT_1/u_a^2$, (for notation see p. 1531). The **theoretical power coefficient is** $C_t = 0.02571C_sC_p$. The characteristic curve for C_t should be computed and drawn from readings from the *smooth* curve of C_p against C_s. The **shaft power coefficient** is C_s = shaft h.p./u_a^3. The **rotation loss coefficient** is $C_r = 0.0737 \times 10^{-6} D_a d_m$, where d_m is the average density of the gas between p_1 and p_2, lb. per cu. ft. By adding the values of C_r to the values of C_i, a characteristic curve (practically a straight line) of fluid input plus rotation loss is obtained, and this curve will in a correctly designed compressor nearly touch the shaft power characteristic curve at the value of Q/u_a corresponding to the rated load of the compressor.

Hydraulic and Shaft Efficiencies. The ratio of C_t to C_i for any value of C_s gives the hydraulic efficiency e_h for that particular load. (For $C_s = 0$, the general formula $e_h = 5955\ C_p$ must be used). Similarly, ratios of C_t to C_s give values of e_s, the shaft efficiency. The efficiency curves thus obtained will of course be smoother and more reliable than if the efficiencies were computed directly from the individual observations of pressure and power.

Uses of Characteristic Curves. Besides affording smooth curves of hydraulic and shaft efficiencies, a set of characteristic curves as shown in Fig. 2 enables one readily to draw reliable pressure and power curves against quantity for any given wheel speed or r.p.m. In that case, the load-coefficient scale may be replaced by a quantity scale, while the readings of the C_p and the C_s curves will give the data for the corresponding pressures and powers. (In Fig. 2 the wheel speed has, in all the coefficients, been replaced by the r.p.m.) The system of characteristic curves is found to hold true for various sizes of centrifugal compressors, centrifugal blowers, and centrifugal pumps, giving in each case consistent curves regardless of the actual speeds, pressures and powers.

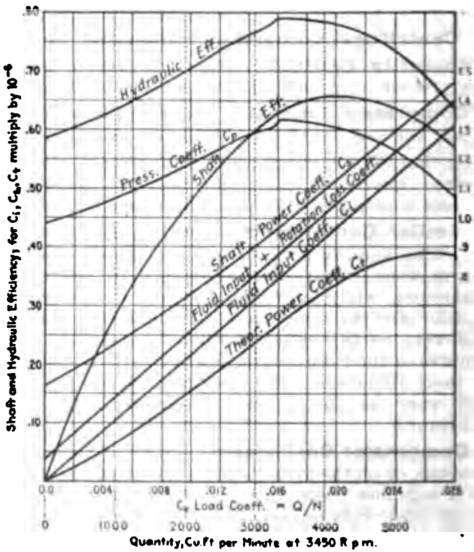

FIG. 2.—Characteristic Curves of Centrifugal Compressors.

Only in ventilating-fan blowers do there seem to be occasionally some serious discrepancies near the point of maximum efficiency.

Numerical Examples

Power Required. Find the power required to compress adiabatically 20,000 cu. ft of air per min. from atmosphere to 30 lb. per sq. in. gage, the shaft efficiency of the compressor being 75 per cent.

SOLUTION: From Table 2 the theoretical horse power is $8.4 \times 20{,}000/100 = 1680$, and the shaft h.p. is $1680/0.75 = 2240$.

Equivalent Suction Pressure. What suction can be obtained with a compressor rated to deliver 2500 cu. ft. of air per min. against 2 lb. per sq. in. gage?

SOLUTION: The compressor is rated for an *initial* pressure of 14.7 lb. per sq. in. Since the *pressure ratio* depends only on the wheel speed, the hydraulic efficiency and the initial temperature, all of which are supposed to remain the same, the initial suction pressure is $(14.7/16.7) \times 14.7 = 12.94$ lb. per sq. in. abs., and the suction obtained is $14.70 - 12.94 = 1.76$ lb. per sq. in.

Equivalent Pressure when Compressing Gas. What pressure can be obtained when compressing water gas with a standard unit rated 25,000 cu. ft. of air per min. and 15 lb. per sq. in. gage, and what power will be required if it requires 2000 h.p. to compress the air to 15 lb. pressure?

SOLUTION: The density of water gas is 0.05167, and its specific gravity (compared with air) is 0.677. The mean effective pressure (m.e.p.) corresponding to 15 lb. per sq. in. is 11.44 for air (see also Table 1). For water gas, everything remaining the same, m.e.p. $= 11.44 \times 0.677 = 7.74$ lb. per sq. in., and from Table 1 the corresponding final pressure is 9.3 lb. per sq. in. gage. The theoretical power for the air rating (from Table 2) is $5 \times 25{,}000/100 = 1250$ h.p. For water gas the theoretical horse power is $1250 \times 0.677 = 846$ h.p., and the actual power $= 2000 \times 0.677 = 1354$ h.p.

Equivalent Rating at Other Speeds. A standard centrifugal compressor rated 4500 cu. ft. of air and 15 lb. per sq. in. pressure is to be speeded up from 3450 r.p.m. to 4000 r.p.m. What increase of pressure and of quantity will result?

SOLUTION: The m.e.p. for 15 lb. per sq. in. is 11.44. At 4000 r.p.m. it will increase to $(4000/3450)^2 \times 11.44 = 15.38$, and the corresponding final pressure from Table 1 is 22.05 lb. per sq. in. abs. Also the new quantity will be $(4000/3450) \times 4500 = 5220$ cu. ft. per min. if the same ratio of v_a/u_a, and therefore the same hydraulic efficiency, is to be maintained. See "Quantity Constant" and "Load Coefficient," p. 1533.

General Problem. What standard compressor can be used to exhaust 18,500 cu. ft. of anthracite producer gas per min. against a suction of 7 lb. per sq. in.? The compressor is to be installed 2000 ft. above sea level. What horse power is required?

SOLUTION: The barometer at 2000 ft. altitude is 13.56. The compressor is therefore required to compress the gas from $13.56 - 7.00 = 6.56$ lb. per sq. in. abs. to 13.56 lb. This is equivalent to compressing the gas at sea level to a final pressure of $(13.56/6.56) \times 14.7 = 30.4$ lb. per sq. in. abs. or 15.7 lb. gage. The density of anthracite producer gas is 0.065 lb. per cu. ft. The m.e.p. corresponding to 15.7 final pressure is (Table 1) 11.9 lb. per sq. in. The corresponding m.e.p. for air is $(0.0764/0.065) \times 11.9 = 14.0$, and the final pressure from Table 1 is 19.4 lb. per sq. in. gage. Suppose the nearest standard compressor is rated 16,000 cu. ft. per min., and 15 lb. per sq. in. at 3200 r.p.m. The m.e.p. for 15 lb. is 11.44 and for 19.4 is 14.0. The standard compressor must therefore be speeded up to $3200 \times \sqrt{14/11.44}$, or 3540 r.p.m. For a constant "load coefficient" Q/N, the new quantity will be $16{,}000 \times 3540/3200 = 17{,}700$. So if it is desired to use the standard compressor and save the extra cost of a special size, then only 17,700 cu. ft. per min. of the gas can be exhausted with a suction of 7 lb. per sq. in. gage; or the compressor can be speeded up to handle 18,500 cu. ft. per min., but the suction will be somewhat above 7 lb. If the h.p. required by the standard compressor is 1300 (corresponding to a shaft efficiency of 0.615) the h.p. for the desired conditions will be $1300 \times (17{,}700/16{,}000) \times (11.9/11.44) = 1495$.

Multi-stage Centrifugal Compressors

General. A multi-stage compressor consists of a number of single-stage compressors connected in series. When the number of single-stage compressors is small they are usually enclosed in the same casing; but when the number exceeds eight or ten they are generally subdivided between two or more casings, separated by **intercoolers.** Multi-stage compressors are frequently built with single-inlet impellers, depending for the overcoming of the axial thrust on balancing pistons, on special grouping of the impellers, and on similar devices; also with backward-discharge impellers, when they are supplied with substantial shrouds to prevent the blades from bending or breaking under the action of centrifugal force. They are also built with all the impellers of the double-inlet type, thus obviating the need of all balancing means and requiring a much smaller number of impellers; the interstage passages, however, become rather complicated.

Similar Compressors. The successive impellers in a multi-stage compressor, handling smaller and smaller volumes of air, should be designed on the principle of similar compressors if all stages are to be equally efficient. Since the r.p.m. is the same for all impellers, the diameters and all the other dimensions should vary *inversely as the cube root of the density.* In practice, however, the impellers are divided into two or more groups, and each group designed for its own average conditions.

Cooling. The cooling of the gas during its passage through a multi-stage compressor is of paramount importance for high efficiency and low power consumption, and ample passages for cooling water must be provided in the diaphragms between the stages. For pressures below 50 lb. per sq. in., it is generally aimed to keep the temperature down to that corresponding to adiabatic compression; while for higher pressures, isothermal compression is more usually aimed at by the introduction of intercoolers between groups of stages. In the latter case, the hydraulic efficiency is given on the basis of isothermal compression.

Pressure Rise. For adiabatic compression, if the cooling is just enough to remove the heat above that corresponding to adiabatic compression:

$$p_2/p_1 = [1 + e_h d_1 (K - 1)\, u_a{}^2 S/144\, p_1 g K]^{K/(K-1)}$$

where S is the number of stages, while the other symbols have the same meaning as on p. 1531. If the cooling is such that each stage starts with the same temperature, the temperature corresponding to p_1, then

$$p_2/p_1 = [1 + e_h d_1 (K - 1) u_a{}^2/144\, p_1 g K]^{S(K-1)/K}$$

For strictly isothermal compression,

$$\log_{10}\frac{p_2}{p_1} = \frac{e_h d_1 u_a{}^2 S}{144\, p_1 g \times 2.302} = \frac{e_h d_1 u_a{}^2 S}{10{,}663\, p_1}.$$

In all these formulæ axial inlet flow and radial impeller exit are assumed; for all other cases $u_a{}^2/g$ should be replaced by the proper value for H.

Theoretical Power. The theoretical horse power required to compress adiabatically and deliver 100 cu. ft. of gas per min. (initial pressure, p_1 lb. per sq. in.), is $\text{h.p.}_a = 1.501 p_1[(p_2/p_1)^{0.29} - 1]$; and for isothermal compression it is: $\text{h.p.}_i = 1.004 p_1 \log_{10}(p_2/p_1)$. Table 3 gives the ratio of the theoretical work for isothermal compression to that for adiabatic compression for the largest range of pressures likely to be met with in practice.

Table 3

p_2/p_1	1.5	2.0	2.5	3	4	5	6	7	8	9	10
(Isoth. ÷ Adiab.)	.940	.904	.875	.85	.812	.784	.763	.744	.728	.715	.703

Leakage. To reduce the leakage between stages and from the inlet of the last stage to the atmosphere, labyrinth packings are usually provided. A formula for the amount of leakage is given on p. 989. In general, the leakage may be assumed as about 3 per cent. of the rated quantity, about two-thirds of this taking place between the inlet of the last stage and the atmosphere. This loss is fairly independent of the number of stages.

Details of Design

The **impeller hub diameter** is generally from 1 to 2 in. larger than the shaft diameter, and usually between $\frac{1}{4}D_a$ and $\frac{1}{3}D_a$. The **casing inlet diameter** (D_c) is determined by the velocity desirable to allow in the annulus between the casing inlet and the impeller hub and varies generally between $\frac{1}{3}D_a$ and $\frac{2}{3}D_a$. For an axial-inlet type D_c (in.) $= 12(Q/KN)^{\frac{1}{3}}$, where Q = quantity, cu. ft. per min., N = r.p.m. and $K = 1$ for single-inlet impellers, and 2 for double-inlet impellers. In radial-inlet-type impellers the **impeller inlet diameter** is from $\frac{3}{4}$ in. to $1\frac{1}{2}$ in. larger than D_c, to allow the air to turn into a radial direction before striking the impeller blades. In axial-inlet-type impellers the outer diameter of the impeller inlet blades is just sufficiently smaller than the casing inlet diameter to allow for mechanical clearance. The total **axial width of blade** at the inlet (on both sides of the impeller web in a double-inlet impeller) is from $\frac{1}{8}D_a$ to $\frac{1}{4}D_a$; at exit, from $\frac{1}{8}D_a$ to $\frac{3}{8}D_a$. Frequently the impeller exit width is designed to give a sufficiently small discharge-vane angle and then the blade is made of constant overall width (parallel edges). The **number of impeller blades** (z_i) should be as small as possible consistent with the proper guiding of the gas. The usual number is between 16 and 24, with an equal number of half-blades at the outer periphery, if necessary.

The absolute velocity of the gas, w_e, is computed from Q, D_e and the axial width of the blade (radial-inlet type). u_e is computed from D_e and the r.p.m. The ratio w_e/u_e gives the tangent of the impeller inlet angle b_e absence of impeller inlet guides, which is the usual case, is assumed). For the axial-inlet type, w_e is the *average* velocity in the annulus between the hub and the casing inlet, and u_e and b_e vary with the diameter, giving a helical edge. The **impeller inlet passage height** is the perpendicular from the tip of a blade to the surface of the next blade. Its theoretical value is $(\pi D_e \times \sin b_e)/z_i$, and this should be increased by from 10 to 30 per cent. The r.p.m. is generally determined by that of the driver or by other considerations. From the formulæ given before for pressure rise, the wheel speed u_a and the **outer impeller diameter** D_a can then be determined by assuming a reasonable value for the hydraulic efficiency e_h. The rotation loss should now be computed to make sure that it is not excessive in comparison with the theoretical horse power. The impeller stresses should also be computed to see that they are not excessive for the available material. Increasing the number or stages will reduce both the rotation loss and the stresses. The inner diameter of the **discharge vanes** should be from $1.1D_a$ to $1.2D_a$. Three to six vanes are ample for most purposes. The overlap of one vane on the other, or the definite passage between vanes, need not be very great. The **discharge vane angle** d_a is found in the same way as explained for b_e, the inlet gas quantity being multiplied by a compression factor according to the wheel speed u_a, as per Table 4. Generally, d_a is made between 3 deg. and 5 deg. The theoretical **passage height** of the discharge vanes (perpendicular to the axial width) is $(\pi D_a \sin d_a)/z_d$, where z_d is the number of discharge vanes (same axial width of impeller and discharge vanes is assumed). The actual passage height should be from 50 to 100 per cent. larger.

Table 4

Impeller wheel speed, ft. per sec.	200	250	300	350	400	450	500	550	600	650	700

Centrifugal Compressor Tests

Acceptance Tests. In making acceptance tests, the compressor is tested with no piping at the inlet, the air being taken directly into the unrestricted compressor inlet, which is to be at a distance from the wall or from the floor equal to at least its own diameter. At the discharge end a length of pipe equal to about ten times the discharge diameter is attached. At about the middle of this pipe, a blast gate is inserted, while at the far end the measuring orifice, or a header containing a number of small orifices, is bolted on.

Size of Orifice. The orifice is usually selected to pass a quantity about 35 per cent greater than the rated quantity. The following rough formulæ are frequently used: $Q = 109d^2\sqrt{P} = 21d^2\sqrt{i}$, where Q = cu. ft. of air per min.; d = diam. of orifice, in.; P = pressure above atmosphere, lb. per sq. in., and i = inches of water. Readings are generally taken at about six or seven different loads, the readings taken being the inlet temperature, the discharge pressure, the orifice pressure and temperature and the r.p.m. The **discharge pressure** is taken with an impact tube inserted into the discharge pipe about midway between the compressor and the blast gate, pointing upstream and reaching a little more than half way into the pipe. A second impact tube nearer the blast gate is desirable. The **orifice pressure** is taken with an impact tube placed opposite the center of the orifice at a distance from the plane of the orifice equal to about one-fifth of the orifice diameter. The orifice temperature is taken in the straight part of the pipe before the orifice. The bare bulb of the thermometer should protrude for about 2 in. into the stream of air, the air velocity rarely exceeding 60 or 70 ft. per sec.

Efficiency. The efficiency of a centrifugal compressor is the ratio of the theoretical power, adiabatic or isothermal, corresponding to the rated quantity and pressure, divided by the power delivered to the compressor shaft. There is, however, considerable room for controversy and misunderstanding in this connection, owing to the difficulty of measuring accurately the output of the driver. The input of the driver, however, is generally easily determinable. It is therefore customary to specify that the input of the driver per 100 cu. ft. of air delivered by the compressor shall not exceed so many kilowatt-hours, or so many pounds of steam, the steam conditions being those of the customer's plant.

Centrifugal Compressor Types

General Electric Compressor. The principal characteristic of the compressor manufactured by the General Electric Co. is the double-inlet impeller, which admits air on both sides of its central web. This impeller, used both in the single-stage and in the multi-stage compressors, is free from axial thrust, and permits the number of impellers in a multi-stage compressor to be either even or odd. It also makes possible the handling of very large quantities of air without entailing the use of too wide blades. In the smaller sizes, the impellers are of the radial-inlet type, the blades being curved in a plane perpendicular to the shaft, and attached to the central web by a cast welding process. In the larger sizes, the impellers are of the axial-inlet type, and the blades are frequently milled out from the solid disk which forms the impeller, separate entrance buckets curved in a plane tangential to the shaft being supplied. With this latter construction, wheel speeds of 600 to 800 ft. per sec. may be safely used, so that compressors designed for pressures as high as 30 lb. per sq. in. have only three or four stages. Each impeller is surrounded by a set of stationary discharge vanes which connect either directly with the discharge pipe, or, in multi-stage compressors, with the opposite sides of the succeeding impeller by means of two sets of passages at right angles to each other in an intervening diaphragm. To reduce the temperature of the air and thereby also the work necessary for compression, large passages are cored out in the diaphragms to permit the efficient use of cooling water.

Commercial sizes of the single-stage compressors have pressure ratings from 0.75 to 4 lb. per sq. in. and capacities from a lower limit of 500 cu. ft. per min. to a higher limit which ranges from 12,000 cu. ft. at 0.75 lb. pressure down to 3000 cu. ft. at 4 lb. pressure. The multi-stage compressors are built of the following sizes:

Cu. ft. per min.	4,500	9,000	16,000	25,000	40,000	50,000
Pressure, lb. per sq. in.	6–35	6–25	6–25	12–30	12–30	12–30

Multi-stage compressors have also been built for pressures as high as 150 lb. per sq. in., the volumes being comparatively small.

With a driver allowing speed variation, like a steam turbine or direct-current motor, a centrifugal compressor of a given rating will operate with a number of different combinations of pressure and volume without excessive loss in efficiency. The different rated pressures of multi-stage compressors are usually obtained by the use of a different number of stages, all stages in a given size of machine being similar. A given compressor may, however, operate successfully between, say, 15 and 30 lb. per sq. in., if the driver will allow of the necessary speed variation.

Pressure and Power Variations. Without any special governing device a centrifugal compressor driven at constant speed will maintain a substantially constant pressure, regardless of the volume of air delivered. Should there be temporarily no demand for air while the compressor is being driven at full speed, the casing will become slightly hotter, but otherwise the machine will not be subjected to any particular strains. The power required by a centrifugal compressor between half-load and, say, 25 per cent. overload varies approximately as the load. The following table shows the usual variation of pressure and power with the volume handled by a single-stage compressor at constant speed.

Characteristics of Centrifugal Compressors at Constant Speed

Volume, per cent. of full load	0	20	40	50	60	70	80	100	120
Pressure, per cent. of full load	92	94	97.5	100	103	105	105	100	91
Power, per cent. of full load	50	53	58	62	66	73	81	100	120

For blast-furnace purposes, where a constant quantity of air is to be delivered against varying pressures, a constant-volume governor, Fig. 3, has been developed, which consists mainly of a disk suspended in a vertical, slightly conical pipe attached to the compressor inlet. This disk is connected to one end of a lever, the other end of which is connected to the throttle valve of the driving turbine or to the rheostat of the driving electric motor. The lever carries a sliding weight, which by its position on the lever determines the position of equilibrium of the disk in the conical pipe. If the pressure in the blast furnace drops, so that the compressor tends to pass more air than the quantity for which the sliding weight on the lever was set, the velocity of the air in the annular passage between the disk and the conical pipe increases, the disk rises, and the lever actuates the speed-varying mechanism of the driver so as to reduce the speed and the generated pressure. Should the pressure in the blast furnace rise, then the reduced velocity of the air in the annular passage will

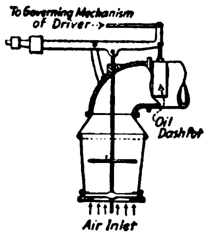

Fig. 3.—General Electric Co. Constant-volume Governor.

cause the disk to drop and the lever will speed up the driver till the compressor generates enough pressure to pass the desired quantity.

The Rateau Compressor, built by the Ingersoll-Rand Co., by the Southwark Foundry and Machine Co., and by others, has a single-inlet impeller, admitting the air on only one side of the web. In the single-stage compressor, the axial thrust is overcome by the use of a balancing piston or otherwise, while in multi-stage compressors the impellers, of which there is always an even number, are divided into two equal groups through which the air passes in opposite directions. The two groups of impellers are mounted in separate casings and on separate shafts, the two shafts being connected by a flange coupling. The air enters the impeller nearest the middle bearing, passes through the first group of impellers, into the receiver pipe which acts also as an intercooler, and then in a reversed direction through the second group of impellers which raise its pressure to that existing in the discharge pipe. The impeller is usually a steel plate, to which straight sheet-steel blades are riveted so as to give backward discharge; the main blades are interspersed at the outer periphery with short half-blades. On leaving the impeller, the air passes outward into a parallel-sided bladeless diffuser, and is then led inward between fixed blades to the inlet of the next impeller. The diaphragms carrying the fixed return blades are cored out to allow ample space for cooling water.

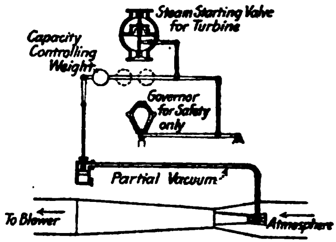

FIG. 4.—Rateau Constant-volume Governor.

The Rateau constant-volume governor (Fig. 4) for blast-furnace work is based on the Venturi meter principle. The increased velocity in the throat formed in the inlet pipe causes the pressure there to drop below atmospheric pressure, and this partial vacuum is conveyed to one side of a spring-controlled piston, the other side of the piston being open to the atmosphere. The piston rod is connected through a lever to the speed-varying device of the driver, and the position of a sliding weight on this lever determines the quantity of air which the compressor is to pass continuously. Should the resistance to air flow in the furnace rise or fall, tending to change the volume of the air from the normal, the vacuum in the throat of the governor will fall or rise correspondingly and the piston will actuate the control lever so as to speed up or to slow down the driver and the compressor.

CENTRIFUGAL FANS

FUNDAMENTAL FORMULÆ

Notation

H	= head of air, ft.	B	= Barometer reading, inches of mercury
h	= velocity head, inches of water	a.h.p.	= air horse power
h_s	= static head, inches of water	b.h.p.	= brake horse power
h_i	= impact head, inches of water	E	= mechanical efficiency
v	= velocity, ft. per sec.	N	= revolutions per min.
V	= velocity, ft. per min.	D	= diameter of fan wheel, ft.
W	= weight of air, lb. per cu. ft.	r	= radius of fan wheel, ft.
P	= pressure, lb. per sq. ft.	b	= width of fan wheel, ft.
A	= area, sq. ft.	M	= manometric efficiency
Q	= volume, cu. ft. per min.	C_1	= tip speed, ft. per sec.
q	= volume, cu. ft. per sec.	T	= tip speed, ft. per min.
t	= temp., deg. fahr.		

Velocity. From the formula $v = \sqrt{2gH}$ the velocity of air at standard atmospheric conditions ($W = 0.075$) is given by $V = 4000\sqrt{h}$. For any given air temperature t and pressure B, neglecting the slight effect of a variable humidity, $V = 956\sqrt{(460 + t)h/B}$.

Pressure is generally expressed in inches of water or in ounces per sq. in. 1 oz. per sq. in. = 1.732 in. of water. $H = 5.2h/W$; $P = HW$, and $P = 5.2h$. For air at density $W = 0.075$, a head of 1 in. of water equals that of 69.3 ft. of air. Three pressures must be considered in a column of moving air, namely, static, velocity and impact. The first represents the compression, the second kinetic energy of the blast, and the third the total pressure or the sum of the static and velocity pressures. The static pressure in a system through which air passes is often referred to as **maintained resistance.**

Air Horse Power. The horse power in a column of moving air is a.h.p. = $VAP/33{,}000 = QP/33{,}000 = 5.2Qh_i/33{,}000 = 0.1728Ah_i\sqrt{h/W}$.

Mechanical Efficiency is the ratio of a.h.p. to b.h.p. Sometimes the a.h.p. is computed by use of only the static pressure—positive, negative or both—against which the fan operates; it being assumed that static pressure represents the useful pressure and that the kinetic energy or velocity pressure is thrown away on leaving the system and entering the atmosphere. Since in most fan systems the velocity at the point of delivery into the atmosphere is considerably lower than at the fan outlet, the kinetic energy or velocity pressure which can rightfully be deducted from the impact or total head produced by the fan is only that existing at the point of leaving the system, and not the velocity pressure at the fan outlet. The impact or total head produced by the fan is more generally used in computing the a.h.p.

Manometric Efficiency or pressure efficiency is the pressure developed by the fan divided by the pressure against a plane surface due to a velocity equal to the peripheral speed of the fan wheel. $M = gH/C_1^2$. Manometric efficiency is defined by some engineers as $2gH/C_1^2$.

Volumetric Efficiency is not really an efficiency and might better be called **volumetric capacity**. It is defined as the quantity of air delivered per revolution divided by the overall cubical contents of the wheel, and is represented by the formula Vol. Eff. $= Q/\pi r^2 bN$.

Performance of Fans at Various Air Temperatures. In Table 3 are given factors for determining the influence of the air temperature on the volume of a given weight (col. 2) and on the weight of a given volume (col. 3) of air; on the pressures (cols. 2 and 3) corresponding to constant weight and constant volume, respectively, of air handled by a fan; on the speeds (cols. 2 and 4) corresponding to constant weight and constant pressure, respectively, of air handled by a fan; on the power (cols. 3 and 5) corresponding to constant volume and constant weight, respectively, of air handled by a fan; and the power (col. 2) necessary to handle a given weight at a given pressure with a fan proportioned to operate at a given efficiency. All these factors are to be applied to the quantities corresponding to the standard air temperature of 65 deg. fahr.

Table 3. Factors for Determining the Performance of Fans at Various Air Temperatures (see text)

For the **weight of 1 cu. ft. of air** at any temperature, pressure and humidity within the usual range, see p. 1512.

FAN CHARACTERISTICS

The characteristics of any fan can best be shown graphically. The characteristic curves from any size of a series of similar fans suffice for the entire group. This follows from the fact that the area of the frictional surfaces varies directly with the area of the various passages through which air flows when passing through the fan. The different bases upon which these characteristic curves can be plotted are as stated in the following paragraphs.

Static No Delivery (S.N.D.). This gives a useful basis for calculating the performance of various fans. Fig. 1 is the chart of a fan known as the "steel-plate" or "paddle-wheel" type. Data for these curves are obtained by running the fan at some convenient constant speed and taking a set of readings at each of six to eight air deliveries produced by as many different restrictions placed on the discharge and varying from a condition of closed outlet to wide open or free discharge. All data are taken at the fan outlet. The abscissæ are the static pressures or maintained resistances in percentages of the pressure which the fan will exert with its outlet completely closed; this latter pressure with a few exceptions is the maximum pressure a fan will exert at any given speed, and is symbolized S.N.D. Four curves are plotted, using as ordinates (1) the ratio of the velocity through the fan outlet to the peripheral speed of the wheel and designated V/T; (2) the mechanical efficiency E; (3) the ratio of impact pressure to S.N.D., designated h_i/S.N.D.; and (4) the ratio of static pressure to impact pressure, designated h_s/h_i. From these curves can be computed the performance of any size of symmetrical fan under any conditions of pressure, volume or speed within its structural possibilities.

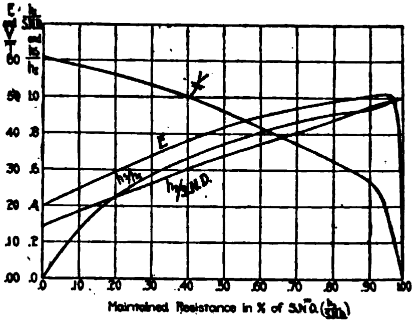

Fig. 1.—Characteristic Curves of a Steel-plate Paddle-wheel Fan.

As an example of how these curves are applied, let it be assumed that a size of fan is required which will operate most efficiently when delivering 10,000 cu. ft. per min. against 2 in. static pressure. Assume the fan to operate at a mechanical efficiency of 50 per cent. At this efficiency the abscissa h_s/S.N.D. is 0.857, from which S.N.D. = 2.0/0.857 = 2.33 in. For the same efficiency h_i/S.N.D. = 0.923, therefore h_i = 0.923 × 2.33 = 2.15 in.; $h_i = h_s + h$, hence h = 0.15 in.; and $V = 4000\sqrt{0.15}$ = 1548 ft. per min. For 10,000 cu. ft. per min. the area of the fan outlet must then be 6.47 sq. ft. Knowing that for this particular design of fan the outlet area is expressed by the equation $A = 0.306D^2$, the diam. D is found to be 4.59 ft. Corresponding to h_s/S.N.D. = 0.857 is found a value of V/T = 0.298, from which the peripheral speed = 1548/0.298 = 5200 ft. per min., and the speed of the fan is computed as 360 r.p.m. The other dimensions of the fan are found from the basis of design, in which these dimensions should be expressed as functions of the diam. of the wheel D. Air horse power = a.h.p. = 10,000 × 2.15 × 5.2/33,000 = 3.39; b.h.p. = 3.39/0.50 = 6.78.

As a second example suppose a fan with a wheel 3 ft. in diam. is to deliver 5000 cu. ft. per min. against 2 in. maintained resistance or static pressure, leaving r.p.m. and b.h.p. to be determined. From the equation $A = 0.306D^2$, A = 2.76 sq. ft., therefore V = 1810 ft. per min. From $V = 4000\sqrt{h}$, h = 0.205 in. making h_i = 2.205 in. Here h_s/h_i = 0.907, at which point on the curves of Fig. 1 V/T = 0.322; hence T = 5620 ft. per min. As D = 3 ft., r.p.m. = 597. a.h.p. = 5000 × 0.205 × 5.2/33,000 = 1.74. From the curves E = 49.2 per cent., hence b.h.p. = 3.54.

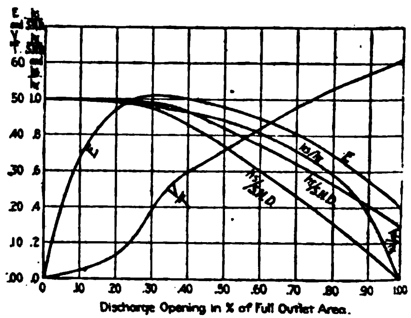

Fig. 2.

The curves of Fig. 1 may also be plotted using for abscissæ the static pressures or maintained resistances expressed in percentages of the pressure which would result from a velocity equal to the peripheral or tip speed of the blades and which is referred to as **tip-speed pressure.**

Discharge Opening in Percentage of Full Outlet. Fig. 2 is for the same fan as Fig. 1 and shows the same ordinates plotted against the discharge outlet area (during the test) expressed as a percentage of the full outlet. As the majority of fan problems require solution on a basis of static pressure or maintained resistance rather than on a percentage of full outlet (a laboratory condition), Fig. 1 proves of greater utility. A curve of "discharge opening in percentage of full outlet" could be plotted on Fig. 1 as another ordinate against maintained resistance if desired.

Reduced Orifice. This term is more common in European practice and is used as an abscissa against which are plotted volumetric, manometric and mechanical efficiencies. Reduced orifice is expressed by the equation $O_r = q/(r^2\sqrt{gH})$. Since this equation contains the factor r, it is evident that regardless of the size of fan of any given type the reduced orifice will be the same when the same relative restriction exists. This approaches the basis of Fig. 2, but instead of dealing with the percentage of opening of outlet, it deals with a value that is in reality some constant times the true percentage of full opening.

Equivalent Orifice. This term is also more common in European practice and differs from "reduced orifice" in that the equation contains no term bearing on the proportions or size of the fan; hence the equivalent orifice is an actual quantity in sq. ft. varying with the volume delivered. Equivalent orifice is expressed by the equation $O_e = q/(K\sqrt{2gH})$. It represents the area of a circular hole in a thin plate which will produce a restricting effect equal to that which exists in the system under consideration regardless of the nature of the actual restriction. The value of K generally used ranges from 0.60 to 0.65, making $O_e = q/0.65\sqrt{2gH}$. It is more of a laboratory characteristic than one adaptable to general use.

Volumetric and manometric efficiency curves could be plotted, but the usefulness of such curves is limited. Volumetric efficiency is a direct function of the V/T-curve and may be represented by the product of V/T and a constant, the latter depending on the design of the fan. As the volume delivered at a given r.p.m. varies as D^3, the volume per revolution $= K_1D^3V/T$, and since the overall cubical content of the wheel is K_2D^3, the volumetric efficiency $= KV/T$, where K equals K_1/K_2. K_1 and K_2 depend on the design and proportions of the fan. The volumetric efficiency is maximum with free intake and discharge and runs as high as 400 to 500 per cent. in fans of the multiblade type designed for high pressures at low peripheral speeds, while it runs as low as 100 per cent. in fans designed for low pressures at high peripheral speeds. The manometric efficiency is generally highest when the outlet is closed and lowest when maximum volume is delivered. There are, however, types where the maximum value occurs at light loads varying from ¼ to ½ maximum volumetric delivery. In cased fans of the multiblade type the maximum efficiency (gH/C_1^2) attained is about 150 per cent., while in open-running fans it is as low as 30 per cent. High mechanical efficiency (and generally high volumetric efficiency) is desirable, but with manometric efficiency it is usually the method of drive which determines the desirable value. The higher the speed of the driver the lower the manometric efficiency of the fan best adapted to the drive.

Effects of Variations in R.P.M., Volume, Pressure, Horse Power, Efficiency, Etc. Where a given fan is operating with a given restriction on its inlet or outlet, the volume delivered will vary directly with the r.p.m. (N), the various pressures as N^2, and the air horse power as N^3. The mechanical efficiency will remain the same, therefore the b.h.p. will also vary as N^3. The volume delivered by symmetrical fans will vary as D^2 for any given peripheral speed of the wheel and resistance or static pressure.

Under these conditions the mechanical efficiency remains constant, since the area of friction surfaces varies directly with the change in volume. The horse power will therefore vary as D^2. It is sometimes erroneously assumed that at very high speeds a given fan will show a marked decrease in efficiency due to slippage, or what with ship propellers is known as cavitation. This, however, is not the case.

METHODS OF TESTING FANS

Measuring the Flow of Air. For various methods of measuring the flow of air, see p. 1691.

Air-tight Room Test. In this test the fan discharges into a closed room, the outlet of which is a sliding door or a suitable discharge pipe. The static pressure in the room represents the resistance against which the fan is operating. The sliding door is used to vary the output of the fan, but as the coefficient of efflux varies with different openings as a result of their varying shape, it is better to measure the volume delivered through a discharge pipe of such length as will practically eliminate eddies. The room should be of such size that there are no heavy swirls, and even though extra caution be used in making it tight, a leakage test should be made. With this method of testing it is impossible to get data for a free and unrestricted discharge, yet if the room is relatively large this condition is approached with reasonable closeness. Prof. R. J. Durley (*Trans. A. S. M. E.*, vol. 27) lets the air discharge from a room or closed vessel through small circular orifices in thin plates of known coefficient of discharge. This, however, is essentially a laboratory method.

Discharge Pipe Test. The discharge pipe, which is preferably of the shape and size of the fan outlet, should have a length of 15 to 20 diameters or 15 to 20 times the mean of the rectilinear dimensions. The Pitot tube should be placed at about 10 diameters from the fan outlet. Traverse readings are taken at this point with a Pitot tube. To get a correct average of the velocity pressure, square-root-of-mean-square-values should be used, but, even with a wide variation in the readings, the inaccuracy of using a plain arithmetical mean is not over 0.5 per cent. Center readings only can be taken, corrected by a coefficient for the pipe if such procedure seems desirable. Credit should be given the fan for the friction loss between the fan outlet and point of measurement. Galvanized iron is the common material of the discharge duct, and the **friction loss** in inches of water can be computed from the formula $H = 4flv^2/d$, where H = head in feet of air, f = coefficient of friction = 0.0001 (about) for galvanized iron pipe, l = length (ft.), v = velocity (ft. per sec.), and d = diam. of discharge (ft.). This formula may be simplified and written as $h_f = lh/kd$, where k = a constant, h_f = head lost in friction, and h = velocity head in the pipe, both in inches of water. The value of k for smooth galvanized-iron piping ranges from 50 to 60, while for 12-in. swaged pipe it may be as low as 40 and in some cases is still lower. (See also pp. 357 and 1358.) Readings taken at conical mouthpieces at the end of this discharge pipe are not as accurate as those taken with a Pitot tube in the pipe.

Suction Pipe Test. A similar pipe can be placed on the inlet and Pitot tube readings taken therein. Here the true resistance against which the fan works will be the impact reading.

FAN DESIGN

Casings

Design is best based upon the characteristic curves of fans wherein the shape and proportions of the fan casings are varied. The principal dimensions of any design can be made functions of the diameter of the wheel, *i.e.*, some constant times the diameter to the first power for straight dimensions and to the second power for areas. This procedure should be adhered to in making calculations for fans of different sizes of a given type, and should always refer to the inside or effective dimensions.

The Spiral or Scroll. If the air is given off equally for each unit of length around the periphery of a centrifugal-fan wheel, the casing should have a uniform increase in area outside the wheel for the passage of air. The curve of the outer or scroll sheet of the casing is therefore that of the spiral of

Archimedes, and its equation is $R = r + Ka$, where R is the straight-line distance from the center of the wheel to any given point on the curve, r the radius of the wheel, a the angle of advance in radians, and K a constant. The air is not uniformly given off all around the circumference of the wheel except when the fan is properly loaded; when the load is too light the air will blow back between the blades at certain points while being delivered at other points. The curve of the spiral scroll is stopped some distance from the point of intersection with the wheel and formed into the cut-off piece. The value of the constant K in a casing for a given wheel is best determined by experiment. The point where the curve of the spiral would, if extended, intersect the circumference of the wheel, varies from about 30 deg. back of a point from which a tangent would be parallel to the axis of the discharge opening (and from which point the angle of advance is measured) to about 30 deg. ahead of this point. (See Figs. 3 and 4.) The former is found in some of the older designs of steel-plate or paddle-wheel fans, while the mean of the two extremes is more general in the multiblade types of recent development. Unless the curve of the spiral intersects the wheel at the point from which the angle of advance is measured, the equation becomes $R = r + Ka + K_1$; the value of K_1 depending on the point of intersection. In the spiral equation for a series of fans of a given design, the constant K varies with the diameter of the fan and can be written rK. A common commercial form of paddle-wheel fan, having eight flat radial blades of a depth about one-sixth the diameter of the wheel, has a spiral equation $R = r(1 + 0.118a + 0.074)$; a common fan of the multiblade type has the spiral $R = r(1 + 0.198a)$. The following table, from tests on a standard form of multiblade fan, shows the effect of varying the value of K.

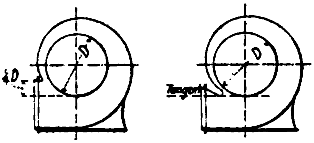

FIG. 3. FIG. 4.
Spirals of Fan Casings.

Scroll Equation	Maximum Efficiency, Per Cent. Mechanical	Volumetric	Manometric
$R = r(1 + 0.148\,a)$	48.5	367	130
$R = r(1 + 0.198\,a)$	52.0	452	128
$R = r(1 + 0.396\,a)$	36.0	493	117

Casings are often made with two discharges 180 deg. apart. In these the spiral is developed as for a single-discharge fan, stopping off at 180 deg. and starting at this point a second spiral. Although this gives the same total outlet area and the same velocity outside of the wheel with a given volume flowing as with a single-discharge fan having the same spiral equation, the mechanical and manometric efficiencies fall off to a marked degree and the volumetric efficiency more or less. The following table shows the effect on efficiencies of double discharge in a standard type of multiblade fan with a given spiral equation, and also the effect of changing the spiral equation in a double discharge casing.

Discharge	Spiral Equation	Maximum Efficiencies, Per Cent. Mechanical	Volumetric	Manometric
Single...........	$R = r(1 + 0.198\,a)$	52.0	452	128
Double..........	$R = r(1 + 0.198\,a)$	43.6	416	105
Double..........	$R = r(1 + 0.269\,a)$	45.5	490	98

With forward-curved-blade fans where the velocity of the air leaving the fan is high, a scroll whose radius increases in a geometrical ratio is sometimes used. By this means a more complete conversion of kinetic to static pressure is obtained within the fan casing, thereby eliminating the need for the use of an expansion piece at the outlet if high efficiency is desired.

Cut-off Point. The point where the scroll or spiral discontinues its approach to the circumference of the wheel is called the cut-off point. In some types of fan nearly half the diameter of the wheel is exposed when looking along the axis of discharge, while the other extreme is found where no part of the wheel is exposed, in which case a tangent to the wheel passing through the cut-off point is parallel to the axis of discharge. A fan with a large exposure of wheel will deliver, with very little or no restriction to the flow of air, a relatively greater volume at a given number of r.p.m. than the fan in which there is little or no exposure of the wheel, while the latter will deliver a relatively greater volume against average restrictions or resistances met with in practice. The following table, from tests on a multiblade fan, shows the difference in efficiencies at various pressures or resistances at a given speed in r.p.m. when 25 per cent. of the diameter of wheel is exposed [col. (*a*)] and when a tangent to the wheel passing through the cut-off point is also parallel to the axis of discharge [col. (*b*)]. The same wheel and casing, except for the cut-off piece, were used in each case. Figs. 3 and 4 show the feature being considered.

Static Pressure, in. of water	Efficiencies, Per Cent.					
	Mechanical		Volumetric		Manometric	
	(*a*)	(*b*)	(*a*)	(*b*)	(*a*)	(*b*)
0.6	40.0	40.0	396	383	79.4	76.8
1.0	47.2	49.5	335	340	94.6	94.6
1.1	48.2	51.0	305	322	96.2	98.5
1.2	48.5	51.5	262	301	96.0	100.7
1.3	47.0	51.5	189	271	94.7	102.4
1.4	41.0	50.0	116	215	96.0	103.7

When a fan operates against considerable restriction or resistance to the flow of air, there is a strong tendency in the air to leak back through the wheel at the point where it is about to leave the spiral to pass through the fan discharge. If the delivery is restricted, it leaks back through the wheel at the point of maximum pressure. The above table shows how the efficiencies drop off in the fan of Fig. 3 as compared with that of Fig. 4. The maximum pressure in the air is at the fan discharge, while from the bottom of the wheel to the cut-off point (that is, the exposed portion of the wheel) the air has only that pressure imparted to it by the blades in that section of the wheel. This produces leakage back into the wheel as soon as the pressure at the discharge builds up due to restriction. Experiment shows that cut-off points with very small clearances have a merit which exists only in fancy. The effect upon efficiency of a reasonably large clearance at this point is negligible; the amount of clearance may be 5 per cent. of the wheel diameter in medium-sized fans. Most of the noise in a fan originates at the cut-off, the function and form of which make it like a reed that will give a musical note unless this is guarded against. A blunt, rigid construction as in Fig. 4 will keep the noise down, whereas small clearance and a sharp, knife-like edge will give a loud, shrill noise. In very-high-speed fans the cut-off is sometimes made of a material less subject to vibrations than metal, such as soft wood.

Width of Spiral Casing. In general, low-pressure volume fans have a width of casing 20 to 40 per cent. greater than the width of the wheel at its periphery. As the relative width is increased beyond this the air must distribute itself laterally to such extent that serious eddy currents are produced in the casing, resulting in loss of efficiency. Fans with cast-iron casings for high pressures are often made with a casing of gradually increasing width; a section at any point along the spiral air passage being circular and of increasing diameter with increase in the angle of advance. The table following shows the effect of a change in the width of the casing. The tests were made on a multiblade wheel 17¼ in. in diam. and 9 in. wide. Casing A was 13½ in. wide and casing B 12 in. wide. The equation of the spiral was in each case such as to produce the same sectional area of air passage outside the wheel at any given angle of advance, and the inlet connections to the casings were the same.

		Casing A		Casing B	
Volume, cu. ft., per min.	Static pressure, in. of water	R.p.m.	Mech. effy., per cent.	R.p.m.	Mech. effy., per cent.
2800	1	796	47.5	728	53.5
3400	1	800	45.7	736	53.2

The position of the wheel relative to the width of the casing is important in single-inlet fans, owing to the tendency of the air to crowd to the back. The wheel should be placed centrally in the casing or nearer the inlet side so as to reduce this crowding effect. Casings are frequently made double-width, double-inlet, which, for a given volume, pressure and efficiency, gives a rotative speed 41 per cent. higher. This has decided advantages where direct-connected high-speed drivers such as electric motors and steam turbines are used.

Inlet of Casing. The following table (from "Fan Engineering," published by The Buffalo Forge Co.) shows how the dimensions, horse power and speed of a steel-plate paddle-wheel fan vary, for the same capacity and pressure, as D_1/D varies from the standard value, 0.625. D_1 is the diameter of the fan inlet.

D_1/D	Relative diameters		Relative widths, b	Relative horse power	Relative r.p.m., N
	Wheel, D	Inlet, D_1			
0.700	0.82	0.92	1.09	1.12	1.23
0.650	0.93	0.98	1.03	1.04	1.10
0.625	1.00	1.00	1.00	1.00	1.00
0.600	1.07	1.03	0.98	0.97	0.93
0.550	1.24	1.09	0.92	0.91	0.78
0.500	1.45	1.17	0.86	0.87	0.65
0.450	1.71	1.23	0.81	0.83	0.53
0.400	2.07	1.32	0.76	0.80	0.43
0.350	2.55	1.43	0.70	0.78	0.35

A common form of inlet still used on many casings has a diameter equal to (and in some cases less than) the inlet of the wheel, a casting or rolled angle being used to facilitate connection to a pipe, as in Figs. 5 and 6. With these forms the contraction of the entering stream of air constitutes a restricted area and is a source of loss, as it requires a higher velocity for a given volume of air. The shape of the inlet connection should be conformed to the natural path of the outer particles of air by means of a conical or bell-shaped inlet connection such as shown in Fig. 7. A connection in the form of a frustum of a cone is preferable from a manufacturing standpoint. Variation in the form of inlet connection produces change both in the mechanical efficiency and in the volumetric efficiency. The fol-

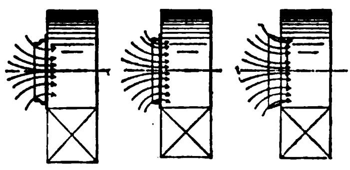

FIG. 5. FIG. 6. FIG. 7.
Inlets of Fan Casings.

lowing table gives results obtained with three inlet connections, *a*, *b*, and *c*, similar to Figs. 5, 6 and 7, respectively. The diameter of the wheel inlet was 14 in. Connection *a* was 12¼ in. in diam. at the entering end, *b* was 14 in. in diam., or the same as the wheel inlet, and *c* was 14 in. in diam. at the small end with a 16-deg. taper to its axis and an axial length of 4 in.

Inlet connection	Cu. ft. per min.	Static pressure, in. of water	R.p.m.	Mechanical efficiency, per cent.
a (Fig. 5)	1680	1	726	40.5
b (Fig. 6)	1680	1	698	45.5
c (Fig. 7)	1680	1	682	51.8

Another fan, of lower average efficiency, was tested with inlet cones identical in all respects except as to axial length. In the table below test *a* is with a plain inlet like that of Fig. 6, while tests *b*, *c* and *d* are with the cones just mentioned wherein the small diameter is 14 in. and the taper 16 deg. to the axis.

Test	Depth of cone, in.	Cu. ft. per min.	Static pressure, in. of water	R.p.m.	Mechanical efficiency, per cent.
a	....	2500	1	960	34.2
b	2	2500	1	950	36.3
c	4	2500	1	888	41.1
d	7	2500	1	884	42.8

The angle of convergence or taper of the inlet cone is best taken at about 15 deg. to the axis (under which condition the coefficient of influx is nearly unity), and should not exceed 30 deg. Its larger diameter should be at least 25 per cent. greater than the small diameter. (See also Fig. 18, full lines.) Where a fan draws its air direct from the atmosphere or from the room in which it is placed and does not have a pipe attached to its inlet, it is of material advantage to use a fan with two inlets. For a given volume delivered the inlet velocity where two inlets are used will be one-half (and therefore the inlet velocity pressure one-quarter) that with one inlet. The effect of this reduction in inlet losses is illustrated in the table below, where the two fans are identical except as to inlets.

Inlet	R.p.m.	Static pressure, in. of water	Cu. ft. per min.	Air h.p.	B.h.p.	Mechanical efficiency, per cent.
Single	265	1.5	39,200	12.50	25.0	50.0
Double	265	1.5	44,100	14.95	27.7	54.0

Another test, in which the volume and static pressure were held constant instead of the r.p.m. and static pressure, shows the decrease in r.p.m. and increase in mechanical efficiency of the double-inlet fan, as follows [see also Figs. 18 (full lines) and 19]:

Inlet	R.p.m.	Static pressure, inches of water	Cu. ft. per min.	Air h.p.	B.h.p.	Mechanical efficiency, per cent.
Single	265	1.5	39,200	12.50	25.0	50.0
Double	253	1.5	39,200	12.50	22.6	55.2

This gain in volumetric and mechanical efficiency holds only with a single-width fan. A double-width, double-inlet fan is in effect simply two single-width, single-inlet fans placed back to back. Obstructions to the flow of air into the inlets, such as bearings and bearing supports, are often important offenders. The inlet area is reduced and the inlet losses for a given volume increase as the square of the decrease in inlet area due to this cause, while the interference with stream lines adds further to these inlet losses. The table below gives the results of tests on a multiblade type of fan (*a*) with a free and unobstructed inlet, and (*b*) with a bearing and its support mounted directly in the inlet. The effect on the volumetric and mechanical efficiencies with a given number of r.p.m and static pressure is very noticeable.

Test	R.p.m.	Pressure, Inches of Water Static	Impact	Velocity	Cu. ft. per min.	Horse Power Air	Brake	Mechanical efficiency, per cent.
(*a*)	900	3.0	4.45	1.45	26,500	18.6	37.0	50.3
(*b*)	900	3.0	3.91	0.91	21,000	12.9	27.0	48.0

Outlet or Discharge of Casing. The area of the outlet of a spiral casing is seldom made as small as the area between the wheel and spiral at the point of maximum area or where the air passes the cut-off in leaving the casing. A relatively large velocity pressure exists at this point and it is general practice in fans of small and medium size to make no attempt whatever to conserve the kinetic energy in this blast. In most installations this velocity pressure will be from 25 to 50 per cent. of the total head developed. Fans in general have outlets varying from 25 per cent. to 75 per cent. larger than the area at the cut-off point. The expansion is abrupt, so that although some of the velocity pressure is transformed into static pressure, there is nevertheless considerable loss. If the fan discharges directly into the atmosphere the entire velocity pressure in the outlet is lost. Most of this can be saved, however, if the outlet is fitted with a proper evasé discharge piece. (See also Figs. 19 and 20.) In larger fans such as are used for mine ventilation the evasé chimney is started from the cut-off point and thereby conserves the larger portion of the velocity head at that point. If the fan is connected to a duct larger than the outlet it should have a long, tapered connection.

It is not practical to carry the expansion piece on a fan outlet to a point where the velocity is below 1000 to 500 ft. per min. The velocity head due to a velocity of 500 ft. per min. is but $\frac{1}{64}$ in., and is negligible. The angle between the sides and the axis of an efficient chimney or diffuser should be from 7 deg. to 10 deg. The use of a diffuser produces a lower static pressure at the cut-off point and consequently the fan may run at a lower speed and at higher volumetric efficiency. Actual tests on a multiblade fan for mine ventilation showed that, when fitted with a chimney whose larger end was twice the cut-off area and whose sides had a taper of 8 deg. from the axis, the volumetric capacity was increased 12 per cent. when operating against a given static pressure and at a given number of r.p.m. The horse power, however, increased only 5 per cent.

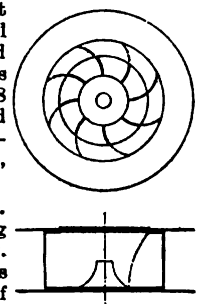

Fig. 8. Diffuser Casing.

Diffuser Casing Open Around Circumference. Similar results may be obtained with wheels discharging into circular diffusers open all around their periphery. Fig. 8 shows this form of diffuser, which incidentally has still another effect on the outflow of air. This type of fan must deliver its air against the pressure in the chamber into which it discharges, and this pressure acts in a radial direction at all points. It follows, therefore, that the resultant direction of flow should be as near radial as possible. This necessitates a blade curved backward relative to rotation, but it can be considerably helped by a radial diffuser. Fig. 9 shows that the velocity of the air decreases in this diffuser and at the same time the direction of the flow becomes more nearly radial; also, that the radial component of the air velocity becomes greater relative to the resultant as the distance from the center increases, thus utilizing a greater part of the resultant velocity. In Fig. 9, r_2 is the radius of the wheel or entrance to diffuser, r_3 the outer radius of diffuser, and A_2 is the circumferential area at entrance to the diffuser. The volume delivered is $u_2A_2 = v_2 \sin b_2A_2$. No force acts on the air as it passes through the diffuser and its direction is unchanged, but its radial component varies inversely as the radius, or $u_3/u_2 = r_2/r_3$. The direction of the air leaving the diffuser is known, and its velocity is determinable since u_3 is known. Both v_3 and w_3 decrease much more rapidly than inversely as the radius, and the ratio of u_3 to v_3 is greater than that of u_2 to v_2. This type of diffuser is generally made stationary and its sides are made radial, converging or diverging. With a slight convergence there can still be an increase in circumferential area with an increase in radius. When the sides diverge the angle of divergence should not exceed from 7 deg. to 10 deg., in order to conserve a full section of flow. (See Fig. 24.) A diffuser of this sort is also at times applied to a fan wheel running in a spiral casing, the air passing from the wheel to the diffuser and thence to the spiral, which must have small radial depth.

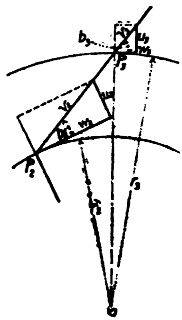

FIG. 9.

Fan Wheels

Blade Curvature, Diagrams, Losses. The losses in the wheel are caused by surface friction and by sudden changes in direction and velocity which produce wasteful eddies. The force necessary to overcome the surface friction is represented by the formula $P_fA = fWv^2S$, where P_f is the pressure loss, lb. per sq. ft.; A the sectional area, sq. ft.; f the coefficient of friction or loss in lb. per sq. ft. per ft. (velocity) per sec.; v the velocity, ft. per sec., and S the surface, sq. ft. For smooth iron f is approximately 0.00008. The formula may also be written as $h_f = fWv^2S/5.2A$, where h_f = pressure loss in inches of water. The loss due to a sudden change in velocity is computed from the formula $H_g = v_2(v_1 - v_2)/g$, where H_g = feet of air, or from $h_g = v_2 \times (v_1 - v_2)/69.3g$, where h_g = loss in inches of water. The losses due to change of direction are computed from the triangle of forces. In Fig. 10 let the velocity v represented by BA be changed to v_1, represented by BC, and the angle ABC be called a; then the loss of head $H_c = \overline{AC}^2/2g = (v^2 + v_1^2 - 2vv_1 \cos a)/2g$. This has its least value when AC coincides with BD the perpendicular on AC, that is, when $v_1 = v \cos a$. Let the static pressures before and after the change be represented by P and P_1, respectively; then $(P_1/w) + (v_1^2/2g)$ + loss of head $= (P/W) + (v^2/2g)$. The gain of static pressure $= (P_1 - P)/W = (v^2 - v_1^2)/2g - (v^2 + v_1^2 - 2vv_1 \cos a)/2g = (vv_1 \cos a - v_1^2)/g = BC \times BD/g$. This has a maximum value when $BC = CD$. Therefore, if it is afterward expected to convert a large part of the velocity head into static pressure by means of an expanding pipe, v_1 should equal $v \cos a$, but when no expanding pipe is to be used BC should equal ½ BD, or $v_1 = ½v \cos a$.

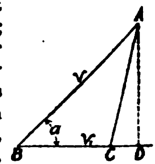

FIG. 10.

The performance of a wheel is dependent on the casing in which it is placed. The volume, pressure, and efficiency of a wheel are functions of the shape, relative size, length, depth, curvature, inclination and number of blades.

[See Figs. 18, 21, 22, (full lines) and 23 (broken lines).] Figs. 11, 12 and 13 give velocity diagrams for wheels with blades with their generatrices parallel to the axis, curved backward, radial and curved forward, respectively. Air enters the ports between the blades in a radial direction and follows a path similar to *ED*, which may differ slightly from the actual surfaces of the blades. The lighter the load the nearer will the path of air approach the curve of the blade. As the blade curvature changes from convex forward to concave forward the resultant velocity for a given tip speed increases in value and approaches more nearly a tangential direction. Where

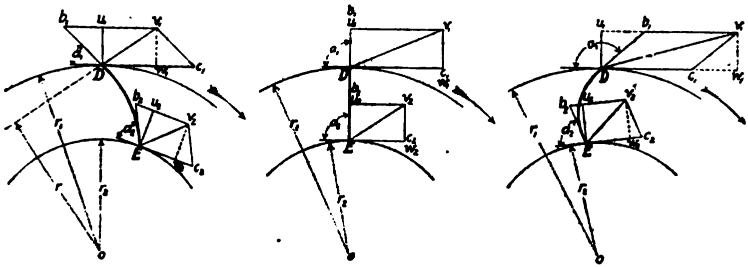

Fig. 11. Fig. 12. Fig. 13.

Velocity Diagrams for Fan Wheels.

a wheel is placed in a spiral casing, the blade curved forward is best; where the wheel is not fitted with a spiral casing but discharges directly into a chamber or the open atmosphere, whether through a radial diffuser or not, the convex forward blade is best, since the pressure against which it discharges acts in a radial direction.

The following symbols apply to Figs. 11–13, the subscript 1 being used for discharge from, and subscript 2 for entrance to, the blades. The angle between the tangent to an element of the blade and the tangent to a circumference through that element is denoted by a, b is the velocity in the direction of an element of the blade, c the tangential velocity of an element of the blade, u the radial component, v the resultant velocity relative to stationary objects, and r the radius. A particle of air weighing W and leaving the wheel at a velocity v_1, has a momentum of Wv_1/g, and if r is a perpendicular on the direction of v_1 drawn through the center of the wheel, the moment of momentum (or angular momentum) of the particle is $Wv_1\, r/g$. By a solution of triangles, $v_1\, r = w_1\, r_1$; therefore, the angular momentum equals $Ww_1\, r_1/g$. The particle had no angular momentum when entering the wheel, so $Ww_1\, r_1/g$ is the angular momentum of all the forces acting on it. Now if W_a is the total weight of air passing through the fan per second and o equals the angular velocity in radians, $W_a w_1\, r_1\, o/g$ equals the work done per second by the wheel on the air. Since $r_1\, o$ equals c_1, the peripheral speed per second, the work done per second is equal to $W_a w_1\, c_1/g$.

The loss of head at entrance to the blades, for instance in Fig. 11, is $L_1 = w_2{}^2/2g$, w_2 being the length from E to w_2. The length w_2c_2 equals $u_2 \cot a_2$, therefore $L_1 = (c_2 - u_2 \cot a_2)/2g$. To minimize this loss $\cot a_2$ should equal c_2/u_2. If the fan discharges directly into the atmosphere, all the kinetic head $v_1{}^2/2g$ is lost. If the fan discharges into a spiral casing, the loss of head here is $L_2 = (r_1\, v_3)^2/2g$, where $v_1\, r_3$ represents the length between those points in Fig. 14, and v_3 the velocity in the spiral, whose direction is nearly tangential to the wheel. $L_3 = [u_1^2 + (w_1 - v_3)^2]/2g$. To minimise this loss, v_3 should equal w_1 where the spiral is fitted with an expansion outlet, and equal ½ w_1 when an expanded outlet is not employed. The value of v_3 in terms of w_1 will vary with the restriction against which the fan operates. In Figs. 11–13 the same peripheral speed of wheel c_1 and radial component u_1 are used, so that the relative effect upon the resultant v_1 is shown graphically.

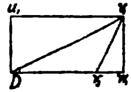

FIG. 14.

The blades in these figures have their generatrices parallel to the axis of the wheel. There are types, however, which include a compound curved blade taking the form of a screw or propeller at the intake and gradually changing into a true centrifugal blade at the discharge. Where the exact duty to be imposed upon this type of fan is known and the pitch of the screw portion of the blade is made accordingly, this form of blade has merit.

In order to equalize the flow of air from the ports of the blades or wheel periphery, different methods have been resorted to. One is to form the blade with spherical depressions along its axial length, in this way pocketing the air as it slides along the blade axially in its changing from axial flow at inlet to radial flow at discharge, and thereby reducing the slippage. Another is to allow the end of the blade nearest the intake to lag behind in rotation, that is, the outer peripheral edge of the blade is in a plane not parallel to the plane of the axis but advancing in the direction of rotation from the inlet end toward the back of the blade. Still another method is to make the diameter of the outer peripheral edge of the blade greatest at the end of the blade nearest the inlet and of gradually decreasing diameter as the rear or center of the wheel is approached, according as the fan may have one or two inlets. Whatever the form of curved blade—and especially with blades of relatively small radial depth, the inclination with respect to the axis is very important, it being found in a case where blades were curved forward that a variation of 1 deg. backward resulted in an increase of approximately 1 per cent. in speed to get the same volumetric delivery. This same rate held approximately up to a variation of 30 deg., but the mechanical efficiency began to suffer greatly after a few degrees departure from the inclination for which the blades were designed. Obviously, the inlet and outlet port areas between blades are seriously affected.

Axial Length of Blade. A common rule for maximum efficiency is to make the port area between blades less than or equal to the inlet area of the wheel, but practice has exceeded this limit in many instances. In a fan with radial blades, neglecting their thickness, this rule would limit the axial length of the tip of the blade to $d^2/4D$, where d is the diam. of the inlet and D

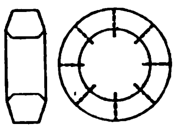

FIG. 15.

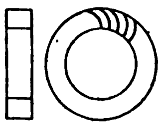

FIG. 16.

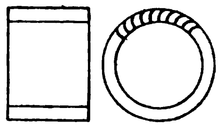

FIG. 17.

Fan-wheel Blade Constructions.

the diam. of the outer edge of the blades. Radial-blade wheels are almost invariably made with the axial length of the edge of the blade at intake materially greater than that of the outer or peripheral edge, as in Fig. 15. This is for the purpose of keeping up the area of the ports at the intake edge, yet in many fans the length of the inner edge is for reasons of construction not increased sufficiently to make the port area at intake to blades equal to that at discharge. In wheels with flat parallel sides in planes perpendicular to the axis, the port area can be kept constant from intake to discharge by the use of blades having the curve of an involute of a circle, as in Fig. 16, in which case the height of a normal from one blade to the next is constant for all points along the blade and the port area equals the inlet area when the axial length of blade is ¼ *d*. When the blade is curved to some other form, such as that of a circle, it is seen that the port area is reduced and depends on the length of a line drawn through the tip of one blade and normal to the next adjacent blade, this representing the minimum distance between blades. The axial length of the blade may, therefore, be considerably more than ¼*D*, depending on the curvature and radial depth of blade. Decreasing the radial depth of the blade augments the inlet area to the wheel, hence, in itself, allowing of greater axial length of blade. Following this method and by the use of shallow, curved blades, there is developed the multiblade construction of Fig. 17, in which the axial length of blade reaches values from 4 to 8 times the radial depth.

Radial Depth and Number of Blades. A blade of small radial depth permits a larger inlet area to the fan, thereby decreasing the inlet losses for a given volume and increasing the volumetric capacity of the wheel. [See Figs. 18 and 21 (full lines).] The inlet area will increase as d^2 and the loss of head at the inlet for a given volume will decrease as $1/d^4$. Again, the rotative speed is increased for a given duty, making the fan more applicable to the more modern direct-connected drives such as electric motors, turbines, etc. Decreasing the radial depth, however, reduces the blade area, which can only be obviated by increasing the number of the blades. When the number becomes too great, not only do constructional interferences arise but also the port area between the blades becomes reduced and surface friction increased to a point where both are detrimental. It therefore becomes a matter of experiment to find the most desirable number from the standpoint of both volumetric capacity and mechanical efficiency. As the number is increased the volumetric capacity will still be on the increase after the mechanical efficiency has passed its maximum. (See Fig. 19.) A fan with many shallow blades has considerably higher volumetric capacity and manometric efficiency than the older types with few deep blades. The extent to which the radial depth can be decreased is limited entirely by the strength of the blade to resist the stresses that come upon it in operation. Most of the stress arises from the centrifugal force due to the weight of the blade itself. The blade can be considered as a uniformly loaded beam, so that the radial blade is strongest, while the strength of the curved blade depends entirely on its curvature. In fans for very high pressures and speeds it is common practice to cut the length of the blade into parts and insert annular rings or sheets such as are used regularly for side plates on the wheel.

Support of Blades. Both deep-bladed and shallow-bladed wheels are generally built up in either of two forms. (1) All or some of the blades are attached to the outer ends of spider arms emanating from a central hub. In this case the driving effort is applied to the center of the wheel and the work is fairly well balanced on either side of the spider. The force F (lb.) exerted by each of the spider arms is small: $F = (\text{h.p.} \times 33{,}000)/(T \times \text{number of arms})$. Where there are more blades than spider arms, the intermediate blades are supported only from the end rings or side plates, to which are also fastened the ends of the driving blades. (2) The other common form of support is that in which all of the blades are fastened at one end to a driving disk connected to a hub, and at the other or inlet end to a sheet-metal annulus. All the driving effort being placed upon the rear end of the blades, it becomes necessary, except for low speeds, to run stay rods out from the central hub to the sheet-metal annulus or side plate nearest the inlet, thus counteracting the tendency of this portion of the wheel to lag behind the driven end.

The weight of the fan wheel is generally so great that the use of a flywheel for direct-connected engine drive is not necessary. The diameter of the fan wheel is always considerably larger than would be that of the flywheel for the engine, and in fans of the multiblade construction the radius of gyration is approximately 80 per cent. of the radius of the fan wheel.

Characteristics of Various Designs and Effect of Change in Elements of Design and Proportions. The effect of a change in a single element of design on the principal factors of fan performance is seen by comparison of the characteristic curves in Figs. 18 to 24. The curves are drawn for fans handling standard air at a density of 0.075 lb. per cu. ft., having wheels 1 ft. in diam. and operating at a peripheral speed of 4000 ft. per min. or at 1274 r.p.m. This facilitates comparison of one with another. The speed of 4000 ft. per min. is not only a good average speed, but for standard air represents the velocity producing a pressure of 1 in. of water gage. The diam. of 1 ft. was chosen in order to establish as a basis unit diameter and thereby simplify calculations. From these curves the performance at any other peripheral speed can be computed by considering the volume to vary as the 1st power, the pressures as the 2nd power and the h.p. as the 3rd power of the speed, while the efficiency remains constant for any given load point on the curves. The performance of a symmetrical fan of different size or the computation of size, h.p., r.p.m., etc. necessary to do a given work, is readily accomplished by use of the above rules and the further rule that the capacity of a given design of fan operating against a given static pressure at a given peripheral speed varies as the square of the diameter. All effective fan dimensions will vary as the 1st power and areas as the 2nd power of the diameter. Where the fan handles air or gas at a density different from standard, the pressure and horse power will vary directly with the density, and the mechanical efficiency will not be affected. For factors to apply with variations to the air (or gas) temperature, see Table 3.

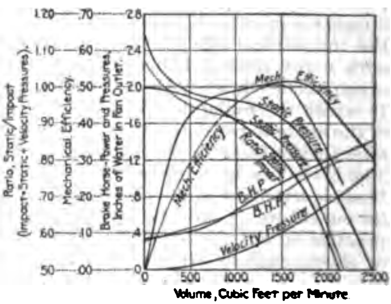

Fig. 18.—Characteristics of a Multiblade Fan with Single-inlet Spiral Casing.

Fig. 18 deals with a multiblade type of wheel fitted with a single-inlet spiral casing. The blades are of relatively small radial depth. The curves with solid lines are for blades having radially disposed corrugations equally spaced along the axial length of the blade; the broken-line curves are for similar blades without corrugations. They are curved so that the concave surface moves forward in rotation and are so inclined forward that a chord of the arc of the blade is about 18 deg. ahead of a radius through the tip of the blade, thereby making the outlet ports smaller than the inlet ports of the blades. The principal proportions, given as functions of the wheel diameter, are as follows: Number of blades, 60; radial depth of blades, $0.066D$; axial length of blades, $0.52D$; diam. at inlet of wheel, $0.868D$; equation of spiral, $R = r(1 + 0.198a)$; width of spiral, $0.69D$; number of inlets, 1; diam. of inlet cone, $1.05D$; area of cut-off point, $0.434D^2$; area of outlet, $0.59D^2$.

Method of Using Characteristic Curves.—Example. To illustrate the use of these characteristic curves a problem may be taken, as follows: What will be the size of a fan with corrugated blades of the type covered by Fig. 18 which will be required to deliver 50,000 cu. ft. per min. against 1.5 in. static pressure, the fan to operate at approximately maximum mechanical efficiency? The diam. of the fan found by calculation will vary according to the point on the curves of Fig. 18 taken as a basis, and will become less as the volume represented by that point increases. Assume as a basis the delivery of a fan 1 ft. in diam. at 51.5 per cent. mechanical efficiency where it delivers 1500 cu. ft. per min. against 1.67 in. static pressure at 1274 r.p.m., requiring 0.95 b.h.p. Operating at the same point on the mechanical efficiency curve but against 1.5 in. pressure would require the speed to be lowered in proportion to the square root of the decrease in pressure, or be multiplied by the factor 0.947. The volume would decrease in the same proportion and the b.h.p. as the 3rd power of 0.947, giving a delivery of 1412 cu. ft. per min. against 1.5 in. static pressure at 1200 r.p.m. and requiring 0.81 b.h.p. Since a delivery of 50,000 cu. ft. per min. is desired at this static pressure of 1.5 in., the peripheral speed will remain the same but the diam. will vary as the square root of the increase in volume. The speed in r.p.m. will vary inversely as the diam. and the b.h.p. directly as the volume, giving a fan 5.95 ft. in. diam. to deliver 50,000 cu. ft. per min. against 1.5 in. at 202 r.p.m. and requiring 28.7 b.h.p. Since the diam. obtained is an odd figure, it might be decided to use a fan of even diam., say 6 ft., in which case its performance would be calculated by considering that a similar fan 1 ft. in diam. at the same mechanical efficiency would deliver a volume in proportion to the square of the diameters, or 1/36 of 50,000, which is 1390 cu. ft. per min., against 1.5 in. pressure. Since the area of outlet is 0.59 sq. ft. the velocity in the outlet is 2350 ft. per min. and the velocity pressure 0.347 in., hence the ratio of static to impact pressure is then 0.813. Fig. 18 contains a curve of this ratio, which facilitates such computations and does away with cut-and-try methods. From Fig. 18 it is seen that when the ratio of static to impact pressure equals 0.813, the 1-ft.-diam. fan delivers 1465 cu. ft. per min. against 1.69 in. static pressure for 0.93 b.h.p. at 1274 r.p.m. Now to deliver 1390 cu. ft. per min. against 1.5 in., the fan speed would drop in direct proportion to the volume, or to 1209 r.p.m., and the b.h.p. as the cube, or to 0.79 b.h.p. From this the speed and horse power of the 6-ft. fan when delivering 50,000 cu. ft. per min. against 1.5 in. are found to be 201 r.p.m. and 28.5 b.h.p.

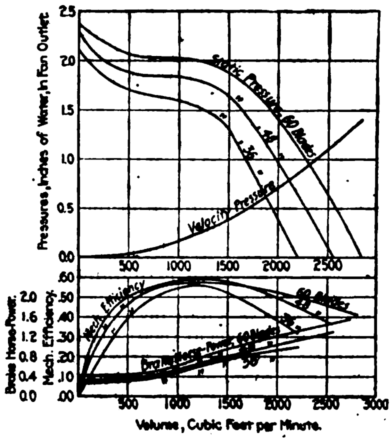

FIG. 19.—Characteristics of Multiblade Fans with Double-inlet Spiral Casings.

Fig. 19 covers a double-inlet fan with wheels and casing of the same proportions as the fan of Fig. 18; the three wheels tested in this casing had respectively 60, 48 and 36 blades. The one with 60 blades was the same wheel as used in Fig. 18. The effect of making the casing with a double inlet was to increase the volumetric capacity and mechanical efficiency by an appreciable amount. The effect of a reduction in the number of blades was a decrease in volumetric capacity and pressure developed, yet the mechanical efficiency increased somewhat with 48 blades. Fig. 20 is for the same fan as that having 48 blades in Fig. 19, and shows what an evasé (expanding) discharge on the fan will do in raising the resistance against which a given volume can be delivered or raising the volume delivered against a given resistance. The evasé discharge connection increased in area with a taper to its sides of about 7 deg. until it was twice that of the fan outlet. For any given volume the b.h.p. is the same as for the fan of Fig. 19, the gain being in static pressure produced.

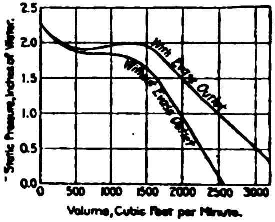

FIG. 20.—Effect of Using an Evasé Discharge on Fan.

Fig. 21 covers a steel-plate paddle-wheel fan with eight flat radial blades of relatively large radial depth and a single-inlet spiral casing. The side plates are inclined inwardly as in Fig. 26. The principal proportions are as follows: Number of blades, 8; radial depth of blades at intake, $0.145D$; maximum radial depth of blades, $0.29D$; axial length of blades (outer edges), $0.39D$; axial length of blades (at intake), $0.46D$; diam. at inlet of wheel, $0.71D$; equation of spiral, $R = r(1 + 0.106a + 0.125)$; width of spiral, $0.5D$; number of inlets, 1; diam. of inlet, $0.71D$; area at cut-off point, $0.306D^2$; area at outlet, $0.306D^2$. While there is not much difference in mechanical efficiency between this fan and the multiblade fan of Fig. 18, there is a great difference in the pressures and volumetric capacities; much less space is required for the multiblade type when performing a given duty.

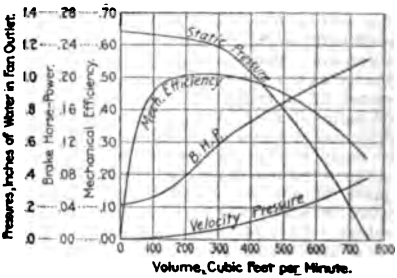

FIG. 21.—Characteristics of a Single-inlet Steel-plate Paddle-wheel Fan with Radial Blades.

Fig. 22 covers a fan designed for high rotative speeds at relatively low ressures. The wheel is fitted with single-inlet spiral casing and has 16 ep blades with radially disposed rrugations equally spaced along eir axial length. They are so urved that the concave surface moves forward in rotation and are so inclined rearwardly that a chord of the arc of the blade is about 35 deg. back of a radius through the tip of the blade, thereby making the outlet ports larger than the inlet ports of the blades. Reference to Fig. 18 will show the greater peripheral speed required of the fan of Fig. 22 for a given pressure.

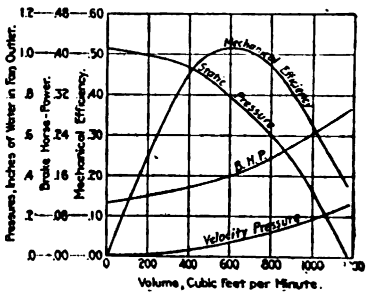

FIG. 22.—Characteristics of a Single-inlet Fan for High Speeds and Low Pressures.

The principal proportions are as follows: Number of blades, 16; radial depth of blades, 0.135D; axial length of blades, 0.52D; diam. inlet of wheel, 0.868D; equation of spiral, $R = r(1 + 0.198a)$; width of spiral, 0.69D; number of inlets, 1; diam. of inlet cone, 1.05D; area at cut-off point, 0.434D^2; area of outlet, 0.59D^2.

The full-line curves of Fig. 23 cover a fan designed for high rotative speeds at relatively high pressures such as are found in forced-draft applications. The wheel has no casing and discharges directly into the compartment in which the fan maintains a pressure. The wheel has 16 blades so curved that the convex surface moves forward in rotation. The blade is of variable depth, being most shallow at the intake side of the wheel and deepest at the part farthest from the intake side, forming a type known as a cone fan. The blades have a very decided back slope, which, as previously shown, is essential in an open-running wheel. The efficiency curves of Figs. 23 and 24 are those obtained by the use of static pressure in computing the air horse power, since obviously the kinetic energy at discharge from the fan is not useful as in a cased fan where the air generally travels along ducts. The principal proportions are as follows: Number of blades, 16; radial depth of blades, intake side, 0.052D; radial depth of blades, rear of wheel, 0.28D; axial length of blades, 0.38D; diam. of inlet of wheel, 0.896D; outlet port area of wheel, 0.56D^2. The broken curves of Fig. 23 cover the same fan, except that the wheel is fitted with a single-inlet spiral casing. The volumetric capacity and pressure are increased slightly and the mechanical efficiency considerably; the latter increase being due to the gain in pressure head incident with the expansion from the outlet ports of the wheel into the casing and from the cut-off of the casing to its outlet. This fan is particularly adapted to high-speed drives such as steam turbines. The principal proportions of the casing are as follows: Equation of spiral, $R = r(1 + 0.318a)$; width of spiral, 0.64D; number of inlets, 1; diam. of inlet cone, 1.2D; area at cut-off, 0.64D^2; area of outlet, 0.785D^2.

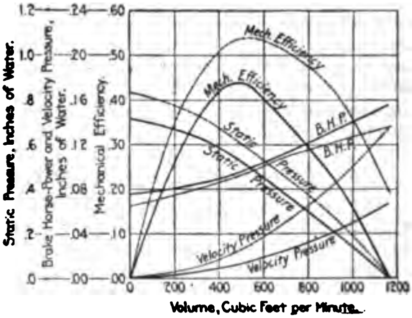

Fig. 23.—Characteristics of a Casingless Fan for Forced-draft Applications.

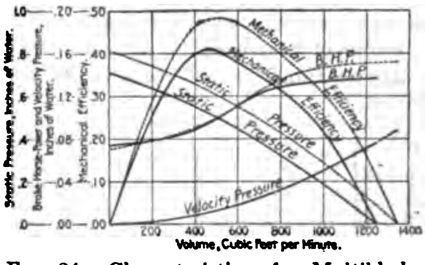

Fig. 24.—Characteristics of a Multiblade Casingless Fan for Forced-draft Work.

Fig. 24 covers a fan of practically the same design as Fig. 23, except that the wheel has 32 blades. The full-line curves show its performance when it is not fitted with a casing and discharges directly into a closed compartment. The greater number of blades gives it increased volumetric capacity and causes

the mechanical efficiency to hold up a little better on heavy load due to the increased blade area. The blade shape is the same as that in the fan of Fig. 23, as are also all the proportions. The broken-line curves show its performance when the wheel is fitted with a radial diffuser with its sides tapering toward each other, thereby reducing the circumferential area at the discharge of the diffuser below that it would have were its sides perpendicular to the axis of the fan. The volumetric capacity, pressure and mechanical efficiency are all materially increased due to the gain of head incident to the expansion of the air path from the blade ports to and through the diffuser. The principal proportions of the diffuser are as follows: Diam. of diffuser, $1.5D$; width at discharge, $0.24D$; area at discharge, $1.13D^2$.

CAPACITY TABLES

The accompanying tables give average performances of fans of the stated types, for a limited number of sizes and for given speeds. The performance at other pressures, speeds and diameters can be computed in the manner shown on p. 1545. The approximate height in col. 2 is the overall dimension for horizontal discharge. The abbreviation "c.f.m." is for cu. ft. per min.

Multiblade Fans

Makers and Trade Names. Am. Blower Co., Sirocco; Buffalo Forge Co., Conoidal; Keith & Blackman, Keith; N. Y. Blower Co., Seri-Vane; B. F. Sturtevant Co., Multivane.

Description. The wheels contain from 30 to 60 blades, generally of shallow radial depth and curved with concave surface forward in rotation. The inlet is exceptionally large compared to the wheel diam. A spiral casing encloses the wheel. (See Fig. 25.)

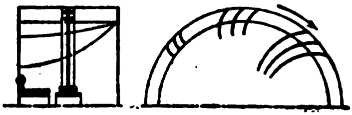

Fig. 25.—Multiblade Fan.

Range of Pressures. 0 to 5 in.

Applications. Forced draft, induced draft, heating, ventilating, cooling, drying, etc.

Steel-plate Planing-mill Fans (Slow-speed Type)

Makers. American Blower Co., Buffalo Forge Co., Green Fuel Econ. Co., Sterling Blower Co., B. F. Sturtevant Co., etc.

Description. Wheels have 12 to 18 paddle-type blades, curved forward. Casing is of spiral form, about the same as in common steel-plate fans. (See Fig. 28.)

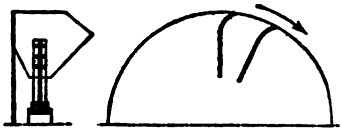

Fig. 28.—Steel-plate Planing-mill Fan.

Range of Pressures. 0 to 6 oz.

Applications. Conveying materials such as refuse from wood-working machinery, shoe machinery, buffing and emery wheels, etc.

Wheel diam., in.	Approx. height, in.	Static pressure, oz.

Steel-plate Paddle-wheel Fans

Makers. American Blower Co., Buffalo Forge Co., Garden City Fan Co., Green Fuel Econ. Co., N. Y. Blower Co., B. F. Sturtevant Co., etc.

Description. Wheels have 8 to 12 blades which are deep radially and connected to spider arms emanating from a central hub. Casings of spiral form. (See Fig. 26.)

Range of Pressures. 0 to 5 in.

Applications. Forced draft, induced draft, heating, ventilating, cooling, drying, etc.

Steel-plate Cone Fans

Makers. American Blower Co., Buffalo Forge Co., Green Fuel Econ. Co., N. Y. Blower Co., B. F. Sturtevant Co.

Description. These fans are of the paddle-wheel type, but built on a back or supporting cone instead of a spider having arms emanating from a central hub; 8 to 12 blades are employed and no casing is used. The fan discharges directly into the atmosphere or a large room, as the case may be. (See Fig. 29.)

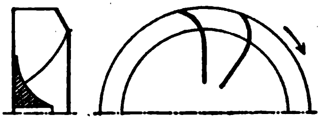

FIG. 29.—Steel-plate Cone Fan.

Range of Pressures. 0 to 1½ in.

Applications. Heating, ventilating, cooling, drying, etc.

MAGNETIC AND ELECTRICAL UNITS

Systems of Units. Two systems of electrical units exist, the electrostatic and the electromagnetic. The electrostatic system is based upon the force exerted between two unit charges of electricity at points 1 cm. apart in a medium of unit dielectric constant. The electromagnetic system is based upon the force exerted between two unit magnetic poles placed at points 1 cm. apart in a medium of unit magnetic permeability. The **practical units** are based upon the electromagnetic system.

Unit Magnetic Pole is one which will repel an equal and like pole with a force of one dyne at a distance of 1 cm. (A dyne is the force which, acting upon a mass of 1 gram during 1 sec., gives the mass a velocity of 1 cm. per sec.)

Magnetic Potential is measured by the work involved in moving a unit magnet pole from the boundary of the field to the point at which the potential is desired.

Unit Magnetic Field is that which acts upon a unit magnet pole with a force of one dyne. Unit field has one line of force per sq. cm., and the magnetic flux density in this case is one **gauss**. Magnetic flux density ($\mathcal{B}$) is expressed in lines of force Φ (**maxwells**) per sq. cm. Frequently, magnetic flux density is expressed in lines of force per sq. in.

Magnetizing Force ($\mathcal{H}$). Unit magnetizing force will establish in air one line of force per cm. cube; it is also the magnetic potential gradient or the change of magnetic potential per cm. length in air when the magnetic flux density is one maxwell per sq. cm.

Magnetomotive Force ($\mathcal{F}$). Magnetomotive force (m.m.f.) is the line integral of the magnetizing force, that is, the total magnetizing force integrated over the length of the complete magnetic circuit. The unit is the **gilbert**.

Magnetic Permeability (μ) expresses the ratio of the magnetic flux density to the magnetizing force. $\mathcal{B}/\mathcal{H} = \mu$. It is the specific magnetic conductance. The permeability of air is unity.

Reluctivity (ν) or specific magnetic reluctance expresses the magnetic reluctance of a cm. cube of the magnetic medium. Unit reluctivity is that through which unit magnetizing force will establish unit flux density. Reluctivity is the reciprocal of permeability.

Magnetic Reluctance ($\mathcal{R}$) expresses the total resistance to the passage of magnetic flux. In a homogeneous medium of constant cross-section, the reluctance is the reluctivity multiplied by the length and divided by the cross-section of the medium. The unit of reluctance is the **oersted.**

Ampere (I,i). The practical unit of current flow is the ampere, which is equal to one-tenth the absolute unit of current, and is the current that will flow through a conductor having a resistance of 1 ohm and a difference of potential of 1 volt between its ends. The absolute unit of current is that which flowing in a conductor perpendicular to the lines of force in unit field causes to be exerted upon each centimeter of the conductor a (unit) force of one dyne. One ampere (direct current) will deposit 0.001118 gram of silver per second from a silver solution.

Ampere-turn. Magnetic effects of current are proportional to the product of amperes flowing and the turns or convolutions of the electric circuit. The ampere-turn, coupled with the proper constant, is used as a unit of magnetomotive force.

Coulomb. The unit of quantity is the coulomb, and is that quantity which passes a cross-section of the conductor in 1 sec. when the rate of flow is 1 ampere.

Volt. The practical unit of electromotive force (e.m.f.) is the volt. An electrical conductor cutting lines of force at the rate of one per second has induced in it one absolute unit of e.m.f. The volt is 10^8 times the absolute unit.

Ohm. The practical unit of resistance is the ohm, and is that resistance through which the fall of potential is 1 volt when the current strength is 1 ampere. The ohm equals 10^9 absolute units of resistance.

Conductance. Conductance is the reciprocal of resistance and is expressed in reciprocal ohms or mhos ("mho" is ohm spelled backward).

Farad. The unit of electrical capacity is the farad, and is that capacity whose potential will be raised 1 volt by the addition of a charge of one coulomb. As the farad is too large a unit for practical purposes the microfarad, which is one-millionth of a farad, is generally used. The absolute unit of capacity is 10^9 farads.

Dielectric Constant. Air has a dielectric constant of unity. The dielectric constant is the ratio of the conductivity of a dielectric for electrostatic lines of force to that of air. Therefore, it is the ratio of the electrostatic capacity of a given condenser having a certain dielectric to the capacity of the same condenser with air as the dielectric.

Self-inductance. The practical unit of self-inductance is the **henry.** The henry is also called the **coefficient of self-induction.** An electric circuit possesses 1 henry when a rate of change of 1 amp. per sec. will induce a counter-pressure of 1 volt. It also follows that in such a circuit 1 ampere will set up 10^8 linkages of magnetic lines (product of turns and flux) in the circuit, since a change of 10^8 linkages per sec. is required to induce 1 volt. One henry is equal to 10^9 absolute units of self-inductance.

Mutual Inductance. Mutual inductance relates to the e.m.f. induced in an electric circuit by the mutual magnetic flux produced by current in a separate electrical circuit. The unit of mutual inductance is also the henry. When a change of current of 1 ampere per sec. in either of two separate circuits sets up an e.m.f. of 1 volt in the other circuit, their mutual inductance is 1 henry. Also, 1 ampere in one circuit induces 10^8 magnetic linkages in the other circuit when their mutual inductance is 1 henry. If M

denotes the mutual inductance of a pair of circuits and if there is no magnetic leakage, that is, when all the lines set up link both circuits, then $M^2 = L_1 L_2$, where L_1 and L_2 are the coefficients of self-induction of the two circuits, respectively.

Watt. The practical unit of power is the watt. One watt is produced when 1 ampere flows under an e.m.f. of 1 volt. One watt equals 10^7 ergs per sec. One kilowatt equals 1000 watts.

1 watt = 0.00134 h.p. = 44.25 ft-lb. per min. = 14.33 gram-calories per min. = 0.737 ft-lb. per sec., = 0.057 B.t.u. per min.

Watts = volts × amperes × cosine of angle of phase difference for an alternating current.

Table 1. Magnetic and Electrical Units

ELECTRICAL UNITS

Symbol	Quantity	Equation*	Practical unit	Value of practical units in electro-magnetic units
I, i	Current	$I = E/Z,\ I = Q/T$	Ampere	10^{-1}
	Current density	I/A	Amp. per sq. in.	1.55

			Ampere-hour	360
R, r	Resistance	$R = P/I^2 = E/I$	Ohm	10^9
E, e	Electromotive force	$E = W/Q = d\Phi/dT$	Volt	10^8
ρ	Resistivity†	$\rho = RA/L$	Ohms per circular mil-foot	166.4
			Ohms per centimeter cube	10^9
			Ohms per sq. mm. per meter	10^5
C	Capacity	$C = Q/E$	Farad	10^{-9}
			Microfarad	10^{-15}
G, g	Conductance	$G = R/Z^2$	Mho	10^{-9}
B, b	Susceptance	$B = X/Z^2$	Mho	10^{-9}
Y, y	Admittance	$Y = \sqrt{G^2 + B^2} = 1/Z$	Mho	10^{-9}
λ	Conductivity	$\lambda = 1/\rho$	Mhos per unit volume.	....
	Time constant	L/R	Second	1
			Henry per ohm	1
T	Period or cycle	$T = 1/f$	Second	1
f	Frequency	$f = 1/T$	Cycles per second	1
ω	Angular velocity	$\omega = 2\pi f$	....	....
L	Coefficient of self-induction	$L = n\Phi/I$	Henry	10^9
X_L	Inductive reactance	$X_L = 2\pi fL$	Ohm	10^9
X_C	Condensive reactance	$X_C = 1/2\pi fC$	Ohm	10^9
X, x	Reactance	$X = X_L - X_C$	Ohm	10^9
Z, z	Impedance	$Z = \sqrt{R^2 + X^2}$	Ohm	10^9
P	Electric power	$P = EI = I^2R = EI \cos \phi$ (a.c.)	Watt	10^7
			Kilowatt	10^{10}
W	Electric energy	$W = PT$	Joule	10^7
			Watt-hour	36×10^9
			Kilowatt-hour	36×10^{12}
	Power factor	$\dfrac{EI \cos \phi}{EI} = \dfrac{\text{real } P}{\text{apparent } P}$		
	Reactive factor	$\dfrac{EI \sin \phi}{EI} = \dfrac{\text{reactive } P}{\text{apparent } P}$		

MAGNETIC UNITS

Symbol	Quantity	Equation*	Practical unit
m	Pole strength	$\mathfrak{F}/\mathfrak{R}$	
$\mathfrak{M}$	Magnetic moment	$\mathfrak{M} = mL$	
$\mathfrak{H}$	Field intensity	$\mathfrak{H} = \mathfrak{F}/m$	Gauss
$\mathfrak{I}$	Intensity of magnetization flux	$\mathfrak{I} = \mathfrak{M}/V$	
Φ	Flux	$\Phi = \mu\mathfrak{H}A$	Maxwell
$\mathfrak{B}$	Flux density	$\mathfrak{B} = \Phi/A$	Gauss
$\mathfrak{H}$	Magnetizing force	$\mathfrak{H} = 4\pi nI/10L$	
$\mathfrak{F}$	Magnetomotive force	$\mathfrak{F} = 4\pi nI/10$	Gilbert
ν	Reluctivity	$\nu = 1/\mu$	
$\mathfrak{R}$	Reluctance	$\mathfrak{R} = \nu L/A = \mathfrak{F}/\Phi$	Oersted
μ	Permeability	$\mu = \mathfrak{B}/\mathfrak{H}$	
$\mathfrak{P}$	Permeance	$\mathfrak{P} = 1/\mathfrak{R}$	
κ	Susceptibility	$\kappa = \mathfrak{I}/\mathfrak{H}$	
W	Magnetic energy	$W = \Phi\mathfrak{F}$	Erg
	Magnetic potential	$= W/m$	
P	Magnetic power	$P = \Phi\mathfrak{F}f$	

* L = length; V = volume; A = sectional area; n = number of turns; T = time; f = frequency.

† See also p. 1586 for the practical units.

Volt-amperes or apparent power = volts × amperes.

Watt-hour. Watt-hours and kilowatt-hours are the units of energy used in commercial electrical work.

1 watt-hour = 3600 joules = 2655.4 ft-lb. = 859.975 gram-calories = 3.412 B.t.u. = 0.001341 h.p-hr.

Joule. The practical unit of electrical energy is the joule. One watt-second is a joule. One joule is produced when a steady current of one coulomb per sec., *i.e.*, 1 ampere, passes through a resistance of 1 ohm for 1 sec. One joule is equivalent to 0.2388 gram-calorie, and also equals 10^7 ergs. (An **erg** is a dyne-centimeter.)

ELECTRIC AND MAGNETIC CIRCUITS

Electric Circuits

Ohm's Law states that the current in a circuit at any instant is $I = E/R$, where I is the current in amperes, E the e.m.f. impressed upon the circuit in volts, and R its resistance in ohms. The law as stated above is equally applicable to direct- and alternating-current circuits, but in the latter case effective values of e.m.f. and current are almost always used, and the above simple relation must in general be modified as explained later.

The following are the most important relations between the electrical units:

$$I = E/R; \quad Q = It; \quad C = Q/E; \quad W = \tfrac{1}{2}QE; \quad W = \tfrac{1}{2}LI^2; \quad P = IE$$

The following relations may be derived from the above by simple algebraic transformations:

$$Q = \frac{E}{R}t; \qquad C = \frac{I}{E}t; \qquad W = IEt = \frac{E^2}{R}t = I^2Rt = Pt$$

$$E = IR; \qquad R = \frac{E}{I}; \qquad P = \frac{E^2}{R} = I^2R = \frac{W}{t} = \frac{QE}{2t} = \frac{LI^2}{2t}$$

where Q is in coulombs (ampere-seconds), P in volt-amperes, W in joules (volt-coulombs), C in farads, and L in henrys.

Kirchhoff's Laws (derived from Ohm's Law) are of special value when dealing with networks of conductors. The first law states that at any point in a circuit the sum of the currents directed toward the point is equal to the sum of the currents directed away from the point. The second law states that in any closed circuit the algebraic sum of the e.m.f.'s and IR drops is equal to zero. By setting up suitable algebraic equations in accordance with these principles, otherwise complicated network problems can be solved without difficulty.

Series Circuits. The combined resistance of a number of series-connected resistances is the sum of the separate resistances. When batteries or other sources of direct e.m.f. are connected in series the total e.m.f. of the combination is the sum of the separate e.m.f.'s. The open-circuit e.m.f. of a battery is the total generated e.m.f., and may be measured at the battery terminals only when no current is being furnished by the battery. The internal resistance is the resistance possessed by the battery alone. The current which will flow in a circuit connected in series with a source of e.m.f. is $I = E/(R + r)$, where E is the open-circuit e.m.f., R the external resistance, and r the internal resistance of the source of e.m.f. Ohm's Law is similarly applicable to the magnetic circuit, as explained under Magnetic Circuit.

Parallel Circuits. The combined conductivity of a number of parallel-connected resistances is the sum of the separate conductivities.

$$\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ . \ . \ .$$

The equivalent resistance for three parallel resistances, R_1, R_2, R_3, is

$$R = \frac{R_1R_2R_3}{R_1R_2 + R_2R_3 + R_3R_1}$$

and for four parallel resistances, R_1, R_2, R_3, R_4,

$$R = \frac{R_1R_2R_3R_4}{R_1R_2R_3 + R_2R_3R_4 + R_3R_4R_1 + R_4R_1R_2}$$

To obtain the resistance of combined series and parallel resistances, the equivalent resistance of each parallel portion is obtained separately and then these equivalent resistances are added to the series resistances according to the principles stated above.

Joule's Law. When an electric current passes through a resistance the number of heat units developed is proportional to the square of the current, directly proportional to the resistance, and directly proportional to the time that the current flows. $p = 0.2389i^2rt$, where p represents the number of gram-calories, i the current in amperes, r the resistance in ohms and t the time in seconds. p (in B.t.u. per sec.) $= 0.000948i^2rt$.

Magnetism

The Magnetic Circuit. In dealing with electromagnetism, a conception of the magnetic circuit quite analogous to that of an electric circuit is generally used. Ohm's Law of the magnetic circuit is stated thus:

$$\text{flux} = \frac{\text{m.m.f.}}{\text{reluctance}}, \text{ or, in symbols, } \Phi \text{ (maxwells)} = \frac{\mathfrak{F} \text{ (gilberts)}}{\mathfrak{R} \text{ (oersteds)}}$$

The m.m.f. acting in any magnetic circuit is always $4\pi nI_a$, where n is the number of turns in the circuit and I_a the current in absolute units. Permeability expresses the ability of a medium to conduct magnetic flux. Unit magnetic permeability is the permeability of a cm. cube of air. Reluctivity or specific reluctance is the reciprocal of permeability and expresses the opposition to the passage of magnetic flux through a medium, and is the reluctance possessed by a cm. cube of air. As in electric circuits, the total reluctance is proportional to the length and inversely proportional to the cross-sectional area of the magnetic circuit. Reluctances in series are added to obtain their combined reluctance. Ohm's Law of the magnetic circuit becomes: flux $= \dfrac{0.4\pi nI}{(1/\mu)l/A + (1/\mu')l'/A' + (1/\mu'')l''/A'' + \ldots}$, where I is expressed in amperes, μ, μ', μ'' are the magnetic permeabilities and hence $1/\mu$, $1/\mu'$ and $1/\mu''$ are the reluctivities or specific magnetic reluctances, l, l', l'', etc., are the lengths and A, A', A'', etc., the cross-sectional areas of the various portions of the magnetic circuit, expressed in centimeter measure.

Magnetization and Permeability Curves. The magnetic permeability of air is a constant and is taken as unity. The permeability of iron and other magnetic substances is not constant but varies with the flux density. No satisfactory equation has been found to express the relation between magnetizing force and flux density, so it is usual to plot curves showing the variation of permeability with magnetic flux density (or permeability curves; see Fig. 1). It is more usual to express the magnetic properties by a magnetization curve, which shows the magnetic flux density and magnetizing force; see Fig. 2. The data must be experimentally determined for the iron it is proposed to use in constructing a magnetic circuit. The magnetization curve shows that in order to drive any value $\mathfrak{B}$ (flux density in lines of force per sq. cm.) through the iron whose magnetization curve is given, the corresponding value of $\mathfrak{H}$ must be applied for each cm. of length through which the flux is driven.

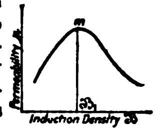

FIG. 1.—Permeability Curve.

The total magnetizing force, that is, the magnetomotive force, of a coil is $0.4\pi nI$, where I is given in amperes, so that $0.4\pi nI/l$ is the force per unit length of circuit to which the force $0.4\pi nI$ is applied. Or, one ampere-turn produces 1.257 gilberts of m.m.f. It is more convenient to express the magnetizing forces of the magnetization curves directly in ampere-turns per cm. of length, and it is usual in engineering work to plot the magnetization curves in terms of lines of force (lines of magnetic induction) per sq. in. and ampere-turns per inch of magnetic circuit length. To convert from one scale to another, use the relation $\mathfrak{H} = 0.4\pi nI/l$, where n is the number of turns, I the current in amperes, and l is in cm. One unit of magnetizing force or 0.796 ampere-turn is required to drive one line of force per sq. cm. through a length of 1 cm. of air, and 0.313 ampere-turn to drive one line per sq. in. through a length of 1 in. Since the permeability of air is constant, its magnetization curve is a straight line of constant slope. To determine the number of ampere-turns necessary to set up a given total flux in a magnetic circuit composed of various cross-sections and permeabilities, determine the flux density if the cross-section is fixed, or otherwise choose a cross-section to give a suitable flux density, and from the magnetization curve obtain the ampere-turns necessary to drive this flux density through unit length of the portion of the circuit considered and multiply by the length. Add together the ampere-turns required for each portion

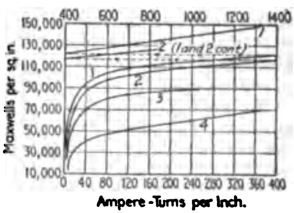

FIG. 2.—Magnetization Curves.

of the magnetic circuit to obtain the total ampere-turns necessary. Magnetisation curves of a number of commercial samples are given in Fig. 2.

Flux = $\Phi = \mathfrak{F}/\mathfrak{R}$; $\mathfrak{R}$ = 1/permeance; permeance = $\mu a/l$, in which μ = permeability, a = cross-section of path of lines of force, sq. cm., and l = length of path, cm. Hence $\Phi = \mathfrak{F}\mu a/l$. As one ampere-turn ($nI$) produces 1.257 gilberts of m.m.f., Φ in inch measure = $3.192\mu anI/l$; or, the ampere-turns necessary to produce a given flux Φ in a given circuit of dimensions a, l, will be $nI = \Phi l/3.192\mu a = 0.3133\Phi l/\mu a$. Also, since $\Phi/a = \mathfrak{B}$, the ampere-turns required to produce a density $\mathfrak{B}$ in lines of force per sq. in. of path section = $nI = 0.3133\mathfrak{B}l/\mu$.

Magnetic Leakage. It is impossible to completely confine magnetic lines of force to any desired path for the reason that there is no known non-conductor of lines of force. In the case of the magnetic circuit shown in Fig. 3, some lines of force will leak back across the air space separating the limbs of the magnet. The ratio of the maximum number of lines to the useful lines is called the **leakage coefficient.** This coefficient can never be as low as unity, and in modern dynamos ranges from 1.2 to 2.0. Accurate predetermination of magnetic leakage, except in the case of the simplest geometrical configurations, is a matter of great difficulty.

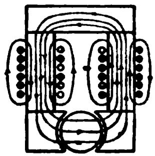

FIG. 3.

Magnetic Hysteresis. The magnetization curves shown in Fig. 2 are average curves. A different set of values of $\mathfrak{B}$ will result for each value of the magnetizing force when the magnetizing force is increasing from that when it is decreasing. A complete magnetization curve is shown in Fig. 4. It can be shown that the energy stored in the magnetic field is $\int \mathfrak{H}d\mathfrak{B}/4\pi$. In a magnetic field set up in air, all the energy stored in the form of magnetism is returned to the electric circuit when the magnetism disappears. When iron undergoes cyclic magnetization, as represented in Fig. 4, an amount of energy proportional to the area of the closed hysteresis loop, *GCDEFA*, appears as heat. The area of the hysteresis loop is dependent upon the final value of the flux density, and the hysteresis loss is represented by the Steinmetz Law: Loss in ergs per cu. cm. per cycle = $\eta\mathfrak{B}^{1.6}$, η being the hysteresis constant and $\mathfrak{B}$ the flux density. The loss in watts per cu. cm. is $W = \eta f\mathfrak{B}^{1.6} \times 10^{-7}$, f being the frequency, or number of complete cycles per sec. Steinmetz gives the following values for η:

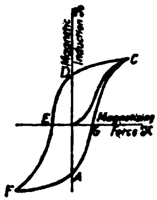

FIG. 4.—Hysteresis Loop.

Silicon steel	0.001	
Average sheet steel	0.002	
Wrought iron, sheet iron and sheet steel	0.0012–0.0055	(mean 0.003)
Cast iron	0.011 –0.016	(mean 0.013)
Soft cast steel	0.0032–0.012	(mean 0.060)
Hard cast steel . . . . up to	0.028	
Forged steel	0.015 –0.025	
Magnetic iron ore	0.020 –0.024	
Nickel	0.013 –0.039	
Cobalt	0.012	

A permanent increase in the hysteresis constant occurs if the temperature of operation remains for some time above 80 deg. cent. This phenomenon is known as **aging**, and may be much reduced by proper annealing of the iron. Silicon steels containing about 3 per cent. of silicon have a lower hysteresis loss, somewhat larger eddy-current loss, and are practically non-aging. **Eddy-**

current losses, also known as Foucault-current losses, occur in iron subjected to cyclic magnetisation. Eddy-current losses are minimised by laminating the iron, which subdivides the e.m.f. and increases greatly the length of path of the parasitic currents. Eddy currents have also a screening effect, that is, the full cross-section of a magnetic circuit cannot be utilised for an alternating flux unless it is laminated.

The watts loss in sheets per cu. cm. is: $P_e = (\pi t f \mathfrak{B}_{max})^2/6\rho 10^{16}$, where t = thickness in cm., f = frequency, cycles per sec., $\mathfrak{B}$ = flux density, lines per sq. cm., and ρ = specific resistance.

Directions of Lines of Force and of Induced E.M.F.'S. An electric current flowing in a conductor sets up lines of magnetic force in the directions indicated in Fig. 5*a*. The + sign indicates current flowing away from the observer and the negative sign current, toward the observer.

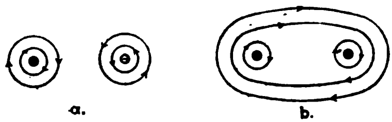

FIG. 5.

Lines of magnetic force are assumed to emanate from a north pole and to enter the magnet at a south pole. Current flowing in a conductor as shown in Fig. 6 will produce magnetic poles as there indicated.

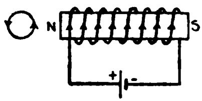

FIG. 6.

Currents flowing in the same direction in parallel conductors exert an attractive force between the conductors. The lines of magnetic force which combine and link both conductors appear to have the property of shortening themselves like rubber bands. See Fig. 5*b*. Currents flowing in opposite directions in parallel conductors exert a repulsive force between the conductors. The lines of force resist crowding, or an electric circuit always tends to change its geometrical shape so that its magnetic reluctance is a minimum.

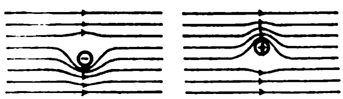

FIG. 7.

The following method may be used to determine the **direction of the e.m.f. induced when a conductor cuts a magnetic field.** If the property of elasticity be ascribed to lines of magnetic force, a conductor cutting them will distort them as shown in Fig. 7. From the direction of the lines of force surrounding the conductor the direction of the e.m.f. induced is determined at once from the relations stated above; that is, with the observer looking along the conductor, lines of force encircling the conductor in the direction of the hands of a clock mean that current is flowing away from the observer, and *vice versa*.

Alternating Currents

The fundamental equation of a circuit containing self-inductance L and resistance R upon which a direct e.m.f. E is impressed, is $E = Ri + Ldi/dt$, where i represents the current at any instant. By Kirchhoff's Law, the sum of all e.m.f.'s of a circuit must be zero, and the interpretation of the above equation is that part of the applied e.m.f. is consumed by resistance and the remainder by the counter e.m.f. of self-induction Ldi/dt. A solution of this differential equation is $i = (E/R)(1 - \epsilon^{\frac{-Rt}{L}})$, where ϵ is the base of the natural system of logarithms.

Time Constant. In the case of an inductive circuit, the time constant is the ratio L/R, where L is the coefficient of self-induction and R the resistance of the circuit. Theoretically, an infinite time is required for a current to reach its ultimate value, $I = E/R$, when a circuit containing self-inductance is connected to a source of direct e.m.f., but practically the ultimate value is reached after a very short time. The time constant expresses the time required in seconds for the current to attain 0.632 of its ultimate value, $I = E/R$. In a circuit containing self-inductance and resistance, the current rises according to the equation $i = (E/R)(1 - \epsilon^{\frac{-Rt}{L}})$. If a resistance r be introduced into the circuit at the time the generator is removed, the current will follow the equation $i = (E/R)\ \epsilon^{\frac{-(R+r)t}{L}}$ and the e.m.f. across the resistance r will be $e = ri = (Er/R)\ \epsilon^{\frac{-(R+r)t}{L}}$, and may be higher than E and will, of course, be very large when r is large as in the case of a spark coil and gap such as is used in gas-engine ignition.

If the equation $E = Ri + Ldi/dt$ is multiplied by idt and integrated between 0 and T, the energy dissipated $= \int_0^T Eidt = RI^2T + \frac{1}{2}LI^2$, where I is the value of i at time T. The term RI^2T represents the energy dissipated in the resistance and $\frac{1}{2}LI^2$ is the energy *stored* in the magnetic field. Likewise, when a voltage E is impressed upon a circuit containing resistance and capacity, at any instant,

$$E = iR + \frac{q}{C} = iR + \int \frac{idt}{C}$$

the solution of which is $i = \frac{E}{R}\ \epsilon^{-\frac{t}{CR}}$. $\frac{1}{CR}$ is the time constant of this circuit, and C must be expressed in farads. Also the energy $\int Eidt = I^2RT + \frac{1}{2}Q/E$. I^2RT is the energy dissipated in the resistance and $\frac{1}{2}Q/E$ is the energy stored in the electrostatic field.

Alternating Currents. In alternating-current theory, the current and e.m.f. are assumed to vary according to the sine law; thus, $i = I_m \sin x$, where i is the instantaneous value of current, I_m its maximum value, and x a variable angle. An **alternation** is a half cycle. A **cycle** or period is generated by the passage of an armature coil past two poles of the generator. Consequently, the **frequency** of a generator is expressed as the speed in revolutions per sec. multiplied by the number of *pairs* of poles. The standard frequencies now in use are 60 cycles for lighting and power and 25 cycles for power. Frequencies of 40 and 50 cycles are used in some localities and 12½ and 15 cycles are used abroad in railway work. One hundred and thirty-three cycles was extensively used some years ago, but is rarely used at the present time.

The Average Value of a Wave. The average value of a sine wave is $(2/\pi)I_m$, or 0.637 I_m, where I_m is the maximum value of the sine wave. The average value is of little practical importance. A direct-current measuring instrument gives the average values of a pulsating wave. The average value is of use only when the effects of the current are proportional to the number of coulombs passing, as in electrolytic work.

The Effective Value of a Wave (root mean square value, or virtual value) produces the same heating in a given resistance as a direct current of the same value. Since the heating effect of a current is proportional to ri^2, the effective value is obtained by squaring the ordinates, finding their average value, and extracting the square root, that is, the effective value

$$I = \sqrt{\frac{2}{t}\int_0^{t/2} i^2 dt}$$

where t is the time of a period. The effective value of a sine wave equals $(1/\sqrt{2})I_m = 0.707I_m$.

Form Factor. The form factor of a wave is the ratio $\frac{\text{effective value}}{\text{average value}}$. For a sine wave this is $\pi/(2\sqrt{2}) = 1.11$. A sine wave of e.m.f. applied to a circuit containing resistance and inductance only, is represented by $E_m \times \sin \omega t = Ri + \frac{Ldi}{dt}$. The solution of this equation is:

$$i = \frac{E_m \sin(\omega t - \phi)}{\sqrt{R^2 + \omega^2 L^2}} + \frac{E_m \sin(\phi \epsilon^{-\frac{Rt}{L}})}{\sqrt{R^2 + \omega^2 L^2}}, \text{ where } \phi = \tan^{-1}\frac{\omega L}{R}$$

The current wave is then made up of a pure sine wave and an exponential curve. This latter disappears a very short time after the closing of the switch.

Inductive Reactance, ωL or $2\pi fL$, opposes an alternating current in passing through an inductance L. It is expressed in ohms. Reactance is usually denoted by the symbol x.

A solution of the equation $E_m \sin \omega t = Ri + \int \frac{idt}{C}$ representing a sine wave of pressure applied to a circuit containing resistance and capacity only, is $i = \frac{E_m}{\sqrt{R^2 + 1/4\pi^2 f^2 C^2}} \sin(\omega t + \phi) + A\epsilon^{-\frac{t}{RC}}$, where $\phi = \tan^{-1}\frac{1}{C\omega R}$. The exponential portion disappears after a few cycles, leaving only a sine wave of current.

Capacity Reactance is $1/2\pi fC = 1/\omega C$. It is convenient to regard inductance as the analog of inertia in mechanics and capacity as the analog of elasticity.

Impedance is also expressed in ohms, and is the total opposition to the flow of an alternating current in a circuit possessing both resistance and reactance. Impedance $= Z = \sqrt{R^2 + \omega^2 L^2}$, for a circuit having resistance and inductance. Resistance and reactance may then be represented as the two legs of a right triangle, but cannot be combined algebraically. In a circuit containing resistance, inductance and capacity, the impedance

$$Z = \sqrt{R^2 + [2\pi fL - (1/2\pi fC)]^2}$$

Phase Difference. When an alternating e.m.f. is impressed upon resistance only, at each instant $i = e/R$. The current wave is therefore similar to the voltage wave and is in phase with it, for the two coincide in time position. When a sine e.m.f. wave is impressed upon a circuit containing inductance only, the current lags 90 deg. or a quarter period behind the pressure wave and they are said to be in quadrature. When a sine e.m.f. wave is impressed upon a condenser, and without resistance in the circuit, the current leads the impressed pressure by 90 deg. Thus inductance and capacity reactances have opposite effects and may be combined algebraically. When resistance is taken into account, as it generally must be, the current lags or leads by less than 90 deg. Symbolically, a lagging or leading current is expressed by $i = I_m \sin(\omega t \mp \phi)$, where ϕ is the angle of phase difference and is equal to $\tan^{-1}[(2\pi fL - 1/2\pi fC)/R]$. The negative sign represents a lag and the positive sign a lead, with reference to the impressed e.m.f.

Vector Representation. It is usually convenient to represent the magnitude and phase position of alternating e.m.f.'s and currents by vectors, which implies that the waves so represented follow the sine law. The vectors may be combined as forces are combined in mechanics. Both graphical methods and the methods of complex algebra are used. Impedances and also admittances may be similarly combined, either graphically or symbolically. In the latter case the usual method is to resolve the impedances, for example, into their component resistances and reactances, then combine all resistances and all reactances, from which the resultant impedance is obtained. Thus, $Z_1 + Z_2 = \sqrt{(r_1 + r_2)^2 + (x_1 + x_2)^2}$, where r_1 and x_1 are the components of Z_1.

Resonance occurs when the inductive reactance equals the capacity reactance, *i.e.*, $2\pi fL = 1/2\pi fC$. In this case the circuit acts as though it contained nothing but resistance. The voltage across the inductance and the voltage across the capacity are opposite and equal, and may be many times greater than the circuit voltage.

The frequency, $f = 1/2\pi\sqrt{LC}$, is the "natural frequency" of the circuit and is the frequency at which it will oscillate if the circuit is not acted upon by some external frequency. This is the principle of the radio sending and receiving circuits. Resonant conditions of this type should be avoided in power circuits, as the "piling up" of voltage may endanger apparatus and insulation.

Power Factor. In alternating-current circuits, the power P is equal to $EI \cos\phi$, where ϕ is the angle of phase difference between E and I. $\cos\phi$ is called the power factor. EI is called the **apparent power.** The ratio $EI\cos\phi/EI$, which is the ratio of true power to apparent power, is the power factor of the circuit. When the pressure and current are sine waves, $\cos\phi$ may be given a trigonometrical interpretation, *i.e.*, it is the angle of phase difference. In general, the power factor is the ratio $\dfrac{\text{true power}}{\text{apparent power}}$.

Active Current is the projection of the total current on the voltage vector and is equal to $I_e = I\cos\phi$. Power $= EI_e$.

Reactive Current $I_w = I \sin\phi$ and represents the component of the current which contributes no power, but increases the I^2R losses of the system. In power systems it should be made as low as possible or eliminated entirely.

Effective Resistance. When power losses in an alternating-current circuit are greater than that due to resistance alone, this additional power must be taken into account in vector diagrams or computations involving impedance and resistance. Power expended because of iron losses as well as resistance brings the current and pressure more nearly in phase with each other. Since $P = I^2R$, $R = P/I^2$ is the effective resistance, or it is that resistance which would cause a power expenditure P (which may include iron losses) with a current I flowing in the circuit. These iron losses vary approximately as $I^{1.8}$ or nearly as I^2, so little error is introduced in assuming the effective resistance constant over considerable current range.

Parallel Circuits

Admittance is the reciprocal of impedance and is usually denoted by Y. $Y = \sqrt{G^2 + B^2}$; $I = EY$.

Conductance is the horizontal component of admittance and is generally denoted by the symbol G. $g_1 = \frac{r_1}{r_1^2 + x_1^2}$. $G = g_1 + g_2 + g_3 \ldots\ldots$ The active current, $I_a = EG$. Conductance in this case is not the reciprocal of resistance.

Susceptance is the vertical component of admittance and is generally denoted by B. $b_1 = \frac{x_1}{r_1^2 + x_1^2}$. $B = b_1 + b_2 + b_3 \ldots\ldots$ The reactive current $I_w = EB$. Susceptance is not the reciprocal of reactance.

The following additional relations hold:

$$\text{Power} = E^2G \qquad \text{Power factor} = G/Y$$

$$r = \frac{g}{g^2 + b^2} = \frac{g}{Y^2} \qquad x = \frac{b}{g^2 + b^2} = \frac{b}{Y^2}$$

$$g = \frac{r}{r^2 + x^2} = \frac{r}{Z^2} \qquad b = \frac{x}{r^2 + x^2} = \frac{x}{Z^2}$$

Ohm's Law for alternating-current circuits is $I = E/Z = EY$.

Solution of Circuit Problems. Alternating-current circuit problems may be solved graphically or analytically. For numerical computations the principles of complex algebra greatly facilitate the work. In **series circuits** containing resistances, inductances and capacities the joint impedance is the vector sum of the separate impedances. The vector diagrams are laid out with the current horizontally to the right to serve as the reference vector because the current has the same phase in every part of the circuit. On the other hand, the voltages across the various parts of the circuit have different phase positions. Resistances, or the voltages across them, are laid off horizontally to the right since the voltage across a resistance is in phase with the current. Reactances or the voltages consumed by them are laid off vertically, inductive reactances upward and capacity reactances downward.

In dealing with **parallel circuits** it is more convenient to take as the initial vector the voltage impressed across all the parallel branches, since this pressure is common to all. The other vectors then represent currents in the separate branches and may be combined vectorially to obtain the joint current, or the vectors may represent conductances, susceptances and admittances. The following examples illustrate the methods used in solving series and parallel circuit problems. The same methods are used for combined series and parallel circuits, the series and parallel portions of the circuit being solved separately and then combined.

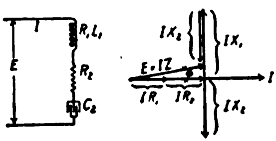

FIG. 8.

Examples. In the series circuit of Fig. 8, $E = 120$ volts, $R_1 = 3$ ohms, $R_2 = 4$ ohms, $L_1 = 0.02$ henry, and $C_2 = 400$ microfarads. Find the joint impedance, the current, power and power factor, if $f = 60$. Solution: $X_1 = 2\pi fL = 2\pi \times 60 \times 0.02 =$

7.54 ohms, $X_2 = 1/2\pi fC_2 = 1/(2\pi \times 60 \times 0.004) = 6.63$ ohms, and joint impedance $Z = \sqrt{(3+4)^2 + (7.54 - 6.63)^2} = 7.06$ ohms. The phase angle $\phi = \tan^{-1}\frac{7.54 - 6.63}{3+4} = 7° 24'$. The current $I = \frac{120}{7.06} = 17$ amperes. Power, $P = I^2R = EI \cos\phi = 2020$ watts. Power factor $= \cos\phi \frac{2020}{17 \times 120} = 99.1$ per cent.

In the parallel circuit of Fig. 9 it is desired to find the joint impedance, the total current, the power in each branch, the total power and the power factor, when $E = 100$,

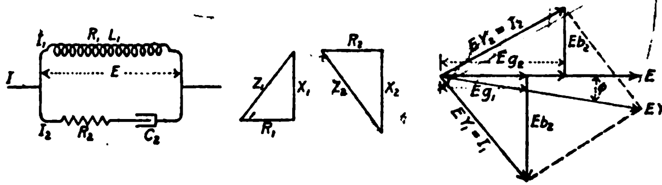

FIG. 9.

$f = 60$, $R_1 = 2$ ohms, $R_2 = 4$ ohms, $L_1 = 0.00795$ henry, $X_1 = 2\pi fL_1 = 3$ ohms, $C_2 = 1326$ microfarads, $X_c = 1/2\pi fC_2 = 2$ ohms, $Z_1 = \sqrt{2^2 + 3^2} = 3.6$ ohms, and $Y_1 = 1/3.6 = 0.278$ mhos. Solution: $g_1 = R_1/(R_1^2 + X_1^2) = 2/13 = 0.154$; $b_1 = 3/13 = 0.231$; $Z_2 = \sqrt{16+4} = 4.47$; $Y_2 = 1/4.47 = 0.224$; $g_2 = R_2/(R_2^2 + X_2^2) = 4/(16+4) = 0.2$; $b_2 = -2/20 = -0.1$; $G = g_1 + g_2 = 0.154 + 0.2 = 0.354$; $B = b_1 + b_2 = 0.231 - 0.1 = 0.131$; $Y = \sqrt{G^2 + B^2} = \sqrt{0.354^2 + 0.131^2} = 0.376$, and joint impedance $Z = 1/0.376 = 2.66$ ohms. Phase angle $\phi = \tan^{-1}\frac{0.131}{0.354} = 20° 18'$. $I = EY = 100 \times 0.376 = 37.6$ amp.; $P_1 = E^2g_1 = (100)^2 0.154 = 1540$ watts; $P_2 = E^2g_2 = (100)^2\, 0.2 = 2000$ watts; total power $= E^2G = (100)^2 0.354 = 3540$ watts. Power factor $= \cos\phi = \frac{3540}{100 \times 37.6} = 94$ per cent.

Circuits. Fig. 10 represents a two-phase generator and receiving apparatus. A two-phase generator has two independent windings *OA* and *OB* displaced 90 electrical degrees apart so that the e.m.f.'s generated are in quadrature. Two entirely independent single-phase circuits could be used to transmit the power to the receiving circuit, but it is simpler to use only three conductors, one conductor serving as a common return. If I_c be the coil current, $\sqrt{2}\, I_c$ will be the value of the current in the common conductor, *OO′*. If E_c be the e.m.f. across *OA* or *OB*, $\sqrt{2}\, E_c$ will be the voltage across *AB*. The power of a two-phase circuit is twice the power in either coil if the load is balanced. Normally, the voltages *OA* and *OB* are equal, and the current is the same in both coils. Due to non-symmetry and the high degree of unbalancing of this system even under balanced loads, it is not used at the present time for transmission and is little used for distribution.

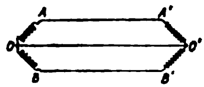

FIG. 10.—Two-phase Circuit.

Quarter-phase Circuit. A quarter-phase circuit is shown in Fig. 11. The windings *AC* and *BD* may be independent or connected at *O*. The e.m.f.'s *AC* and *BD* are 90 deg. apart as in two-phase circuits. If a neutral wire *OO′* be added, 3 different voltages may be obtained. Let

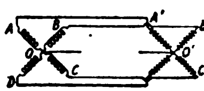

FIG. 11.—Quarter-phase Circuit.

E_1 = voltage $OA = OB = OC = OD$. Voltages $AB, BC, CD, DA = \sqrt{2}E_1$. Voltage $AC = BD = 2E_1$. Due to this multiplicity of voltages and the fact that polyphase power and lamps may be connected at the same time, this system is still used to some extent in distribution.

Three-phase Circuits. Alternating-current generators are usually wound with three armature circuits which generate e.m.f.'s 120 electrical degrees apart. The coils are joined either in Y (star) or in Δ (mesh) connection as shown in Fig. 12. Whether Y- or Δ-connected with a balanced load, the three coil e.m.f.'s and the three currents are equal. In the Y-connection the line and coil currents are equal, but the line e.m.f.'s AB, BC, CA equal $\sqrt{3}$ times the coil e.m.f.'s OA, OB, OC, for they are the vector sum of the coil e.m.f.'s. In the delta connection the line and coil e.m.f.'s are equal, but I, the line current, equals $\sqrt{3}\,I_c$, the coil current, that is, it is the vector sum of the currents in the two coils connected to the line. The power of a coil is $E_cI_c\cos\phi$, so that the total power is $3E_cI_c\cos\phi$. If ϕ is the angle between *coil* current and *coil* voltage, the angle between line current and line voltage will be $(30° \pm \phi)$. In terms of line current and e.m.f., the power is $\sqrt{3}\,EI\cos\phi$. A fourth or neutral conductor is sometimes used with the Y-connection. The neutral point O is frequently grounded in high-voltage transmission circuits. The coil e.m.f.'s are assumed to be sine waves, in which case they balance, so that in the delta connection, for example, the sum of the two coil e.m.f.'s at each instant is balanced by the third coil e.m.f. Even though the 3d, 9th, 15th. . . harmonics, $3(2n + 1)f$, where n = 0 or an integer, exist in the coil e.m.f.'s, they cannot appear on the external line of the three-phase circuit, except when the neutral conductor is used with the Y-connection. In the delta circuit, the same harmonics $3(2n + 1)f$ cause a local current to circulate around the mesh. This may cause a very appreciable heating in the apparatus.

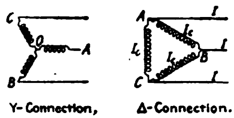

FIG. 12.—Three-phase Circuits.

Equivalent Single-phase Resistance. Three-phase power is expressed as $\sqrt{3}\,EI\cos\phi$, where E and I are the line pressure and current. $\sqrt{3}\,I$ may be called the total current. The equivalent single-phase resistance is that resistance which multiplied by the total current squared will equal the total copper loss of the circuit and is equal to one-half the measured resistance between any two lines of a delta- or Y-connected three-phase circuit. In a Y-connection the measured resistance between two lines is $2r$, where r is the resistance per coil or per phase winding. The equivalent single-phase resistance would be r. Expressed in terms of total current and equivalent resistance, the copper loss would be $(\sqrt{3}\,I)^2 r = 3I_c^2r$, where I_c is the coil current and in this case equal to I. The loss per coil is I_c^2r and for three coils $3I_c^2r$. The measured resistance between two lines of a delta-connected circuit is $1/[(1/r) + (1/2r)] = 2r/3$. The equivalent single-phase resistance is one-half this or $r/3$. The copper loss is then $(\sqrt{3}\,I)^2r/3 = I^2r$. But $I = \sqrt{3}\,I_c$, so the copper loss calculated by this method is again $3I_c^2r$. The practical utility of this method is that in many instances it permits the calculation of three-phase circuits by the methods already applicable to single-phase circuits and without the necessity of knowing whether the connections are delta or Y.

A simple method when calculations of balanced three-phase systems are made is to work with only one conductor to the neutral of the system, assuming that the neutral has zero resistance. In this case ⅓ the power is transmitted over one conductor, the actual line current is used, but the voltage to

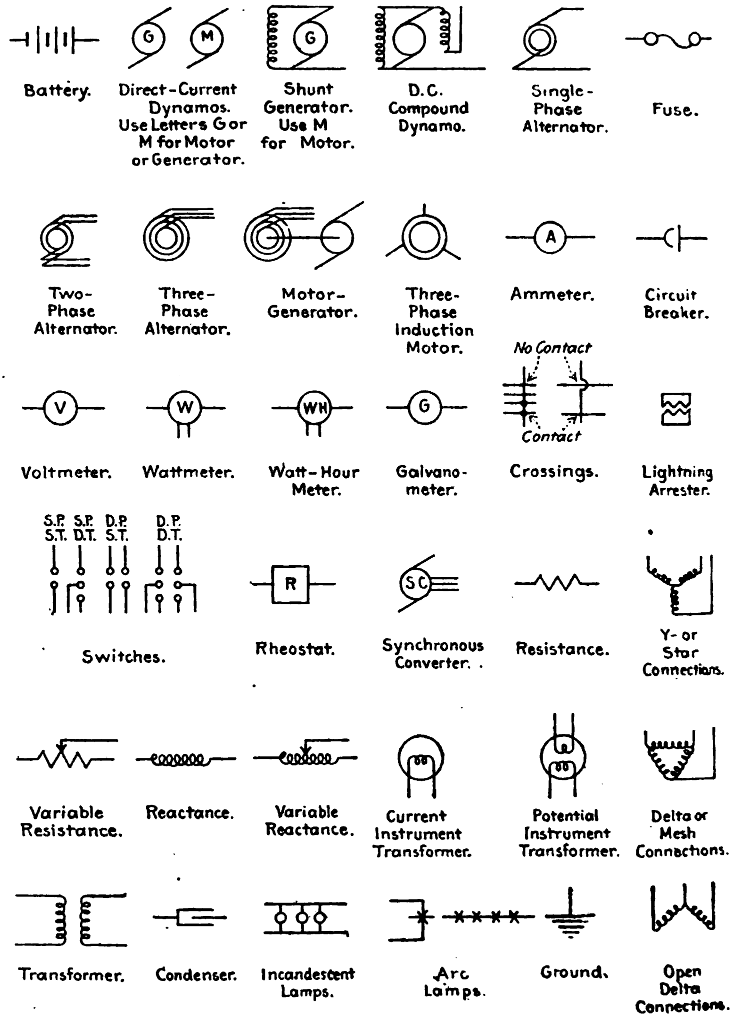

FIG. 13.—Diagrammatic Symbols for Electrical Machinery and Apparatus.

neutral is the voltage between lines divided by $\sqrt{3}$. Calculations of regulation and efficiency under these conditions are also true for the system.

Diagrammatic Symbols for Electrical Machinery and Apparatus have not been standardized to any great extent, but those given in Fig. 13 (taken from various sources) cover general practice. In the designation of switches, *S*, *D*, *P* and *T* are abbreviations of single, double, pole, and throw, respectively; thus, *S.P.D.T.* indicates that the apparatus is a single-pole, double-throw switch.

ELECTRICAL INSTRUMENTS AND MEASUREMENTS

See Circular 20 of the U. S. Bureau of Standards, for a thorough discussion of the various kinds of electrical instruments, their construction, uses and errors.

Direct-current Instruments. For the commercial measurement of direct current and voltage, the permanent-magnet, moving-coil instrument is the standard type. It consists of a light coil free to turn in the field of a fixed permanent magnet. The magnet is usually provided with soft iron pole pieces so shaped as to give a uniform radial field in which the coil moves. The motion of the coil is opposed by a counter force, usually that of two flat spiral springs which also serve to carry the current to and from the coil. The deflection given is proportional to the current flowing, and the instrument is always, in reality, an ammeter, whether used as such or as a voltmeter. When used as a voltmeter the coil is composed of many turns of fine wire, and a resistance coil of comparatively high resistance is connected in series with it. If small currents are to be measured, they may be passed directly through the moving coil; when the current to be measured exceeds that corresponding to full scale deflection, usually a few hundredths of an ampere, it becomes necessary to divert a definite portion of it through a circuit of low resistance connected in parallel with the coil. By this means it is possible to measure heavy currents of any desired magnitude, the heavy current being passed through a suitable low resistance, called a "shunt," from two points on which small leads run to the instrument.

Direct-current and Alternating-current Instruments. Instruments for use on both direct and alternating currents may be divided into four types, namely, electrodynamometer, electromagnetic, hot-wire, and electrostatic. Instruments of the **electrodynamometer** type (probably the most valuable) depend upon the force exerted by one circuit traversed by a current upon another, or by a portion of a given circuit upon another portion of the same circuit. They usually contain one or more fixed coils which set up a magnetic field directly proportional to the strength of the current flowing through them. Within this field is arranged a moving coil or system of coils through which current may be passed. If the two sets of coils are connected in series, the torque exerted upon the moving system, for a given relative position of the coil systems, is proportional to the square of the current strength, and is not dependent upon the direction of the current. Such an instrument constitutes an **ammeter** which is equally correct on direct current and on alternating or pulsating current of any frequency or wave form. Its value is very largely due to the fact that such an instrument calibrated with direct current is accurate with alternating, so may be used as a transfer standard. The electrodynamometer instrument, calibrated on direct current, may be used as a precision instrument for alternating current. The **electrodynamometer voltmeter** has fixed and moving coils of moderately fine wire, connected in series with each other and in series with a non-inductive resistance of low temperature coefficient. This latter resistance (for usual commercial voltages) brings the time-constant (ratio of inductance to resistance) down to a small value, and hence well-made voltmeters of this type, calibrated on direct current, show practically negligible errors on commercial alternating-current circuits. If the fixed coils are made of thick wire and are connected in series with a load, while the moving coils of fine wire are connected (with a series resistance as in a voltmeter) across the line supplying the load, the resulting instrument (a **wattmeter**) will measure the power expended upon the load, and affords a very convenient method of measuring the power taken by alternating-current lamps, motors, etc., and in testing alternating-current watthour meters. With these wattmeters, as usually constructed, it is necessary to take the mean of two readings, when using direct current, in order to eliminate the effect of the earth's field. By modifying the arrangement of the circuits, the wattmeter may be arranged to measure the power factor, or phase angle between current and voltage.

The difficulty of leading heavy currents to a moving coil has led to the development of the **electromagnetic instruments.** Instruments of this type depend upon the action of a coil traversed by a current upon one or more pieces of soft iron. These instruments are also designated as "moving iron," "soft-iron" and "iron vane" type.

The error in the voltmeter due to its inductance is not large over the commercial range of frequencies, and may be computed, for unusual frequencies, from the measured values of resistance and inductance. Ammeters and voltmeters of this type are well suited for commercial measurements on alternating-current circuits, and for direct current when only approximate results (within 2 or 3 per cent.) are required. When intended for use on alternating-current circuits they should be calibrated with alternating current, using suitable transfer instruments which may be checked with direct-current standards. They cannot be checked accurately on direct currents.

Instruments of the **hot-wire type** depend upon the expansion of a wire which is heated by the passage of a current. The more modern instruments have a working wire 6 or 8 in. in length. In the voltmeter this wire is quite fine and a series resistance is provided. In the hot-wire ammeter the working wire is larger, and is connected with several sections in parallel to reduce the required drop in the shunt. Hot-wire instruments except in wireless telegraphy are but little used in this country in practical work.

Instruments of the **electrostatic type** depend upon the attraction of oppositely charged bodies and the repulsion of similarly charged ones. As these forces are relatively small, such instruments cannot well be made as ammeters, and in fact it is difficult to construct satisfactory voltmeters on this principle for the ordinary 110-volt range. The great advantage of this type of voltmeter is that it takes no current when used on direct-current circuits, and an extremely small current when used on alternating-current circuits. Like the hot-wire instrument, it is not affected by frequency changes, wave form, or stray magnetic field. Frictional errors, however, are hard to avoid. For very high voltages the electrostatic voltmeter has some marked advantages over other types, if the use of potential transformers is not considered.

Alternating-current Instruments. Instruments operating only on alternating current depend upon the interaction of inducing and induced currents, and are usually described as induction instruments. The usual form contains a laminated iron core surrounded by one or more coils of wire; an alternating magnetic flux is set up in the air gap of this core when current flows through the coils. Provision is made for securing the effect of a rotating field, either by having more than one group of coils, the currents in them differing in phase, or one coil may be used, with fixed copper plates or bands, in which induced currents are set up; the resultant action of the flux due to the coil and that due to the induced currents in the fixed copper pieces gives the effect of a rotating field. In this field is pivoted a light disk or drum, usually of aluminum, which tends to rotate with the rotating field. If an indicating instrument is desired, the motion of the disk is opposed by a spring or other suitable counter force; an integrating meter is provided with drag magnets and a dial or register to read the total quantity that has passed through the meter. Such a meter tends to vary greatly in its readings with change of frequency. The induction watthour meter is a reliable commercial instrument, having the great advantages of absence of a commutator and brushes, and a very light moving element. Portable induction indicating instruments have a nearly closed magnetic circuit and fairly strong working fields; they are thus sensitive to external stray field. The scales are long, it being possible to make them cover 300 deg. or even more. Such instruments may be used for commercial testing on definite frequencies, after calibration under conditions as nearly as possible like those under which they are used; they should be checked by comparison with proper standards, for important work. They are not suitable for general service in the laboratory.

Watt-hour Meters record the energy of a circuit during some given time interval. The direct-current type consists of two fixed coils in series with one or both lines, and an armature connected across the line through a comparatively high resistance. In the armature circuit is a "starting coil" which compensates for the meter friction. An aluminum or copper disk on the shaft rotates between the poles of permanent magnets, so a retarding torque, proportional to the speed, is produced.

Alternating-current meters are usually of the induction type. The torque is produced by the inductive action of series and shunt coils acting on a disk or a cylinder. The friction is compensated by a small "shading coil" actuated by a lever. A low power-factor adjustment is made by changing the resistance of a small coil wound around the core of the potential coil. Retarding magnets act on the disk as in the direct-current meter. The general formula for the meters is,

$$W \times t = K \times N \times 3600$$

where W = watts; t = sec.; K = meter constant (usually marked on the disk); N = revolutions of the disk. The meters are usually calibrated by measuring the average watts supplied to a load during an interval, with indicating voltmeter and ammeter, or a wattmeter, and counting the disk revolutions with a stop watch. This value of power is then compared with that obtained from the formula. To speed the meter up at high loads, move the magnets nearer the shaft, and to slow down the meter move magnets nearer the disk periphery. Make the light-load adjustment by means of starting coil in direct current or by means of lever in alternating current.

Accessory Apparatus, Including Instrument Transformers. The series resistance of a voltmeter for one or more ranges is usually a part of the instrument. When higher voltages than the maximum thus provided for are to be measured, external series resistance boxes, called multipliers, are used to extend the range. These are used with alternating voltmeters for voltages below 600 volts. For voltages in excess of 600 a small transformer is ordinarily used. Its primary coil is wound for the line voltage to be measured, and the secondary voltage (usually 100 to 110 for normal working line voltage on the primary) is applied to the voltmeter. Such potential transformers are usually wound for some convenient integral value of the ratio of primary applied voltage to secondary terminal voltage. This arrangement has the great advantage of insulating the voltmeter from the high voltage of the line—a very important point in connection with safety to the operator, with voltages of 1000 or greater.

Alternating-current ammeters in excess of 100 amperes as a rule are not accurate, and further are not adapted to operate with shunts. Current transformers may therefore be used, which allow the use of a low-scale ammeter and insulate the instruments from the line voltage. The secondaries usually have a 5-ampere rating. Care should be taken not to connect more instruments than the transformer is designed to operate, especially when one of the instruments is a wattmeter or a watthour meter. For a given transformer the general performance will be better the smaller the load of instruments it is required to operate. As both ratio and phase-angle errors affect the reading of a wattmeter, care should be taken that the series transformer used with the wattmeter is of proper design and capacity and that it is not overloaded with instruments. The secondary circuit of a series transformer should never be opened while current is passing through the primary, not only on account of the rise of voltage at the secondary terminals, which may become dangerously high, but also because the flux in the iron rises to abnormal values. The resulting high flux density in the iron will cause excessive core loss and the temperature of the transformer may become so high as to cause deterioration of the insulation.

Power-factor Measurement. The usual method of determining power factor is by the use of voltmeter, ammeter, and wattmeter. The wattmeter gives the true watts of the circuit, and the product of the voltmeter reading and the ammeter reading gives the apparent power. From the ratio of the two, the power factor is directly determined.

Measurement of Resistance. A common method of measuring resistance, known as the fall of potential method, makes use of an ammeter and a voltmeter. In Fig. 14, the resistance to be measured is indicated by R. A current I is passed through the resistance and ammeter in series and the fall of potential across the resistance is measured by the voltmeter E. The amount of current shunted by the voltmeter is so small that it may generally be neglected. A correction may be applied if necessary, for the resistance of the voltmeter is generally given with the instrument. The potential difference divided by the current gives the resistance included between the voltmeter leads. As a check, determinations are generally made with several values of current, which may be varied by means of the controlling re-

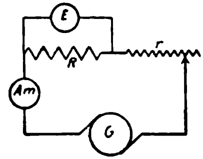

Fig. 14.

sistance r. If the resistance to be measured is the armature of a direct-current machine and the voltmeter leads are placed upon the brush holders, the resistance determined will include that of the brush contacts. To measure the resistance of the armature alone, the voltmeter leads should be placed directly upon the commutator segments under the brushes.

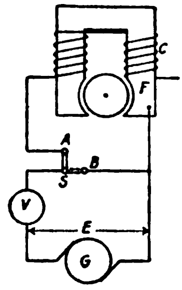

FIG. 15.

Insulation Resistance. A convenient method of measuring insulation resistance by means of a voltmeter is as follows: In Fig. 15 the insulation resistance to be measured is that from the conductor of the field winding C to the frame of the machine F. To measure the current flowing when a pressure E is impressed across the resistance R, a high-reading voltmeter V is connected in series with R. The current which flows under this condition with the switch connecting S and A, is $E/(R + r)$, where r is the resistance of the voltmeter. A high-reading voltmeter is necessary since its resistance is higher than that of a low-reading instrument, and as the method is in reality a comparison of the unknown insulation resistance with the known resistance of the voltmeter, the latter must be comparable to the former, else the deflection of the instrument will be so small that the results will be inaccurate. To determine the impressed pressure, the same voltmeter is used. The switch S connects S and B for this purpose. With these two readings, the unknown resistance is $R = r(E - e)/e$, where E is the impressed pressure and e is the deflection of the voltmeter when closed through the resistance to be measured at contact A. If a special voltmeter, having a resistance of 100,000 ohms per 150 volts, is available, a resistance of the order of 2 to 3 megohms may be measured very accurately.

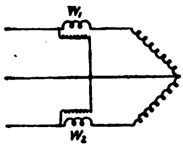

FIG. 16.

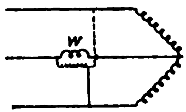

FIG. 17.

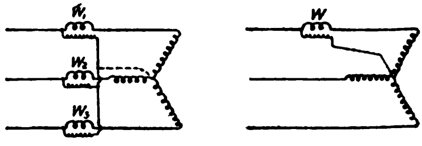
Measurement of Power of Polyphase Circuits. The power of polyphase alternating circuits may be measured by means of one meter, but these methods require special conditions. In a three-wire two-phase circuit, two wattmeters connected as shown in Fig. 16 will give the true power of the circuit whether it is balanced or not, since each of the wattmeters is in a practically independent circuit. If but one wattmeter is available, the power may be measured in one circuit and the result multiplied by 2 if the two circuits are balanced. If not balanced, the wattmeter may be successively connected to the positions of W_1 and W_2, and the sum of the readings taken. In two-phase circuits with a common return, as shown in Figs. 16 and 17, the current coil of a single wattmeter may be placed in the common return and if the pressure coil be connected successively from the common return to each of the outside conductors, the sum of the two readings will be the power of the circuit if it is in balance.

Three-phase power may be measured by means of three wattmeters, one in circuit with each coil so as to measure the power of that coil as in Fig. 18*a*. Unless the common connection of the three potential coils is connected to the neutral of the system O, the resistance of each of the three potential circuits should be equal. Under a balanced load the three wattmeters read the same regardless of power factor. This system is adapted to a three-phase system having a fourth or neutral wire. If the load is balanced, one watt-meter may be used as in Fig. 18*b* and its reading multiplied by 3. The common method for the measurement of three-phase power is the "two-wattmeter method." This method is convenient and is independent of the condition of balance of the load. The con-



(a.) (b.)

FIG. 18.

nections for this method are indicated in Fig. 19. The watt-meters may be placed in any two of the leads and the pressure coils simply connected from the leads in which the current coils are connected to the lead which contains no wattmeter current coil. The sum of the two wattmeter readings is the power of the circuit, regardless of the power factor or the condition of balance of the load. With the load balanced and the power factor 100 per cent., the two wattmeter readings will be equal. In general, however, the two readings will not be equal. With a power factor of less than 50 per cent., one of the wattmeters will be reversed, and in this case it is necessary to reverse the pressure or current coil of the instrument and obtain the true power by taking the difference of the readings. The power factor of a balanced system may be determined directly from the wattmeter readings. $\frac{W_1}{W_2} = \frac{\cos(30^\circ - \phi)}{\cos(30^\circ + \phi)}$ and also $\tan \phi = \sqrt{3}\frac{W_1 - W_2}{W_1 + W_2}$, where ϕ is the coil phase angle. The two-wattmeter method cannot be used when current is flowing in a fourth or neutral wire. The total power of a balanced load may also be measured by one wattmeter. The current coil is connected in one line, Fig. 19, one end of the potential coil to the same line, and the other end of the potential coil touched to each of the other two wires. The sum of these readings gives the total power.

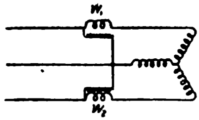


FIG. 19.

Tests for Dielectric Strength may be made either with a voltmeter or with a **spark gap** to measure the voltage. In the latter case, the spark gap is adjusted so that it will break down with a certain predetermined voltage and is connected in parallel with the insulation under test. For values of voltage between 10 kilovolts and 50 kilovolts a **needle spark gap** should be used, consisting of new sewing needles supported axially at the ends of linear conductors which are at least twice the length of the gap. There must be a clear space around the gap for a radius of at least twice the gap length. Needle gap root-mean-square (R. M. S.) sparking voltages at 25 deg. cent. and 760 mm. barometer with No. 00 sewing needles are given below.

R. M. S. kilovolts....................	10.0	15.0	20.0	25	30	35	40	45	50
Millimeters..........................	11.9	18.4	25.4	33	41	51	62	75	90

For the measurement of voltages in excess of 50 kilovolts, a gap between metal spheres should be used. **Sphere-gap** voltages are given below.

Sphere-gap Spark-over Voltages

80	62.0	49.0	100	56	55	160	92	90	240	133	130
90	....	60.5	120	79.7	71	180	109	106	260	148	144
			140	108	88	200	128	123	280	163	158
			160	150	110	220	150	141	300	177	171
			180	....	138	240	177	160	320	194	187
						260	210	180	340	214	204
						280	250	203	360	234	221
						300	....	231	380	255	239
						320	....	265	400	276	257.

The sphere gap is more sensitive than the needle gap to momentary rises of voltage, and the voltage required to spark over the gap should be obtained by slowly closing the gap under constant voltage or by slowly raising the voltage with a fixed setting of the gap. (For detailed specifications for the manipulation of spark gaps, see "Standardisation Rules of the American Institute of Electrical Engineers.")

CONDUCTORS, RESISTANCES, RHEOSTATS

Materials. The materials used for the transmission and distribution of energy are restricted to copper, aluminum, iron and steel. For resistors and heaters, carbon and commercial alloys are most used.

Resistance Units. The **resistivity** or the **specific resistance** of a conductor material is the resistance in ohms of a sample of the material of unit length and unit section. Thus, if l represents the length of the conductor, a its sectional area, r its resistance, and ρ its specific resistance, then $r = \rho l/a$ and $\rho = ra/l$. For purposes of comparison, l and a are usually taken in centimeters and square centimeters, respectively, and ρ thus expresses the resistance in ohms between opposite faces of a centimeter cube. Table 2 gives values of specific resistance for various materials. Since most conductors are drawn wires of circular section, it is customary in engineering work to express the resistivity of a material in **ohms per (circular) mil-foot,** where the mil-foot represents a cylinder of the material 1 mil or 0.001 in. in diam. and 1 ft. in length. A mil-foot of copper has a resistance of 10.4 ohms at 20 deg. cent. The circular mils of a circular conductor may be found by squaring its diameter in mils. Thus, a cylindrical conductor 1 in. in diam. has a section of 1,000,000 cir. mils, and each foot of length has a resistance of 1/1,000,000 of that of 1 mil-foot of the material. In telegraph and telephone work, a still different unit of resistivity is in use—the **weight per mile-ohm.** This is the weight of a conductor of the material 1 mile in length which has a resistance of 1 ohm. It is equal to the prod-

uct of the weight per mile by the resistance per mile. If the weight per mile-ohm is 2000, the resistance of a wire weighing 20 lb. per mile is 100, or, for a wire weighing 200 lb. per mile, is 10 ohms per mile. The relations between the various constants are shown by the following equations:

Microhms per cm. cube	= 0.1662	× ohms per mil-foot.
Ohms per mil-foot	= 6.015	× microhms per cm. cube.
Pounds per mile-ohm	= 57.07	× microhms per cm. cube × sp. g.

Matthiessen's Standard of conductivity is the conductivity of a copper wire having the following characteristics at 0 deg. cent., and is taken as the standard at 100 per cent.:

Specific gravity....	8.89	Resistance...........	0.141729 ohm
Length...........	1 meter	Specific resistance.....	1.594 microhms/cm.^{3}
Weight...........	1 gram	Relative conductivity.	100 per cent.

Since the time of adoption of Matthiessen's Standard, advances in the refinement of copper have been made so that to-day it is possible to obtain copper of 102 per cent. conductivity. It is customary in specifications, in order to insure high conductivity, to specify a conductivity of at least 98 per cent. according to Matthiessen's Standard for annealed copper wire, and 97 per cent. for hardened copper.

Temperature Coefficient. For practically all conductors the resistivity is not constant but varies with the temperature. The general equation which shows this variation is $\rho_t = \rho_0(1 + \alpha t + \beta t^2)$, where ρ_t is the resistivity at t deg. cent., ρ_0 that at 0 deg. cent., t is the final temperature, deg. cent., and α and β are temperature coefficients. For practical work this equation may be taken as $\rho_t = \rho_0(1 + \alpha t)$. The average value of α for copper between 0 and 100 deg. may be taken as 0.0042. Table 2 gives α for various metals for temperature rises above 20 deg. cent. For all pure metals the temperature coefficient is very nearly the same and may be taken as 0.004 per deg. cent. or 0.0023 per deg. fahr. For alloys in general the temperature coefficient is less than the mean of the coefficients of the constituent metals. Electrolytes and carbon have negative coefficients.

Wire Gages. For a comparison of the various gages, see p. 498. The American or **Brown and Sharpe (B. & S.) Gage** is the standard for copper wire used for electrical purposes. The diameters in this system form a geometric series (in which No. 0000 has a diam. of 460 mils and No. 36 a diam. of 5 mils) and follow the law $d = 324.9/(1.123)^n$, where n is the gage number and d the diam. in mils. (It should be observed that in this equation No. 0000 = −3, No. 000 = −2, No. 00 = −1, and No. 0 = 0.) Since the sectional area varies as the square of the diameter, an increase of 3 in the gage number means a doubling of resistance with the sectional area and weight reduced by one-half. Also, an increase of 10 in gage number increases the resistance tenfold and reduces the section and weight to one-tenth. Also No. 10 has a diameter of 0.1 in. and a resistance of 1 ohm per 1000 ft. The **Roebling or Washburn and Moen Gage** is used almost entirely in this country for iron and steel wire. Except for iron wire, the **Birmingham or Stubs Gage** is used in America for wires made for other than electrical purposes.

Stranding. In sizes larger than No. 0000 (B. & S.) and in many cases for sizes larger than No. 6, copper conductors are usually made stranded rather than solid, to facilitate handling and splicing. Wires may be laid up in a **rope** or in a **concentric strand.** A 7 × 7 rope is one made up of seven strands of seven wires each. To obtain a smooth and symmetrical cable, certain combinations of wires must be used which are laid over a center wire in layers wound spirally in opposite directions, giving what is known as a concentric strand. Starting with one conductor in the center, 6 can be laid around it, 12 around this layer, then 18, 24, etc., making total strands of 1, 7, 19, 37, 61, etc.

Magnet Wire is a soft copper wire of high conductivity insulated in a manner suitable for winding in as small a space as possible in coils and on spools and bobbins. Magnet wire may be obtained in square, rectangular and circular section, but the round or cylindrical wire is used most extensively. **Cotton covering** finds its greatest use on wires of large and medium size, and **silk covering** is used upon the smallest of wires because of the smaller space it requires. Both cotton and silk insulation char at about 260 deg. fahr. and so are unsuitable for high-temperature operation. **Enameled magnet wire** is used where it is necessary to have the thinnest insulation possible and still retain high insulation resistance. Because of the liability of abrasion, enamel insulation is used mostly on the smaller wires, and great care must be taken in winding. Enamel insulation will withstand a temperature of 400 deg. fahr. for long periods of time without deterioration. A simple test of the adhesion of enamel to wire may be made by drawing the wire between the nails of the thumb and forefinger—it should not be possible to remove the enamel in this manner. **Deltabeston wire** or magnet wire provided with an asbestos covering is used on magnets and spools operating at high temperature. Wire insulated in this manner may be operated at near a red heat without injuring the insulation. **Salamander wire** is very similar to Deltabeston in its properties and has approximately the same diameters as single-cotton-covered magnet wire.

Aluminum is next to copper in the order of importance as an electrical conductor. It has a conductivity of about 62 per cent. of that of hard-drawn copper, but weighs about 50 per cent. as much for the same conductivity. Its elastic limit in tension varies from 16,000 to 20,000 lb. per sq. in., and its average ultimate strength is about 25,000 lb. per sq. in. Thus for the same conductivity as copper, an aluminum conductor would have a section approximately 60 per cent. greater, and with this section the ultimate strength would be 64 per cent. of that of the copper conductor while the weight would be about 50 per cent. as great. For this reason aluminum is much used for conductors for high-tension transmission lines where moderate spans are necessary.

Telegraph and Telephone Wire. Aside from the hard-drawn copper wire which is now being used for telegraph and telephone lines (see p. 523 for specifications), there are three grades of galvanised steel wire in use. "Steel" has the highest tensile strength and the lowest conductivity and is used in telephone service for short lines where a light, strong wire is preferable to a heavier wire of greater conductivity; weight per mile-ohm, 6500 lb. "Best Best" (BB) has a somewhat lower tensile strength but higher conductivity and is used by telephone companies; weight per mile-ohm, 5700 lb. "Extra Best Best" (EBB) has the highest conductivity (see Table 7) and is used largely by telegraph and railway companies; weight per mile-ohm, 5000 lb.

Cables

Underground and Submarine Cables are often used for transmission and distribution purposes, where city ordinances or appearance require that the wires be installed underground, or where power must be transmitted across a bay or river and overhead construction is impossible. Power cables of pressures up to 60,000 volts are now in successful operation.

Three types of insulation are now in common use: rubber compounds, varnished cambric, and impregnated paper.

(a) Rubber compounds consist of pure Para rubber and such mineral ingredients as sulphur, whiting, talc and litharge, which are thoroughly mixed together; the compounds are forced upon the conductors and then vulcanised.

(*b*) Cambric insulation consists of cotton cloth and a viscous filler. Each surface of the cloth is covered with multiple films of insulating varnish. The cloth is then applied to the conductor in the form of tape wound on spirally, the filler being applied between the successive layers.

(*c*) Impregnated paper insulation consists of Manila paper tapes applied spirally and evenly to the conductor, and then thoroughly impregnated with an insulating compound.

Cable Insulation. In underground practice it has been found necessary to protect the insulation by a lead sheath. For submarine installations, cambric and paper-insulated cables usually have lead sheaths armored with steel for protection, although, when rubber is used, the lead sheath is unnecessary. Varnished cambric will resist water to a certain extent, but paper is worthless as an insulator if moisture is allowed to enter the cable.

Sometimes two or more of the insulations are used in the same cable to good advantage. For alternating-current transmission it is advisable to have all the conductors of the circuit in one cable, as the currents neutralize the tendency to set up eddy currents in the sheath. In all high-tension cables, the sheaths should be well grounded to allow the high-voltage static charges to pass readily to earth. When high-voltage conductors pass from the air into the cable, or from the cable into air, a large pot-head should be used; this should have no sharp inside edges, and should be filled with some insulating substance. Use of the pot-head reduces to a minimum the high potential gradient that would otherwise occur at this point.

A cable system differs from an overhead system, in that the linear inductance is usually negligible and the electrostatic capacity much greater. Hence the charging current may be nearly equal to the load current itself. Surges and transient phenomena are much more common than on an overhead line of the same length.

Underground cables for high-tension work are ordinarily installed in standard ducts. Although all underground cables should be lead-covered, the rubber covering may last for years after the lead sheath has been eaten away by electrolysis or has been injured mechanically. The lead sheath may become heavily charged by electrostatic induction and consequently should be grounded at intervals.

Steel-taped cable is a lead-covered cable mechanically protected with steel tapes

and jute and may be buried directly in the ground. It is offered as a safe and reliable substitute for the more expensive conduit system.

Resistance Materials

For furnace resistors, a material having high resistivity and which does not disintegrate or corrode at high temperatures is best. For electrical instrument construction a material of medium-high resistivity together with low temperature coefficient and low thermoelectric power against copper is most valuable. For rheostats and other power-consuming devices, an inexpensive and non-corrosive material of high resistivity and which is suited to stand repeated heating and cooling serves the purpose best. Most of the materials listed in Table 8 may be obtained in ribbon form up to 1 in. in width.

Advance (a copper-nickel alloy) has a low temperature coefficient and is suited for electrical instrument work. **Therlo** (an alloy of copper, aluminum, and manganese) may be used for instrument shunts and coils, since aside from its low temperature coefficient, its thermoelectric power against copper is very low—0.3 microvolt per deg. cent. **Manganin** (copper, nickel, ferro-manganese alloy) is much used for standard resistance coils and units because of its low thermoelectric power with copper—1.5 microvolts per deg. cent.—and low temperature coefficient— − 0.00001 to + 0.000039 ohm per deg. cent. Manganin can be made to have permanent electrical properties by annealing for at least 5 hr. at a temperature of 140 deg. cent., but should not be subsequently heated without immersion in oil. **Nichrome** and Nichrome II are used for electric-furnace and high-temperature work, especially in ribbon form, having high operating temperatures. **Climax** (nickel-steel alloy) is often used for load rheostats and other similar resistors where first cost is the controlling factor in the choice of material. Like all steel alloys, it should be kept dry to prevent corrosion. **Ferronickel** (nickel-steel

alloy) is inexpensive and is much used for rheostats and coils. It corrodes rather readily. **Monel metal** (copper-nickel alloy) is medium priced and varies somewhat in electrical properties. **Superior** (nickel-steel alloy) is much used for rheostat coils. **Ia Ia** (copper-nickel alloy) has low temperature coefficient and permanent electrical properties and is suited for use in instruments. **Constantan** (50 per cent. nickel, 50 per cent. copper) has a low temperature coefficient but its high thermoelectric effect against copper (40 microvolts per deg. cent.) prohibits its use in electrical instruments. **German silver** (alloy of copper, nickel, and zinc) is used extensively, but its properties are not permanent, as it undergoes a change in resistance due to the crystallization of the zinc. It has a high thermoelectric force against copper—20 to 30 microvolts per deg. cent. It is made of various compositions, but alloys of 18 per cent. and 30 per cent. nickel respectively are most common. **Krupp's resistance wire** (nickel-steel) is not suited for use in damp places and should preferably be operated in oil. It should not be insulated with asbestos.

Carbon withstands high temperatures and has a high resistance, while its temperature coefficient is negative; it will safely carry about 125 amperes per sq. in. Amorphous carbon has a resistivity of from 3800 to 4100 microhms per cu. cm., retort carbon about 720 microhms, and graphite about 812 microhms per cu. cm. The properties of any particular kind of carbon depend upon the temperature at which it was fired. Carbon for rheostats may best be used in the form of compression rheostats.

Rheostats

Carbon Compression Rheostats made up of columns of graphite disks are much used for heavy currents and for fine regulation. The resistance variation is obtained by varying the contact resistance between disks by adjusting the pressure on the column. Graphite carbon disks rather than "flint" or coke carbons should be used, as a wider range of resistance may be obtained. The heat-radiating surface may be increased by inserting plates of sheet iron between the carbon disks. Black sheet iron is better than brass or bright tin, since the contact between carbon and iron does not change due to the change of surface condition of the metal at high temperatures. Carbon plates are also used as the resistors of electric furnaces of the resistance type, and carbon electrodes are used for furnaces of the arc type. Table 9 gives data from tests by Prof. A. L. Goddard upon a rheostat composed of a column of 275 Columbia Graphite disks 1 in. square piled alternately with black sheet-iron disks of larger area.

Table 9. Resistance Variation with Temperature and Pressure in a Carbon Compression Rheostat (Goddard)

Water Rheostats. In the testing of electrical machinery where large amounts of power are to be dissipated, some type of a water rheostat is often used as a load because of its comparatively low first cost. A rheostat of this kind consists essentially either of resistance material placed in water for cooling purposes or a set of electrodes immersed in water, the water acting as the conductor. For the dissipation of large amounts of energy at low voltage **coils of wire** or other metallic conductor may be submerged in barrels of water. Enough cold water should be allowed to circulate through the barrels to keep the temperature below 200 deg. fahr. In Table 10 are given the constants for iron wire for use in rheostats of this type. For continuous operation for long periods, especially on direct current, water-cooled coils of this kind are not suitable, since the coils become slimed over due to the heating of the water and must ordinarily be changed or cleaned at intervals of about 1 hr. In order to prevent excessive deposition of lime and magnesia upon the wire, the water should be well circulated. The arrangement shown in Fig. 20 may be used.

* Based on the use of BB galvanized iron wire (or annealed iron in the smaller sizes) having a resistance of 75 ohms per mil-foot, at 68 deg. fahr., a temperature coefficient of 0.00289 per deg. fahr. from 68 deg., and an allowable expenditure of 125 watts per sq. in. of wire surface. The turns of wire should be spaced at least ½ in. c. to c. The minimum length of wire is proportional to the voltage; *e.g.*, for 500 volts the minimum length is 5 times that for 100 volts.

In the **concentric cylinder type** of rheostat, where water is employed as the conductor, use is made of concentric metal cylinders with water flowing between them. (See Fig. 21.) Adjustment is obtained by raising and lowering the inner electrode, the outer cylinder being fixed. Table 11 gives electrode dimensions for the values of specific resistance of water of 500, 1000, and 2000 ohms per in. cube. The cylinders considered are **standard wrought-iron pipes.** Water should be allowed to flow fast enough to prevent boiling, as boiling causes unsteadiness and fluctuations of the current. For operation at 110 volts, it is not economical to build a rheostat of this type of greater than 10 kw. capacity because of the relatively high cost of construction.

When large amounts of power are to be dissipated (up to 5000 kw. and over) plates placed in a tank or lowered into a stream or pond may be used. For voltages below 1000, the conductivity of the water is increased by the addition of a small amount of **common salt** or **sulphuric acid.** Table 12 gives the relations between solution density and resistance for salt and for sulphuric acid. When acid is used the plates should be made of lead, while iron plates are satisfactory for salt-water tanks. The capacity of a rheostat of this type for a given rise in temperature is determined by the volume of solution and not by the radiating area. Table 13 gives the permissible watts per cu. in. of solution for various temperature rises. In general, 400 to 800 cu. in. should be used per h.p. absorbed continuously. The **current density** should not exceed 1 ampere per sq. in. of electrode surface, as above this value there is wasting away of the electrode material and unsteadiness of the current due to the formation of steam. When water rheostats are used on high-voltage circuits and the tanks are not grounded, the

(From chart in Dix-Whittaker's Handbook)

Temp. rise, deg. cent.	10	20	30	40	50	60	70
Watts per cu. in. of solution	0.26	0.60	0.90	1.40	2.10	3.00	4.75

circulating water must be conducted to and from the tanks by means of **rubber hose.** For voltages up to 2500, a hose 15 or 20 ft. in length is sufficient if the diam. is not greater than 1 in., while for higher voltages the hose must be correspondingly longer.

Wire Rheostats. For light and medium current values, resistances and rheostats made of metallic wire or ribbon are more satisfactory than water rheostats. An inexpensive load or starting rheostat for heavy currents may be made up of **poultry netting** (Dix-Whittaker's Handbook, p. 166) supported on iron rods mounted on insulators. Standard galvanised poultry netting of 1-in. mesh and 12 in. wide made up of No. 20 B.W.G. wires has a resistance of about 0.005 ohm per yd. and will carry 100 amperes when properly ventilated.

Enclosed Resistances must be more liberally designed than open-coil resistances because of the smaller radiating surface. In general, the size of the enclosing box should be so proportioned as to allow from 0.5 to 1.0 sq. in. of radiating surface per watt of energy to be dissipated. With good through draft of air, the air temperature should not rise to higher than 200 deg. fahr. under these conditions. For permanent service, a substantial form of rheostat is found in the **enameled type,** which is much used in the shunt-field circuits of generators. Here the wire or ribbon is embedded in enamel which is fused or baked on to one side of a ribbed cast-iron plate. Assuming one side of the plate only to be radiating energy, the allowable expenditure may rise to 5 watts per sq. in. of surface.

INSULATION

Insulation is applied to conductors for the purpose of preventing leakage of current therefrom. Various **insulating materials** are **described** on pp. 626–629 and their properties stated. The prime requisite of an insulating substance is that it shall be able to resist puncture when submitted to the maximum e.m.f. under working conditions. Breakdown potentials given in the tables following are effective values. The maximum instantaneous value of the voltage, however, is the measure of the dielectric strength, and, assuming a sine wave of voltage, the maximum instantaneous value is $\sqrt{2}$ times the values given.

Insulation Resistance is the resistance (measured in ohms or megohms) offered by an insulating coating, cover, material or support to an impressed voltage which tends to produce a leakage of current through it. High temperature and absorbed moisture (generally) lower the ohmic resistance; moisture deposited on the outside surface increases surface leakage.

Dielectric Strength. The dielectric strength of an insulating wall, coating, cover or path is its ability to resist the passage of a disruptive discharge through it, and is measured by the voltage which must be applied in order to effect such disruptive discharge. High temperature lowers the dielectric strength, and many materials break down at comparatively low temperatures. Alternating electric stresses often cause dangerously high rises in temperature.

MAGNETS

A Permanent Magnet is one which retains a constant amount of magnetism indefinitely. Magnets of this kind are used in electrical instruments, magnetos, etc., where a constant magnetic field is desired. They usually consist of hardened steel bars which, after having been placed in a strong magnetic field, retain a portion of the induced magnetism. The best permanent magnet is the one having the greatest hardness together with the greatest amount of free iron. The greater the hardness, the greater is the retentivity, which means permanency. For carbon steels, the greatest retentivity is obtained with 0.97 per cent. carbon. One of the best **permanent magnet steels** contains about 0.6 per cent. carbon and 5 per cent. tungsten and shows the greatest retentivity when quenched at a temperature of from 930 to 950 deg. cent. Another satisfactory steel contains 1 per cent. silicon and 5 per cent. chromium. (Mars, *Stahl u. Eisen*, Oct. 27, Nov. 10, 1909; Burgess and Aston, *El. Wld.*, Dec., 1910.) Unless permanent magnets are subjected to an **artificial aging** process, they gradually deteriorate or weaken. In the case of magnets for use in electrical instruments, where a constant field strength is imperative, artificial aging is accomplished by mechanical vibration or by immersion in boiling water for a period of a few hours.

An Electromagnet is one in which the magnetic field is produced by the flow of an electric current. The core of an electromagnet is usually made of soft iron or mild steel, because, the permeability being higher, a stronger pull may be obtained. When the circuit is opened there is little trouble due to the sticking of the parts of the magnetic circuit. Electromagnets may have the form of **simple solenoids, ironclad solenoids, plunger electromagnets,** and **electromagnets with external armatures.**

Magnetomotive Force and Flux in a Coil. The magnetic potential of a point is expressed numerically by the number of ergs required to bring a unit positive pole from the boundary of the field to the point in question. The magnetic potential of the plane of a loop of any shape carrying a current I_a may be deduced as follows: If a magnetic pole of strength m is moved from infinity to the plane of the loop, the number of lines of force which cut the loop during this process is $2\pi m$, since 4π lines emanate from unit pole. The e.m.f. induced in a circuit is $e = d\Phi/dt$, where Φ is the flux. The energy involved in moving it is $w = I_a\int edt$, but $\int edt = \Phi$, which in this case is $2\pi m$. Hence $w = 2\pi mI_a$, or when the current is expressed in amperes, $w = 0.2\pi mI$. The magnetic potential is numerically equal to w.

The m.m.f. linking an electrical circuit is $0.4\pi nI$. The **magnetizing force,** *i.e.*, potential gradient, is $0.4\pi nI/l$, where l is the length of path taken by the magnetic flux and n is the number of turns in the coil. In the case of a solenoid, the length l is taken to be the length of the solenoid, for it is assumed that all of the magnetomotive force is consumed within the length of the coil since the path outside has an infinite cross-section and hence no reluctance. The magnetizing force of a solenoid is thus $H = 0.4\pi nI$, and with an air core the flux density is numerically the same as H.

Direct-current Tractive Magnets. The **range** of an electromagnet is the distance through which the plunger will perform work when the winding is energized. The range for a solenoid is independent of the number of ampere-turns. After the core is saturated, the pull varies directly with the number of ampere-turns. For long range of operation, the **plunger type** of tractive magnet is best suited, since the length of core is governed practically by the range of action desired, while the **area of the core is determined**

by the amount of pull necessary. The curve in Fig. 22 shows that the maximum pull occurs when the end of the core is in the middle of the winding. The equation for **maximum uniform pull** is

$$P(\text{lb.}) = KAIN/l$$

where A is the area of the core, in sq. in., I the current in amperes, N the number of turns of wire, l the length of the winding in in., and K a constant which represents the pull per sq. in. of core per ampere-turn per in. and which depends upon the coil proportions, degree of saturation, chemical purity of iron, and length and physical properties of the core. Values of K are given in Table 17.

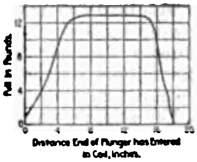

FIG. 22.—Pull of Plunger Magnet.

Table 17. Maximum Pull per Square Inch of Core for Solenoids with Open Magnetic Circuit

(From data by Underhill, *El. Wld.*, vol. 45, pp. 796, 881, 1906)

Length of coil, in., l	Length of plunger, in.	Core area, sq. in., A	Total ampere-turns, $I \times N$	Max. pull, lb. per sq. in., P	$1000 \times K$	Length of coil, in., l	Length of plunger, in.	Core area, sq. in., A	Total ampere-turns, $I \times N$	Max. pull, lb. per sq. in., P	$1000 \times K$
6	Long	1.0	15,000	22.4	9.0	12	Long	1.0	11,200	8.75	9.4
9	Long	1.0	11,330	11.5	9.1	12	Long	1.0	20,500	16.75	9.8
9	Long	1.0	14,200	14.6	9.2	18	36	1.0	18,200	9.8	9.7
10	10	2.76	40,000	40.2	10.0	18	36	1.0	41,000	22.5	9.8
10	10	2.76	60,000	61.6	10.3	18	18	1.0	18,200	9.8	9.7
10	10	2.76	80,000	80.8	10.1	18	18	1.0	41,000	22.5	9.8

Where a **strong pull** is desired at the end of the stroke, a stop may be used as shown in Fig. 23, which gives rise to the pull curve of Fig. 24. Here the pull is made up of two components—that due to the attraction between plunger and winding and that due to the attraction between plunger and stop. The equation for the pull is

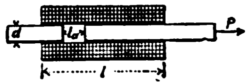

FIG. 23.

$$P = A\left[\frac{IN}{l_aK_1}\right]^2 + \frac{KAIN}{l} = AIN\left[\frac{IN}{l_a^2K_1^2} + \frac{K}{l}\right] \text{ in pounds,}$$

where A is the area of the core in sq. in., N the number of turns, l_a is the length of gap between core and stop, and K and K_1 are constants. At the beginning of the stroke the second member of the equation is predominant, while at the end of the stroke the first member represents practically the entire pull. Approximate values of K and K_1 are $K_1 = 2660$, and (for l greater than $10d$) $K = 0.0096$.

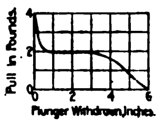

FIG. 24.

The **range of uniform pull** may be extended by the use of **conical ends** of stop and plunger, as shown in Fig. 25. The same effect may be obtained and a stronger magnet obtained mechanically by using an **ironclad solenoid** (Fig. 26), in which an iron return path is provided for the flux. Except for low flux densities and short air gaps the dimensions of the iron return path are of no practical importance, and the fact that an iron

FIG. 25.

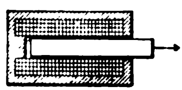

FIG. 26.—Ironclad Solenoid.

return path is used does not affect the pull curve except at short air gaps. A typical pull curve for an ironclad solenoid is shown in Fig. 27.

Mechanical jar at the end of the stroke may be prevented by boring through the end of the solenoid. The plunger then comes to equilibrium when its middle is at the middle of the winding, thus providing a magnetic cushion effect.

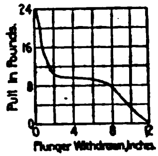

Fig. 27.—Pull of Ironclad Solenoid.

For **short-range work,** electromagnets with external armatures are best adapted, and the best type is the **horseshoe magnet.** The pull for short-range magnets is expressed by the equation $P(\text{lb.}) = B^2A/72{,}134{,}000$, where B is the flux density in lines per sq. in., and A the area of the core in sq. in. It should be noted that a stronger pull may be obtained if the surfaces of the armature and core are not machined and scraped to an absolutely smooth contact surface. Where the surface is slightly rough, the area of contact A is reduced but the flux density B is increased approximately in proportion (if the iron is being operated below saturation), and the pull is increased since it varies as the square of the density B. **Non-magnetic stops** should be used so that the core may release the armature readily when the current is cut off.

Lifting Magnets. It is difficult to state what the lifting capacity of a magnet is, for the reason that the weight that can be lifted depends upon the character and the length of the magnetic path. Table 18 gives the approximate **lifting capacities** of different sizes of commercial magnets with various kinds of load. For instance, the 62-in. Cutler-Hammer magnet will lift as much as 40,000 or 50,000 lb. where a large casting or skull-cracker ball affording a large magnetic contact surface is to be lifted. This same magnet might not lift over 1000 lb. of loose tin scrap. While commercial lifting magnets may be had in various forms for special purposes, those listed in Table 18 are known as **universal magnets,** as they are adapted to nearly all classes of work. See also p. 1110.

Rapid Action in a magnet may be obtained by reducing the time constant of the winding, and by subdividing the metal parts to reduce induced currents which have a demagnetizing effect. The movement of the plunger through the winding causes the winding and its bobbin to cut a field of force; if the bobbin is of metal and not slotted longitudinally, it acts as a short-circuited conductor cutting this field of force and hence consumes energy which would otherwise be available as mechanical pull. In cases where it is found impossible to reduce the time constant sufficiently, an electromagnet designed for a voltage much lower than normal is often used, which, at the completion of its stroke, mechanically connects in series with its winding a resistance of sufficient magnitude to limit the current flowing to a safe value. The solenoids on many automatic motor-starting panels are designed in this manner, as the extremely short time of overload does not injure the winding but causes a very rapid action. When **slow action** is desired, it can be obtained by using solid cores and yoke and by using a heavy metallic spool or bobbin for the winding. A separate winding short-circuited on itself is also used to some extent.

Sparking at switch terminals may be reduced or eliminated by neutralizing the inductance of the winding. This is accomplished by winding a separate short-circuited coil with its wires parallel to those of the active winding. (This method can be used with direct-current magnets only.) This is not economical, since one-half of the winding space is wasted. By connecting a condenser across the switch terminals, the energy of the inductive discharge upon opening the circuit may be absorbed. For the purpose of neutralizing the inductive discharge and causing a quick release, a small **reverse current** may be sent through the coil winding automatically upon opening the circuit. Tinfoil sleeves placed over the various layers of the winding absorb energy when the circuit is broken and reduce the energy dissipated at the switch terminals. This scheme can be used for direct-current magnets only. **Sticking** of the parts of the magnetic circuit due to residual magnetism may be prevented by the use of non-magnetic stops. In the case of lifting magnets subjected to rough usage and hard blows (as in a steel works), these stops usually consist of plates of manganese steel, which are extremely hard and non-magnetic.

Table 18. Dimensions, Weights and Lifting Capacities of Commercial Lifting Magnets

Diam., in.	Head* room, in.	Weight, lb.	Current required at 220 volts, d.c.	Lifting capacity, in pounds†				
				Skull-cracker balls or large castings	Ingots	Pig iron	Fine wire scrap	Maker

* With three-chain suspension.

† The values given are conservative values. Those given for Cutler-Hammer magnets are for kinds of load varying from small scrap to pig iron; large castings of much greater weight can be handled.

‡ E-C-M: Electric Controller & Mfg. Co. C-H.: Cutler-Hammer Mfg. Co.

Alternating-current Tractive Magnets. Because of the iron losses due to eddy currents, the magnetic circuits of alternating-current electromagnets should be composed of laminated iron or steel. For large magnets the iron circuit is usually built up of thin sheets of varnished sheet metal held together by means of suitable clamps. For a small core of circular section a bundle of soft wires is often used. Since the iron losses increase with the flux density, it is not advisable to operate at as high a density as would be permissible with direct current. The current instead of being limited by the resistance of the winding is now governed practically by the inductive reactance, for, in all well-designed magnets, the resistance should be small. In a **single-phase magnet** the pull varies from zero to a maximum and back to zero twice every cycle, which may cause considerable **chattering** of the armature against the stop. This may be prevented by the use of a spring, or, in the case of a solenoid coil, by allowing the plunger to seek its position of equilibrium in the coil. In a **two-phase magnet** the pull is constant and equal to the maximum pull produced by one phase so long as the voltage is a sine function. Similarly, in a **three-phase magnet** under the same conditions the pull is constant and equal to 1.5 times the maximum instantaneous pull of one phase. Should the load become greater than the minimum instantaneous pull, there will be chattering as in a single-phase magnet.

Heating of Magnets. The lifting capacity of an electromagnet is limited by the permissible current-carrying capacity of the winding, which in turn is dependent upon the amount of heat energy which the winding can dissipate per unit time without exceeding a given temperature rise. Coils wound with wire having cotton insulation will in general be operating at a **safe temperature** if a watt expenditure in the coil of 0.5 watt per sq. in. of radiating surface be allowed.

Space Factor of Winding. The "space factor" is the ratio of the net volume of conductor in a given winding to the gross volume of the winding. Only in the theoretical case of uninsulated square or rectangular conductor may the space factor be 100 per cent. For wire of circular section with insulation of negligible thickness, wound as shown in Fig. 28, the space factor will be 78.5 per cent. When the turns of wire are "bedded," as shown in Fig. 29 (which is the case in most windings, particularly with smaller-sized wires), there is a theoretical gain of about 7 per cent. in space factor. (Underhill, *El. Wld.*, vol. 53, p. 155, 1909.) Experiments have shown that in most cases this gain is about neutralized in practice by the flattening out of the insulation of the wire due to the tension used in winding. When wound in a haphazard manner, the space factors of magnet wires vary according to size, substantially as follows:

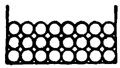

FIG. 28.

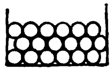

FIG. 29.

	—Double cotton covered—					Single cotton covered

BATTERIES

Primary Cells

Each metal has what is termed its single potential, or the electromotive force of that metal when tested with a mercury or normal electrode. Elements having great differences of single potential, when used in batteries, will give a higher voltage than elements having single potentials which are nearly the same. If two plates, such as copper and zinc, are placed in an electrolyte of diluted sulphuric acid, the direction of the e.m.f. in the cell is from zinc to copper, and if these be electrically connected, hydrogen bubbles accumulate on the surface of the copper. This accumulation of hydrogen not only offers a resistance to the flow of current but also sets up a counter e.m.f. which may result in a lower terminal e.m.f. These two effects may eventually reduce the flow of current to practically nothing; the phenomenon is known as **polarization.**

Mechanical means of **preventing polarization,** such as agitation of the liquid, forcing air through it, and roughening of the plates, have all been tried, with varying degrees of success. Chemical means are used extensively at the present time, various chemicals which contain oxygen in loose combination being used to dispose of the hydrogen as it forms in the electrolyte. Soluble oxidizing agents extensively used are the bichromates of potassium and sodium. To confine the depolarizing agent to the vicinity of the electrode, a type of cell has been developed having a diaphragm (usually a porous cup of unglazed porcelain) which does not interfere with the passage of the electric current, but prevents the passage of electrolyte from one compartment to the other. Such cells give greater efficiency than those without the porcelain cup. The use of bichromates as depolarisers has given the name **bichromate cell** to a battery constructed of zinc and carbon with diluted H_2SO_4 as the electrolyte, which is extensively used for medical purposes. E.m.f., about 2.2 volts.

The **Leclanché cell** is a combination of zinc and carbon electrodes with sal ammoniac solution, and is used where only low values of current and intermittent service are desired. In the original type polarization was retarded by making the carbon electrode very large and porous. In the improved type a porous carbon cup electrode is used, in which are packed lumps of manganese dioxide to serve as an insoluble oxidizing agent. The rather high internal resistance has been reduced by casting or rolling a zinc cylinder which is placed as near the carbon as possible. The cell is set up by putting 3 or 4 oz. of sal ammoniac in the jar, filling it about one-third full with water, stirring until the salt is entirely dissolved, and then inserting the carbon cup and zinc. In the older type the carbon electrode is placed in the porous cup and packed around with manganese dioxide and crumbled carbon, the cup with its contents being then inserted in the jar with the zinc. The e.m.f. of this cell is about 1.4 volts.

Of electrochemical depolarizers, one common type, that of the ordinary **crowfoot cell** (gravity cell), is made up of electrodes of copper and zinc with zinc sulphate and copper sulphate solutions. In setting up this cell the copper electrode (−) is placed at the bottom of a jar, into which about 3 lb. of copper sulphate crystals are poured. The zinc electrode (+) is then suspended near the top of the jar and water poured in to cover it, a tablespoonful of sulphuric acid being added. To prevent "creeping," the electrolyte is then covered with a layer of pure mineral oil free from naphtha or acid and having a flash point above 400 deg. fahr., or the rim of the jar dipped in melted paraffin. When thus set up the cell should be short-circuited for a day or two to form zinc sulphate, which will protect the zinc electrode and also reduce the internal resistance. E.m.f., about 1 volt. Polarization is eliminated because copper is more easily deposited upon the copper electrode from the copper sulphate solution than is hydrogen. It is possible to draw current continuously from a cell of this type for a long period, or until the zinc sulphate solution reaches the copper electrode, and for this reason it is known as a **closed-circuit cell.** Closed-circuit batteries are best adapted to telegraph, railway signal and similar services, which demand a continuous draft of current. To recharge the cell, empty out one-half the solution, fill up with water, add more $CuSO_4$ (blue vitriol) crystals, and the cell is then ready for use. The zinc electrode gradually goes into solution and copper is deposited out on the copper electrode.

The **Edison primary cell** is suitable for either closed- or open-circuit service. The negative electrode is made of compressed oxide of copper, the surface of which is reduced to metallic copper to improve the conductivity, and also acts as a depolarizer. The positive electrode is a casting of pure zinc which is thoroughly amalgamated. The electrolyte is a solution of caustic soda. The surface of the solution is covered with a layer of heavy oil to keep it from evaporating. The cell has an initial e.m.f. of about 1 volt, which drops to about 0.7 volt when the circuit is closed. These cells are made in the following capacities:

Continuous capacity, amp.	1.5	2.5	4.0	6.0	7.0
Maximum capacity, amp.	7.49	9.53	15.51	26.68	33.35
Capacity, ampere-hours	100.00	150.00	300.00	500.00	600.00
Internal resistance, ohms	0.080	0.070	0.043	0.025	0.020

Batteries of the **open-circuit type** polarise quickly and are more suitable where only intermittent service is demanded, such as in gas-engine ignition, door-bell service, and a great variety of other uses.

Dry Batteries. The so-called dry battery is a development of the Leclanché battery and consists of a zinc container lined with paper to prevent the mixture of carbon and manganese, which surrounds the carbon electrode, from coming in contact with the zinc. The mixture is made active by impregnating with a solution of zinc chloride and sal ammoniac. Some types of cells are being made without a paper lining, but the core is held away from the zinc container. In the make-up of such a cell the space between the core and the container is filled with a heavy electrolyte. Commercial sizes range from those used in flash lights (1¼ in. or less in diam.) to the heavy-duty cells used for gas-engine ignition and small lighting sets (about 3 in. in diam.). Because of polarisation it is not possible to use a dry battery for service demanding a continuous draft of current.

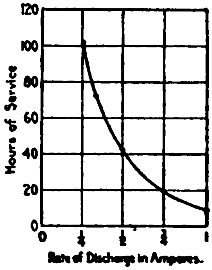

FIG. 30.—Discharge of Dry Cell.

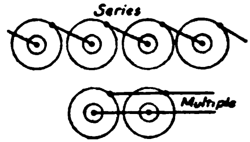

FIG. 31.—Cell Connections.

To get the **maximum efficiency** from a dry cell the discharge rate should be as low as possible. Fig. 30 shows the service and corresponding rates of discharge, and that the maximum output of energy is obtained when the rate of discharge is the lowest. Fig. 31 shows two **methods of connecting** cells. (For series-multiple connections, see p. 1610.) Dry cells can be **temporarily regenerated** by carefully puncturing the zinc and setting the cells in water, or, better, in a salt or sal ammoniac solution. If this water is heated the cell will revive more quickly.

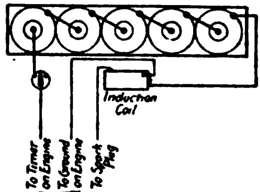

FIG. 32.—Connections of Dry Batteries for Gas-engine Ignition.

Fig. 32 is a diagram for connecting dry batteries in a **gas-engine ignition** system. As a rule, five cells are ample for such service, a greater number in series being likely to burn the platinum points on the coil. Almost all dry-battery ignition systems use 6 volts, which would theoretically require only four dry cells; in service, however, the voltage decreases to some extent, which makes it preferable to use five cells. Fig. 33 shows the dependence of **flash amperage** upon temperature, and indicates why difficulties are sometimes experienced in the use of dry cells in the winter.

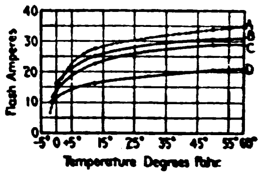

FIG. 33.—Flash-amperage Curves for Four Different Makes of Dry Cells.

Dry cells should be kept where it is cool but not damp. Heat dries out the cells. If space is available, use multiple connection so that the **life of the cells** will be increased and greater efficiency obtained.

Below are stated the elements, electrolytes and voltages of the more common primary cells.

Primary batteries			
Name	**Elements**	**Electrolyte**	**E.m.f., volts**
Daniell (or gravity)	Cu–Zn	$ZnSO_4 + CuSO_4$	1.07
Fuller	Cu–Zn	Dilute H_2SO_4 + $K_2Cr_2O_7$	2.1
Edison primary	Cu–Zn	Concentrated NaOH	0.7–0.95
Leclanché	C–Zn	NH_4Cl	1.4
Dry cell	C–Zn	NH_4Cl	1.0–1.8

All the preceding cells are termed **primary cells** because they are renewed by replacing the used-up elements of the cell.

Secondary Cells—Storage Batteries

In a **storage cell** electrical energy is commercially stored as chemical energy, but returns to electrical energy when the cell is connected to supply an external circuit. The desired voltage is obtained by connecting a sufficient number of cells in series, forming a **storage battery.** There are two general classes; the **lead-lead-acid cell,** and the **iron-nickel-alkaline cell.**

In the manufacture of the lead-lead-acid cells there are two general types of plates or electrodes. In the **Planté** type the active material is electrically formed of pure lead by repeated reversals of the charging current. In the **Faure** or pasted plate the active material is obtained by applying paste to supporting grids, lead peroxide to the positive and lead oxide to the negative plate.

The chemical reactions in a lead cell may be expressed by the following equation, based on the double sulphation theory:

$$\underset{\substack{\text{Positive}\\\text{plate}}}{PbO_2} + \underset{\substack{\text{Negative}\\\text{plate}}}{Pb} + \underset{\substack{\text{Electro-}\\\text{lyte}}}{2H_2SO_4} \underset{\text{Discharge}}{\overset{\text{Charge}}{\rightleftharpoons}} \underset{\substack{\text{Positive and}\\\text{negative plates}}}{2PbSO_4} + \underset{\substack{\text{Electro-}\\\text{lyte}}}{2H_2O}$$

Between the extremes of complete charge and discharge complex combinations of lead and sulphate are formed. After complete discharge a hard insoluble sulphate forms slowly on the plates and this is reducible only by slow charging. This sulphation is objectionable and should be avoided. The **weight of metallic lead actually required** to be reduced to sponge lead on the cathode plates to produce 1 amp-hr. of discharge at ordinary commercial rates is from 0.5 to 0.8 oz., and that converted into lead peroxide on the anode plates from 0.53 to 0.86 oz. These weights are from 4 to 6 times those theoretically required. The **quantity of electrolyte required** by a given cell may be computed from the formula $Q = (1290 - 10.53d)/(D - d)$, where Q = number of ounces (avoirdupois) of electrolyte per 100 amp-hr. of discharge, and $D(d)$ = percentage of sulphuric acid in the electrolyte at the beginning (end) of discharge. For other amounts, multiply Q by the actual ampere-hours and divide by 100.

Voltage. The voltage of a lead cell when fully charged and idle is 2.05 to 2.10 volts. Discharge lowers the voltage in proportion to the current flowing. Complete discharge is reached at 1.7 volts, at the normal discharge rate, fixed by the manufacturer. When charging at **constant current**

and normal rate, the voltage gradually increases from 2.2 to 2.35 volts then increases rapidly to between 2.5 and 2.7 volts. This latter interval is known as the gassing period and during this time the battery should be watched closely to avoid waste of power and unnecessary deterioration of the plates. The **constant potential** method of charging is to be preferred. A potential of 2.3 volts per cell is necessary. Under these conditions the above precautions are unnecessary, as the charging rate automatically drops as the cell voltage rises, and when the battery is entirely charged the current ceases to flow. Fig. 34 shows the change of voltage during charge and discharge. Fig. 35 shows the percentage of rated capacity available when lead batteries are charged under a constant potential of 2.3 volts per cell for various charging periods. Each curve relates to a different initial charge.

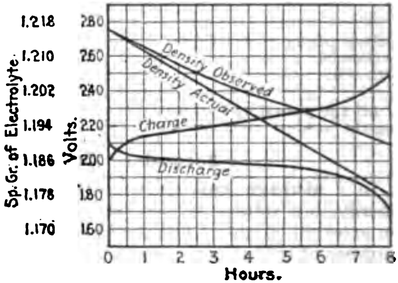

Fig. 34.—Change of Voltage of Lead Storage Cells During Charge and Discharge.

The **Edison storage cell** has a positive plate of iron and a negative plate of steel. The active material for the positive plate is nickel hydrate and for the negative plate iron oxide. The electrolyte is a 21 per cent. solution of potassium hydrate with a little lithium hydrate. Its initial e.m.f. is about 1.5 volts and its average e.m.f. about 1.1 volts throughout its discharge. On account of the high internal resistance of the cell the battery is not efficient from the energy standpoint, 60 per cent. being the efficiency usually attained in practice. It is compact and extremely light and strong, and for these reasons is particularly adapted for service in electric vehicles and for train-lighting systems. Its output is about 15 watthours per lb.; that of the lead storage cell ranges from 3 to 7 watthours for the Planté type to 8 to 14 watthours for the pasted or Faure type.

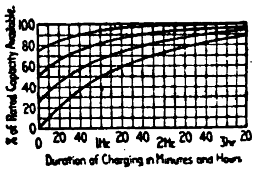

Fig. 35.—Available Capacity of Lead Storage Battery Charged at 2.3 Volts per Cell.

Hard rubber jars, glass-jars, and lead-lined tanks are generally used with lead cells. The first are generally used for portable and vehicle batteries, and the last two are used in power plants.

Installing a Lead Battery. Vehicle and portable batteries are generally shipped assembled (filled with the electrolyte) and ready for use. Plates for stationary batteries are usually received dry and the positive and negative plates separate. When installed they should be carefully handled and the separators placed carefully between the plates. Wood separators are shipped wet and should be kept wet until put in service. The jars should be set in trays filled with white bar sand, and these placed on glass or porcelain insulators. The battery room should be between 50 and 80 deg. fahr., fairly dry, and well ventilated to allow the explosive gases to escape.

When the plates are in place there should be enough space between the plates and the bottom of the jar to prevent the sediment from touching and short-circuiting the plates. The electrolyte is sulphuric acid (specific gravity, 1.21 at 70 deg. fahr.) and may be obtained by mixing one part of sulphuric acid of 1.84 specific gravity (oil of vitriol) to 4¼ parts of water by volume. The acid should be poured into the water, not *vice versa*. Distilled water is preferable, but ordinary tap water may often be used without harm being done. The **initial charge,** after installation, is from 40 to 60 hr. at the normal rate, and should continue 10 hr. after the specific gravity and voltage have ceased to rise. The cells should gas freely during this period. To take out of service for less than 9 months, charge once a month if possible, but if not, give a heavy overcharge before discontinuing service. To remove for a longer period, siphon off the acid (which may be used again) and fill with fresh water. Allow to stand 15 hr., and siphon off water. Remove and throw away the wood separators. The battery will now stand indefinitely. To put in commission again, install new separators, fill with acid (sp. gr. 1.210) and charge at normal rate 35 hr. or until gravity has ceased to rise over a period of 5 hr. Charge at a low rate a few hours longer.

Charging. Lead batteries should be charged at a normal 8-hr. rate until the voltage ceases to rise, and the charge continued from this point about half an hour longer. When fully charged the positive plate should have a chocolate-brown appearance and the negative a grayish color. If the positive plates have a whitish appearance, the sulphate has not been entirely reduced and it is advisable under such conditions to continue the charge at a low rate until the sulphate appearance has been entirely removed. To diminish **sulphation,** overcharging once a week for stationary cells and once every 2 months for portable or vehicle cells is recommended. Water, free from harmful substances, should be used to replace electrolyte lost through evaporation. Several **systems** are used **for charging:** the motor-generator, rheostat or lamp bank from a direct-current lighting system, electrolytic rectifier, mercury-arc rectifier and vibrator rectifier; in some cases for portable batteries a primary battery such as the crowfoot cell is used. With **portable batteries** the charging wires are likely to get confused, so that before charging it may be necessary to determine the polarity of the charging wires. If two wires from the generating system are placed in a container of salty water it will be noticed that one of the wires will generate gas more freely than the other. This is the negative wire and should be connected to the negative pole of the battery. By moistening a strip of litmus paper with salty water and holding the wires from the charging system close together on this strip of paper, an acid reaction develops a red spot under the positive terminal and an alkaline reaction under the other produces a blue spot. The **charging current** should be at the 8-hr. rate, which is from 5 to 10 amperes for the average portable cell. If, however, a more rapid charge is required, it is well to start off at twice the 8-hr. rate and charge until gassing develops freely. Then reduce to the 8-hr. rate and continue to charge until the cell has generated gas for half an hour. This high rate of charge is not as efficient as the lower rate.

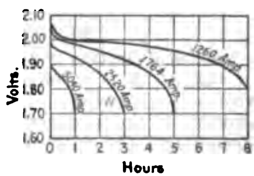

Fig. 36.—Output of Storage Battery at Various Rates of Discharge.

Rates of Charging and Discharging. Fig. 36 is a curve giving the **output at various rates of discharge,** which shows that as the rate of discharge is increased the output in ampere-hours or watthours is materially decreased.

It is desirable to use a battery of such size as to permit of the lower rates of discharge which result in higher efficiencies, but portable batteries have usually to sacrifice efficiency and durability in order to reduce weight and bulk. Portable batteries are made up of many thin plates whose thickness varies from ⅛ to ³⁄₁₆ in. The central-station type of battery (Planté) is developed primarily for long life. The plates are as a rule about ½ in. thick, and with proper care may give service for 10 years or even longer. To obtain maximum efficiency it is necessary to use low rates both of charging and of discharge. Cells fully charged up to 2.5 volts and discharged down to 1.75 volts have an **efficiency** varying from 75 to 80 per cent. according to the type of cell and the rates of charge and discharge. Under ordinary conditions the rates of charge and discharge should be from 6 to 10 amperes per sq. ft. of *positive* plate surface; the surface of one plate is measured as twice the product of height by breadth (omitting ribs and other irregularities of surface).

The **capacity** of a lead storage cell **varies with** the **rate of discharge**, substantially as follows:

Rate of discharge, hours......	8	5	3	1
Percentage of capacity at 8-hr. rate:				
Planté type...............	100	88	75	50
Pasted type...............	100	93	83	60

Care of Batteries. Some of the precautions to be observed in the care of storage batteries are as follows: An ammeter should not be used to test the condition of a cell; a battery should not be left to stand in a discharged condition; a naked flame should not be brought in the vicinity of a battery that is being charged; charging should not be done at a high rate, and the battery should not be allowed to get hot when charging; water should never be added to the concentrated acid—always acid to the water; acid should never be equalized except when the battery is in a charged condition; a battery should never be exposed to the influence of external heat; voltmeter tests should be made when the current is flowing; batteries should always be kept clean. To replace acid lost through slopping, it is well to use a solution of two parts of concentrated sulphuric acid in five parts of water by weight, unless a hydrometer is at hand to enable the solution to be made up according to the specifications of the makers of the cell.

Applications. In connection with central stations as a standby or to level the load peaks; floating on railway systems; electric vehicles, pleasure and commercial; storage battery cars (N. Y. City); automobiles, ignition, lighting and starting; submarines; gun-firing and sighting on battleships; wireless emergency; private lighting plants; telephone centrals; telegraph; fire-alarm; and in testing where a constant voltage is necessary.

ELECTRICAL IGNITION SYSTEMS

Electrical ignition systems utilize electromagnetic phenomena (see p. 1573). In Fig. 37, B is a source of current, N' a coil of wire and S a switch. The magnetic flux is represented by the arrowed lines. If switch S be opened and the current falls to zero, N' is surrounded by a magnetic field which is decreasing in value. Similarly, when S is closed, N' is surrounded by a rising magnetic field. In both cases a pressure of self-induction is generated. Different results occur in N' when S is closed and when it is opened. In making contact no current can flow until the switch is closed. The opposition to the rise of current, or the self-inductive pressure, and the resistance of the circuit are the only op-

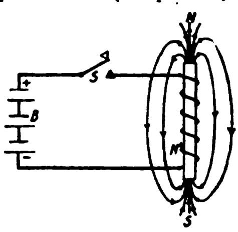

FIG. 37.—Inductance or Spark Coil.

posing forces, and the resistance is comparatively low. When S is opened, however, an air gap is introduced into the circuit, and, as air offers great resistance to the current flow, this resistance is many times greater than when switch S is closed. The current decreases very rapidly and with it the flux present in N'. This causes the generation of a high pressure sufficient to jump the small air gap formed as S opens and to establish an arc across the gap. The resistance of this arc is considerably less than that of air and the current flow will last for a short time after the switch gap is opened. Since the pressure generated in N' is proportional to the rate of change of the flux, and as the resistance of an air gap is practically proportional to the length, the arc established will be long if the gap be opened rapidly.

In closing, the source of power is B, which has a constant pressure. In opening, the energy for the arc at the gap must come almost entirely from the magnetic flux in the coil. A definite amount of energy is stored in the magnetic field, and is available at the gap when the switch is opened.

If an additional coil N'' be wound concentric with N', as in Fig. 38, any magnetic changes in one will occur also in the other. Hence, pressures may be developed in N'' independently from N' as the current is varied in N'. Since the pressures developed are dependent on the number of turns in the coil, any desired value may be generated by winding a sufficient number of turns on N''. If a sufficient number be wound, a pressure sufficient to jump an air gap such as a, b will be produced. Such a pressure is said to be of **high tension.** A coil wound as in Fig. 37 is called an **inductance or a spark coil.** A coil with a double winding as in Fig. 38 is called an **induction coil** or a **jump-spark coil.** The winding N' in an induction coil is called the **primary,** while the N'' winding is called the **secondary.** Whenever a spark jumps between **points,** the metal of which they are made is vaporized or burned. Unless the polarity of the battery or other source of power is alternated frequently, the wear is uneven, one point pitting and the other building up like a cone, resulting in variable action of the coils. Points should be kept flat with a very fine file or stone. The material for points that best resists wear and oxidation is an alloy of platinum and iridium, and this is used in high-grade apparatus. Nickel steel and other cheap alloys need renewal frequently and require considerable adjustment to keep them in good order. Tungsten contacts are now coming into use.

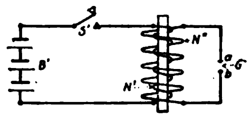

Fig. 38.—Induction or Jump-spark Coil.

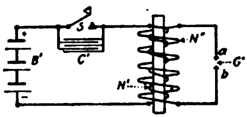

Fig. 39.—Induction Coil with Condenser.

To reduce the arcing at the contact points of the primary circuit, a condenser is shunted around the switch. A **condenser** consists of two conductors separated by some insulating material. It is usual to make it of a large number of sheets of a very thin metal like tinfoil with thin paraffined paper sheets separating them. Every other sheet of metal extends to one side and the balance to the other. By connecting all of one side to one terminal and the remainder to another, the condenser is complete. By connecting the condenser across switch S, Fig. 39, the energy of what would otherwise be an arc is absorbed. This prevents the contacts from being burned away rapidly and increases the induced voltage of the secondary by making a sharper break.

Electrical ignition systems are frequently operated upon low voltages, from primary batteries, storage batteries or small, low-pressure generators.

The power required is very small and on this account batteries are much used. The **primary voltage** is generally 6 volts. Series-multiple connections are much used, as shown in Fig. 40. Sometimes additional cross connections are made as shown in in Fig. 41, so that a loose connection in one series of batteries will not render the entire series useless.

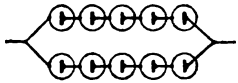

FIG. 40.—Series-multiple Connections.

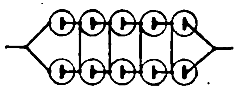

FIG. 41.—Series-multiple with Cross Connections.

The generators used are either **magnetos** or dynamos. A magneto is a generator having permanent magnets for the fields. Referring to Fig. 42, *N* and *S* are the permanent magnet poles. Lines of force pass from *N* to *S* and then through the iron back to *N*, as shown. A set of soft iron poles is attached to these two pole pieces. The fall of magnetic potential is the same by any path, so that with longer air gaps the flux density must be less.

Fig. 42 also shows a simple two-pole or shuttle armature made in the form of an *H* which is turned to fit the bore of the poles with a very small clearance. End plates are provided and a shaft extension added to enable the armature to rotate freely. The air reluctance is reduced to the short length of the air gap between the armature surface and the pole pieces. The total magnetic reluctance is therefore low. If a coil of wire now be wound on the core of the armature, as shown in Fig. 42, and one terminal be connected to the armature metal or **grounded** to the machine and the other be insulated and provided with a sliding connection to an insulated terminal, an elementary magneto results. In the position (*a*) of the armature the coil encloses all of the magnetism passing through the core of the armature. In position (*b*), the armature has rotated one-fourth of a revolution and the magnetic flux cannot now pass through the core and coil, but takes another path across the pole pieces of the armature, as indicated. The magnetic flux threading the armature coil is now zero. Rotating the armature another quarter turn brings it into the same position as in (*a*), with the exception that now the coil is reversed and the flux passes in full strength through the coil but in the opposite direction to that in (*a*). By rotating a second half revolution, the flux will fall to zero and then back to full value as before. In a complete revolution, the flux changes from full value to zero and back again twice. Since the pressure generated in a coil is proportional to the rate of change of flux, the pressure must also go through the same cycle. The cycle of pressure is alternating. A **dynamo** or generator differs from a magneto only in the use of a field excited by a direct current.

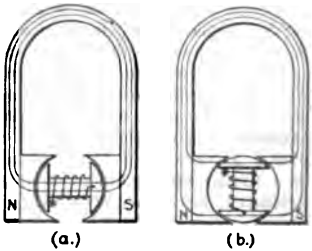

FIG. 42.—Simple Magneto.

The generator when driven by a variable-speed motor will naturally generate a pressure varying with the speed, since the pressure is dependent on the rate of change of flux through the armature. Some form of regulator is therefore required in this case to keep either the speed or the voltage constant. Some friction-driven generators make use of a centrifugal device in which the armature is disconnected the moment the speed, and therefore the voltage, rises above a certain fixed value. Such devices, unless very well made, are not very reliable. Electric clutches are used also and operated either by the load current or the pressure.

The most satisfactory systems are those in which the generator is constantly supplying the circuit with a current. This may charge a storage battery or furnish power for the electric-lighting circuit. A number of successful systems have been developed. The storage battery is kept constantly charged and this insures a steady pressure for operating the ignition system. A switch electrically or mechanically operated disconnects the generator when its voltage is below that of the battery or when the battery is receiving too much current. It is to be noted that any generator takes a certain amount of power to run it and this load is a constant one on the engine.

Electrical Ignition Systems may be classed under two general heads, **low-tension** and **high-tension**. In the former, there is only one circuit, and the device for making and breaking the circuit is applied to the cylinder so that the circuit is opened in the combustion chamber by mechanical or electromechanical means. The spark thus produced is the inductance spark. In the latter, a high-tension pressure is generated by apparatus outside of the engine and conducted to a fixed spark gap which is carefully insulated and screwed with its mounting into the combustion chamber.

Mechanically Operated Low-tension Systems. To produce a hot spark in breaking a circuit, it is necessary to make this break very rapidly. In low-tension systems this is accomplished almost entirely by a spring and cam escapement device. Fig. 43 illustrates the principle of all such apparatus. *K* is a cam rotating in synchronism with the engine shaft. As the cam revolves it moves a follower *F* which turns the shaft *R* in its bearing located in the cylinder wall. Attached to this shaft is the lever *L* which carries one of the sparking points *P*. As the cam advances further, *P* touches *P′* and closes the circuit. *F* is then suddenly pulled by the spring *M* as *F* runs over the cam lip, *P* is as suddenly drawn away from *P′*, and the spark produced. *P′* is located on an insulated stem which is rigidly fastened into the cylinder wall.

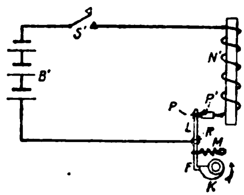

FIG. 43.—Mechanically Operated Low-tension System.

Electrically Operated Low-tension Systems. Fig. 44 shows a system in which the additional device *T* is installed for closing the circuit outside of the cylinder. The points *P* and *P′* are normally held in contact by the spring *M*, and when *T* completes the circuit *N′* attracts an armature *F* which causes the points to separate and draw out the arc. The timer *T* must break contact before *P* and *P′* come together or the action will be repeated. This system admits of ready adjustment of the timing of the spark, but the use of an electromagnet to operate the moving parts in the tignt-ntting bearing through the cylinder wall requires more power than can be furnished by primary batteries advantageously. In the magnetic spark-plug system the timer operates a small electromagnet in the plug, which in turn operates the contact points.

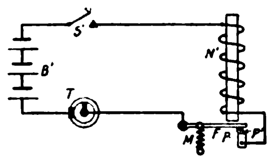

FIG. 44.—Electrically Operated Low-tension System.

Low-tension System Using Magneto. A magneto geared positively to the engine at the proper speed relation can be used as a source of power in a low-tension system, but for high-speed work its use is difficult. The magneto has an appreciable inductance, and if wound properly does not need a spark coil.

High-tension Systems are more numerous and more complex than the low-tension systems. There are, however, only a few basic types. The simplest system is that of the **single break** of the **DeDion** type. **Fig.** 45 shows this mechanism. A cam K, rotating in synchronism with the engine shaft, strikes the fixed spring strip V and forces the contacts P, P' together, after which P is allowed to snap away from P' and thus break the circuit. The high-tension spark produced at a, b is within the cylinder.

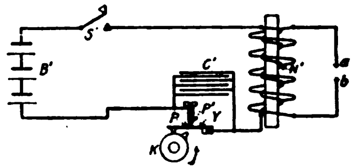

FIG. 45.—Single-break High-tension System.

Fig. 46 shows a **vibrator coil system.** At one end of the coil is placed a spring of steel having an iron head V. One end is firmly fixed while the free or head end may be attracted by the core of the coil. On the spring or vibrator is placed one of the contact points P, while opposite it the other point P' is held by an adjustable screw. When the timer T makes contact the core of the coil attracts the vibrator and pulls the contact points apart, thus breaking the circuit quickly. This induces in the secondary of the coil a high pressure, which can jump the spark gap in the plug. As soon as the circuit is interrupted the core loses its magnetism and the spring returns into contact with P. This re-establishes the current in the coil and the process is repeated. The speed of the vibrator depends on its stiffness; usually it is from 150 to 250 per sec., but in some coils as high a speed as 500 per sec. is attained. At low speed with a given vibrator it is evident that the timer makes a longer contact than at high speed and that the number of vibrations per timer contact decreases with increasing speed of engine. Hence, at low speed a large number of sparks are produced in the plug at each contact, while at very high speed it may reduce even to one. If there is not a sufficient rest between timer contacts for the vibrator to resume its normal state of rest, the timer may make contact before or after it has come into contact with the fixed point; this will disturb its natural period and will result in giving irregular sparks at the plug.

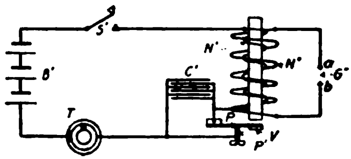

FIG. 46.—Vibrator-coil High-tension System.

If dry cells are used for vibrator coils, each cell should be first tested on short-circuit to see if all cells are uniform, and then all in series should be tested with the coil in circuit with its vibrator screwed down so that it will not vibrate. If the cells then do not test at least 4 to 5 amperes they should be discarded. A vibrator coil is more efficient with a high voltage supply than with low voltage, because the rapidity of the break in the former case is faster than in the latter. Hence, a coil testing ½ ampere on four new cells is delivering more spark energy than the same coil testing the same with four low cells. A slow-speed vibrator will deliver a greater power per spark than a high-speed vibrator when both are tested to the same ampere reading.

High-tension Magneto Systems. A magneto may be substituted for the battery in Fig. 45 if its motion is properly synchronised with that of the timer. A simpler and more effective arrangement of the high-tension magneto with separate coil is shown in Fig. 47. Here the timer remains closed or the circuit is short-circuited until a point is reached where the current flowing is a maximum. Then the contacts are suddenly knocked apart by the cam on the armature shaft. The armature coil will be linked with a strong magnetic flux at this moment. Now the timer, instead of being in the primary circuit of the coil, acts as a by-path or shunt to it, and, as its resistance is very low, nearly all of the current flows through it. When the cam opens the contact at *T*, the current is diverted suddenly through *N′* and a high pressure is generated in *N″*, producing the spark at the plug. If used on a constant-speed motor the operation is satisfactory, but when used with a variable-speed motor, such as an automobile engine, the change of speed makes the current vary. It is difficult to start an engine on a small magneto. The purely high-tension magneto is one which differs from that just described in that it has both the low-pressure coil, or primary, and the secondary on the same armature. Both coils link with the same magnetic circuit and therefore it becomes an induction coil. Fig. 48 shows a pure high-tension magneto. The two windings are shown with one terminal grounded to the machine. The smaller coil of few turns and heavy wire is short-circuited by *T* until the proper moment, when it is opened and *G″* gets the spark.

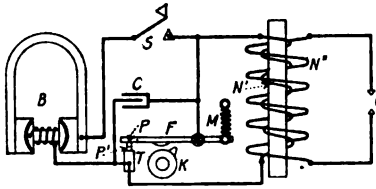

Fig. 47.

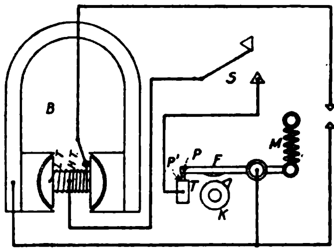

Fig. 48.
High-tension Magneto Systems.

Spark Plugs should be adjusted so that the gap is approximately 1/16 in. in length. A smaller gap will take less pressure, but this may allow carbon or dirt to bridge the points and thus short-circuit the plugs. A gap that is too large will not work at all when the spark is weak.

Voltage. The voltage required to jump a given gap in the cylinder varies with conditions of temperature and atmospheric pressure. In air it varies almost directly as the absolute atmospheric pressure. Since gas-air mixtures are mostly air, this holds practically true for the charge in an engine. Fig. 49 shows tests made for different pressures in compressed air. As the temperature rises the voltage drops.

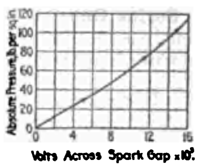

Fig. 49.—Spark Voltage Curve.

All ignition apparatus is designed to run on certain voltages. If a higher voltage is used better sparks may be produced at the expense of greater wear or damage to the apparatus. The condenser applied to the vibrator coils is adjusted for minimum sparking. If a high voltage is used more current flows, the sparking increases, or the condenser is constantly overloaded and finally breaks down.

GENERATORS MOTORS, TRANSFORMERS

General Considerations. The essential elements of a generator or motor are a magnetic field and conductors so arranged that they cut the magnetic lines of force. Either the field or the armature may rotate, or, as in some alternating-current generators, the equivalent of conductors cutting the magnetic field is accomplished by moving inductors which vary the amount of magnetic flux linking with the armature conductors. In alternating-current generators the armature conductors alternately cut lines of magnetic force emanating from a north and a south pole so that the induced e.m.f. reverses in direction as frequently as the armature coils pass by the field poles. In direct-current generators (except the unipolar type), an alternating e.m.f. is generated, but the commutator and brushes provided with this type of machine rectify the alternating e.m.f.'s to produce a unidirectional e.m.f. No fundamental differences exist between generators and motors. Direct-current dynamos may be separately excited, or the very small sizes may have permanent magnet fields, as in the case of magneto generators. The usual types are the series, shunt and the compound-wound machines, these terms indicating the mode of field excitation. The **fundamental equation** which expresses the relation between the generated e.m.f. in volts E_a, the total magnetic flux Φ cut by the armature conductors, the speed in r.p.m. and the number Z of armature conductors in series between brushes, is $E_a = \Phi NZ/(10^8 \times 60)$. The terminal volts $E = E_a - I_aR_a$, where I_a and R_a are the armature current and resistance, respectively. Under no load the generated e.m.f. appears at the terminals, but, under load, armature resistance and armature reactions generally make the terminal e.m.f. somewhat less than that indicated by the equation. A study of the fundamental equation enables one to predetermine much concerning the performance of a generator or motor under various conditions of service. Except in the case of arc-lighting circuits, electrical distribution systems are constant-voltage systems with the receiving units in parallel. The standard voltages commonly employed for direct-current distributions are 110, 220, 440, 550 and 1200 volts, the latter two chiefly for electric railway work. By **voltage regulation** is meant the per cent. variation in voltage from full load to no load at constant speed expressed in terms of the normal full-load voltage; speed regulation of motors is expressed in a similar manner.

Direct-current Generators

Series Generator. In the series generator (Fig. 50) the entire load current passes through the field winding, which consists of relatively few turns of wire of sufficient size to carry the entire load current without undue heating.

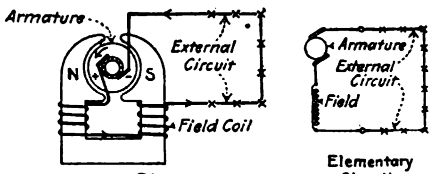

Diagram. Elementary Circuit.

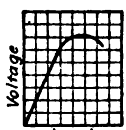

Load Characteristic Curve.

FIG. 50. FIG. 51.

Series D.C. Generator and Its External Characteristic.

The field excitation, and hence the terminal e.m.f., depends upon the magnitude of the load current. An external characteristic showing the relation between load current and terminal e.m.f. is given in Fig. 51. Series generators now find no extended application, but were much used a few years ago to operate series arc-light systems.

Shunt Generator. The connections of a shunt generator are shown in Fig. 52. This machine maintains approximately constant terminal e.m.f.

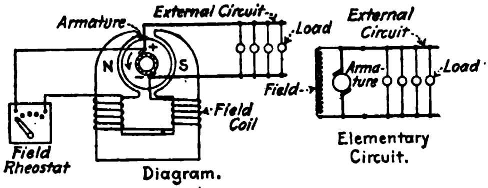

FIG. 52.

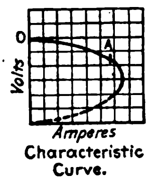

FIG. 53.

Shunt D.C. Generator and Its External Characteristic.

at all loads and is widely used. An external characteristic of a shunt generator is given in Fig. 53. Due to armature resistance and armature reactions the terminal e.m.f. decreases with increasing load. At point *A* the generator commences to "break down." Further attempts to apply load result in an abrupt decrease of voltage and a decrease of current even to short-circuit. *OA* is the operating portion of the characteristic. The breakdown point of large machines is many times their rated load. The field rheostat permits the field current to be adjusted so that constant terminal e.m.f. may be maintained.

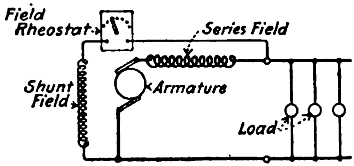

FIG. 54.—Compound-wound D.C. Generator.

Compound-wound Generators (Fig. 54). By the addition of a series winding to a shunt generator the terminal e.m.f. may be automatically maintained constant, or, by properly proportioning the series coil, the terminal e.m.f. may be made to increase with load to compensate also for loss of voltage in the line, so that approximately **constant voltage** is maintained at the load. Compound-wound generators are chiefly used for small isolated plants and for generators supplying a purely motor load subject to rapid fluctuations as in railway work. There is no advantage in using compound generators in central stations supplying lighting load, for the reason that either automatic regulators or manual control must be used to keep the voltage constant at the various centers of distribution, each supplied by separate feeders. Fig. 55 gives the characteristics of a 200-kw. compound-wound generator.

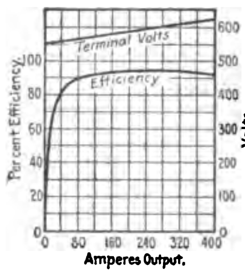

FIG. 55.—Characteristics of a 200-kw. Compound-wound D.C. Generator.

Parallel Operation of Direct-current Generators. To operate shunt generators in parallel it is necessary to see that the switches are so connected that like poles are connected to the same bus bars when the switches are closed. Suppose one generator to be operating; to connect another generator in parallel with it, the incoming machine is first brought up to speed and its terminal pressure adjusted to a value slightly higher than the bus-bar voltage, when they may be connected together without difficulty. The proper division of load between them is adjusted by the field rheostats and will be maintained automatically if the machines have similar voltage regulation **characteristics.** Shunt machines have drooping voltage characteristics and parallel operation is therefore stable. Compound-wound direct-current generators have flat characteristics or frequently rising voltage characteristics. To operate them successfully in parallel an equalizer connection must be provided, as shown in Fig. 56, connecting the generators at the junctions of the armature and series field leads. This connection must be of low resistance so that any increase of load current demanded of the machines will be proportionally divided between the series windings of the two machines. The equalizer switch should be closed first and opened last, if possible. In practice, the equalizer switch is often one blade of a 3-pole switch, the other two being the bus switch, as in Fig. 56. When compound generators are used on a 3-wire system, two series fields—one at each armature terminal and two equalizers, are necessary. It is equally feasible to operate three or more compound generators in parallel in the same way. The average values of **efficiencies** of compound-wound direct-current commutating-pole generators given in Table 19 are fairly representative of modern practice.

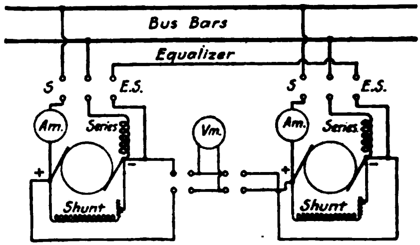

FIG. 56.—Connections for Compound-wound D.C. Generators Operating in Parallel.

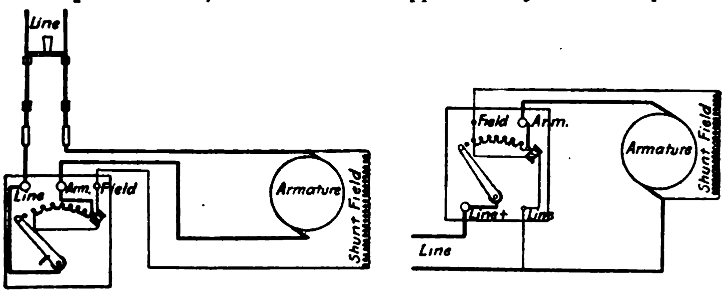
Direct-current Motors

A direct-current motor may be regarded as a **counter-voltage generator.** ts **fundamental** e.m.f. equation is $E = e + I_a R_a$, where E is the e.m.f.

impressed on the armature, e the counter e.m.f. generated by the armature, I_a the armature current and R_a its resistance. Let Z be the total number of conductors on the armature (of a 2-pole motor), Φ the total flux through the armature in c.g.s. lines, and N the speed of armature in rev. per. sec. Then $e = Z\Phi N/10^8$, or $N = e \times 10^8/Z\Phi$, which latter is the **fundamental speed equation** of the direct-current motor. The **torque** of a motor is its turning moment and is generally expressed in lb.-ft., or the number of pounds of effort exerted at a radius of 1 ft. It is proportional to the product of Φ and I_a and its value may be determined as follows: Let T = torque at the shaft in lb.-ft., and P the power in watts delivered to the shaft. Then $P = I_a e = 2\pi NT \times 1.356$, since 1.356 watts ($= 746/550$) are equivalent to 1 ft.-lb. per sec. In a machine with constant flux e is directly proportional to the speed and is equal to $\Phi ZN \times 10^{-8}$, whence $\Phi ZI_a = 2\pi T \times 1.356 \times 10^8$, or T (in lb.-ft.) $= \Phi ZI_a/(8.52 \times 10^8)$, which is the **fundamental torque equation** of the direct-current motor. Also, h.p. $= T \times$ r.p.m. $\times 2\pi/33{,}000 = I_a e/746$, whence $T = 7.04eI_a/$(r.p.m.).

Series Motor. The series motor is **adapted to variable-speed work** such as railway, crane and elevator service, on account of its speed-torque characteristic. Under heavy load the fields are strongly excited so that the **torque,** which is proportional to the product of the field flux and the armature current, is large. Assuming the fields are not saturated, the torque is proportional to the square of the motor current. Under heavy load (and hence strong field flux) the speed is low. The series motor develops almost any torque demanded of it, but with a reduction in speed, so that it is especially adapted to hard work where constant speed is not essential. On light loads it speeds up and may easily attain an unsafe speed if not controlled. For starting and speed control a series resistance is used, which results in loss of power as heat. In railway work, where two motors at least are used for each car, the series-parallel system of speed control is used. (See Speed Control of Series Motors, p. 1637.)

Shunt Motor. The shunt motor is almost universally **used for constant-speed service,** for it maintains approximately constant speed re-



(a) (b.)

FIG. 57.—Connections for Shunt D.C. Motors.

gardless of the load. The speed is such that the counter e.m.f. equals the impressed e.m.f. less the drop of voltage IR due to armature resistance. Methods of connecting a starting rheostat are shown in Fig. 57(a) and 57(b). The fields are first fully excited and then current, controlled by a resistance, is allowed to pass through the armature circuit. The armature resistance is permitted to remain in circuit only during the process of starting. The starting lever is held, against the force of a spring, in the running position by an electromagnet in series with the field circuit, so that if the field circuit is interrupted or the line voltage becomes too low, the lever is released and the armature circuit is opened automatically. The electromagnet is sometimes connected directly across the line, as shown in Fig. 57(*b*), in the four-point starting box. In this type the arm is released instantly upon failure of the line voltage, when in the other some time elapses before the field current drops enough to effect the release. Some **starting rheostats** are provided with an overload device so that the circuit is automatically interrupted if an unsafe current is demanded by the armature. The speed of a shunt motor decreases somewhat with load, because the larger load current causes a greater armature *IR* drop. This effect of armature resistance is somewhat diminished by the effect of armature reactions, as explained later. **Speed control** by means of armature resistance is not satisfactory because it involves a considerable loss of power, and the speed varies with the load because of the variation of the *IR* voltage drop across the resistance, resulting in a variable voltage applied to the armature. In the ordinary shunt motor the speed may be controlled to a limited extent by means of a shunt-field rheostat. Weakening the field increases the speed of the motor, for the decreased field flux means that the speed must increase to develop a counter e.m.f. equal to the applied armature e.m.f. This method of control is limited in range for ordinary shunt motors, as the decreased field flux increases commutation difficulties. Motors for adjustable-speed service are generally built with commutating poles. Ranges as high as 5 to 1 are obtained in many instances.

Compound Motors. A cumulative compound winding of a generator becomes a differential compound winding when the machine is used as a

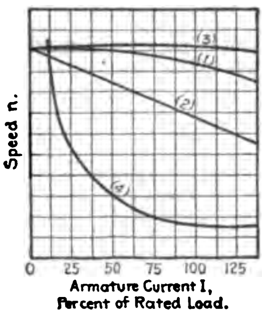


Fig. 58.

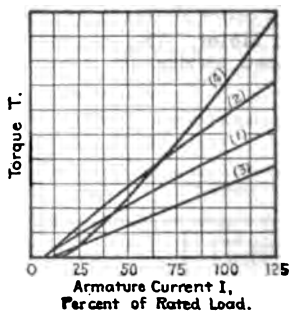

Fig. 59.

Speed and Torque Characteristics of Direct-current Motors.

(1) Shunt motor; (2) compound motor; (3) differential compound motor; (4) series motor.

motor. The differential motor, however, is not ordinarily used except to drive certain textile machines. However, its speed may be made more nearly constant than that of a shunt motor, or, if desired, it may be adjusted to increase in speed with increasing load. Cumulative compound motors have very poor speed regulation, since the field strength is increased with increasing load, and they are used where constant speed is not important and where larger starting torque is desired than would be developed by a shunt motor. Cumulative motors are used for elevators, to drive punches, etc., where a large instantaneous torque is necessary. Figs. 58 and 59 give **speed and torque characteristics** of the different types of direct-current motors.

Commutation. The proper position for the brushes upon the commutator is at the point where the current in the coil under the brushes is passing through zero. In a generator the brushes are given a slight lead in the direction of rotation to obtain sparkless or "black" commutation. In a motor the brushes are given a negative lead, that is, against the direction of rotation. Reversible motors must have the brushes placed in the theoretical neutral plane, so that commutation difficulties are especially difficult to overcome in such motors. The armature current sets up a magnetomotive force proportional to its strength. In shunt motors the armature current sets up a magnetomotive force which decreases the field flux and consequently reduces the decrease of speed with load. The proper position of the brushes then varies with the armature current or load. This undesirable result may be minimized in several days. Motors for adjustable-speed service may be improved by the addition of an **interpole** or commutating pole. In the ordinary motor the field flux performs two functions, that of reacting with the armature current to produce torque, and that of reversing the current in the short-circuited coil under the brush. In the **commutating-pole motor** this latter function is accomplished by auxiliary poles placed between the regular poles. These are excited by a few turns in series with the armature circuit so that their strength is proportional to the motor load. The main field flux strength may be altered without affecting the commutation, consequently such motors are better adapted for adjustable-speed service and counter e.m.f. control by varying the field strength. The development of the commutating pole has made it possible to design generators (see Table 19) and motors for 1200 volts and higher. The same device is also used to some extent in alternating-current commutating machines.

Table 20. Amperes per Motor at Different Voltages for Several Sizes of Motors at Efficiencies Obtained in Ordinary Practice

20	90	16,578	151.0	75.4	30.1						

In many instances commutation difficulties are encountered even in commutating-pole machines. The commutating poles may be connected incorrectly. In a motor, passing from a N main pole in the direction of rotation of the armature, a N interpole should be encountered, as shown in Fig. 60. In a generator under these conditions a S pole should be encountered. The test may be easily made with a compass. If poor commutation is caused by too strong interpoles, the winding may be shunted. If the poles are too weak they may be strengthened by inserting sheet-iron shims between the pole and the yoke.

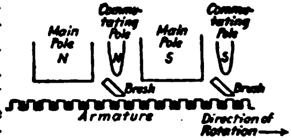

Fig. 60.

Alternating-current Generators

Alternating-current Generator. The usual type of alternating-current generator consists of a separately excited field winding mounted upon revolving field poles, and a stationary armature with coils embedded in slots. The direct current for excitation is carried to the revolving fields by means of slip rings and brushes. The earlier generators, were made with revolving armatures, following the design of direct-current generators, but alternators are generally built for higher voltages, so that the revolving-field type possesses the advantages that the armature insulation problem is more easily met and no slip rings are necessary to conduct the current from the armature. The armature and generally the fields are laminated to reduce eddy-current losses. The armature may have a wave winding or a coil winding. In **single-phase machines** one set of armature coils is provided, in **two-phase machines** two sets of armature coils are placed on the armature and spaced 90 electrical degrees apart, and in **three-phase machines** three sets are spaced 120 deg. apart and may be connected either in delta or in Y. The standard wave shape is the sine curve. With a single turn the wave shape would be that of the magnetic flux distribution under the poles, but where the conductors are in a belt, the voltage wave may differ materially from the flux wave. The designer may control the wave form by varying the flux distribution, by varying the distribution of the turns, by concentrating in two slots or distributing them among several slots. The standard voltages are 1100, 2200, and 6600, and machines can be built to deliver as high as 20,000 volts; however, the successful insulation of such machines imposes difficulties and added cost, which do not often justify their use. In connection with a transmission line of moderate length the elimination of step-up transformers may make the use of high-voltage generators desirable. The **frequency**, expressed in cycles per sec., is always the product of the number of pairs of poles and the number of revolutions per sec. The standard frequencies were formerly 125 and 133, and some of these machines are still in use, but the standards are now 60 for combined lighting and power service and 25 for power. The cost of apparatus is greater for the lower frequencies, but the operation of induction motors, synchronous apparatus and commutating motors is much more satisfactory at low frequencies. An additional reason for using low frequencies is that voltage regulation of machines and transmission lines is better. It is customary to use the **kilovolt-ampere** (kva.) as the unit in rating the capacity of generators rather than the kilowatt, for the reason that the heating of the machine is determined by the value of the current regardless of what the power factor of the load may be.

Fundamental Equation. If the useful flux per pole linking with the armature conductors is Φ and there are N conductors in series, the **average generated e.m.f.** in volts with a frequency of f will be $E = 2\Phi N f \times 10^{-8}$, since for each cycle 2Φ lines of force are cut by each armature conductor.

The effective value of the generated e.m.f. is $E = k \times 2\Phi Nf \times 10^{-8}$, where k is the form factor of the wave of e.m.f. and also of the flux distribution curve. It is assumed that there is no differential action, that is, that the armature conductors are concentrated so as to pass similar points of the flux curve simultaneously so that the e.m.f.'s generated in the armature conductors are all in phase. If this is not the case, a new constant k' must be introduced into the equation to express the magnitude of the differential action. The relation then is $E = k'k \times 2\Phi Nf \times 10^{-8}$.

Inductor Alternators. Especially before alternators were built with revolving fields and when higher frequencies were standard, certain advantages pertained to inductor alternators in which neither armature conductors nor field windings revolved. The flux linking with the armature conductors was varied by masses of iron passing the poles and armature so as to increase and decrease alternately the magnetic reluctance in the path of the flux. At the lower frequencies now used they do not seem to possess advantages over the revolving-field type and are not generally used.

Merits of Single-phase versus Polyphase Generators. In a single-phase machine not more than half of the armature can be utilized for armature conductors on account of differential action. In two- and three-phase machines the entire armature may be utilized, consequently a single-phase generator has not more than about 66 per cent. of the capacity of a polyphase machine using the same frame. It is possible to generate as polyphase and transform to single-phase power. Single-phase current may be taken from a three-phase generator either by simply using one phase, or the three-phase windings may be connected in series. In either case the phases will be equally unbalanced and no advantage is to be gained by the latter method. Three-phase generators are frequently used to supply three separate single-phase circuits, so that advantage may generally be taken of the greater weight-efficiency of polyphase generators even where single-phase power is desired.

Regulation. The factors entering into the voltage regulation of an alternating-current generator are the armature resistance, the armature leakage reactance, and the armature reactions. The leakage reactance is due to the lines of force generated by the armature current which link with the armature conductors only. The armature reactions are the effects produced by the magnetomotive force of the armature ampere-turns upon the field flux. The effect of the component of current ($I \cos \phi$) in phase with the generated e.m.f. is to strengthen the trailing pole tip and to weaken the leading pole tip of a generator. The effect of the quadrature component of current ($I \sin \phi$) is to oppose the field m.m.f. in the case of an inductive load and to aid it in the case of a leading current. These various reactions are represented in terms of e.m.f.'s in Fig. 61, where OA, AB, BC and CD are respectively the voltages consumed by load resistance, reactance, armature resistance and leakage reactance; EF, FD and ED respectively represent the effects on the voltage of the demagnetizing effect of armature, the cross-magnetization of armature ampere-turns and the combined effect of armature ampere-turns; and CE and BE are the voltages respectively consumed by synchronous reactance and by synchronous impedance. OB is the terminal voltage of the machine and OE is the voltage on open circuit with the same excitation. The open-circuit voltage OE may be determined trigonometrically as follows:

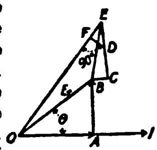

Fig. 61.

$$OE = \sqrt{(E_t \cos \theta + IR)^2 + (E_t \sin \theta + IX_s)^2}$$

where E_t = terminal volts = OB; θ = angle between load current and voltage; I = load current; R = effective armature resistance; X_s = synchronous reactance.

$$\text{Percentage regulation} = \frac{OE - E_t}{E_t} 100$$

The term **synchronous impedance** is a fictitious but useful one by which the combined effect of the armature resistance, reactance and armature reactions may be expressed. The synchronous impedance is not quite constant for all loads, but is frequently assumed to be so without serious error. The method of measuring it is to short-circuit the armature through an ammeter and then gradually increase the field excitation from zero until full-load current is indicated by the ammeter. A reading of the terminal voltage of the machine with the armature open, and with the same field excitation, is then taken. The assumption is made that the e.m.f. measured upon open circuit is that consumed by synchronous impedance when the current I flows, consequently impedance Z equals the ratio E/I. The synchronous reactance $X_s = \sqrt{Z^2 - R^2}$, but R is usually so small that $Z = X_s$ nearly. Due to slot iron losses the apparent alternating-current or effective armature resistance is from 1.2 to 1.6 times the resistance measured with direct current. The demagnetizing effect of the armature current may be somewhat different under the conditions described for determining synchronous impedance than it would be with the fields fully excited, especially if the magnetic density is above the knee of the magnetization curve under normal excitation. As a result, determinations of alternator regulation by this method may be unfavorable. An inspection of Fig. 61 shows that with a fixed armature current the regulation is much poorer when the current lags than when it is in phase with the terminal volts. A leading current may produce 0 regulation or even negative (no-load volts less than rated-load volts). The magnetomotive force method of determining regulation is as follows: Add the IR drop vectorially to the rated terminal voltage E_t. From the saturation curve look up field current I' (Fig. 62) corresponding to E'. I_2 is the field current necessary to send rated current through the armature under short-circuit conditions. Add I_2 and I' vectorially as shown, obtaining current I_0. The voltage corresponding to I_0 is the open-circuit voltage, E'.

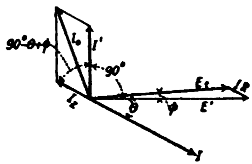

FIG. 62.

$$\text{Percentage regulation} = \frac{E' - E_t}{E_t} 100$$

The angle ϕ is usually negligible and can be assumed equal to 0. At unity power factor, $I_0 = \sqrt{I'^2 + I_2^2}$. This method yields results which are better than the actual regulation. The actual regulation lies somewhere between the values obtained with the synchronous impedance and the magnetomotive force methods. **Voltage regulators** have been perfected which maintain constant voltage satisfactorily under all conditions of load. In the **Tirrill regulator** a voltage relay operates to vary the resistance in the field of the exciter so that constant voltage is maintained at the switchboard. Similar regulators are also applied to direct-current generators.

Parallel Operation of Alternators. Successful parallel operation of alternating-current generators demands that the generators so coupled shall have similar characteristics; unless they have very nearly similar voltage wave forms, a prohibitive amount of current will circulate between the machines, causing needless heating and thereby reducing their useful output. For parallel operation, too close voltage regulation is not desirable, for, although close regulation may mean low armature impedance and therefore greater synchronizing force, there is greater danger of an excessive rush of current at the instant of synchronizing them and greater liability of excessive current if one machine is thrown out of step. The armature impedance should be large enough to prevent a dangerous current flowing when it is short-circuited across the bus bars. A machine having 8 per cent. regulation has sufficiently close voltage regulation and at the same time is rugged enough to insure immunity from burnout in case it falls out of step. Especially in the case of large generators there is an advantage in using machines of low armature impedance and inserting an air-core impedance in the external circuit to limit the short-circuit current, because the magnetic circuit is sluggish and armature reactions are slow to act to limit the short-circuit current. Successful parallel operation is as much a function of the prime-mover characteristics as of the generators. Since the generators, and consequently the prime movers, are in step, the division of load among them cannot be controlled by the field rheostats, as is the case with direct-current generators. The machine ammeters apparently indicate a shifting of the load when the field excitation is varied, because the wattless interchange current is changed, but the wattmeters indicate no appreciable change of load. The division of the load depends upon the adjustment of the engine governors. If the speed-load characteristics of the prime movers are identical, the machines will assume their proper proportion of the total load as it varies. If the speed-load characteristics differ as shown in Fig. 63, each will take the load indicated by the intersection of its characteristic with a horizontal line representing the speed. Very close speed regulation is not desirable on account of the greater difficulty of adjusting the governors to insure proper division of load, and 5 per cent. regulation is commonly used. The governors should be adjusted for proper division of load under full-load conditions, because unequal loading is not detrimental at partial loads. A more important requirement of the prime movers is that the angular velocity be uniform, otherwise the machines will alternately lead each other during a revolution, and if the natural period of mechanical oscillation of the revolving elements corresponds with the forced oscillations, troublesome hunting or mechanical resonance ensues. Water and steam turbines are inherently better adapted to parallel operation than reciprocating engines, on account of their uniform angular velocity. For successful parallel operation it is recommended that the rotating element shall not be allowed to deviate by more than one-sixtieth of a pole pitch or three electrical degrees from the mean position it would occupy if the angular velocity were exactly uniform. It is common practice to provide alternating-current machines with dampers or "amortisseur" windings to minimize the tendency to hunt. These consist of grids of conducting material surrounding or embedded in the pole pieces, so that any change of field flux, which must accompany hunting, will set up eddy currents in the dampers and oppose the action which induces them.

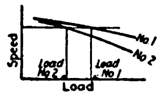

FIG. 63.

Stability in parallel operation results from having the leading machine always more heavily loaded than the lagging machine. Stable operation will result so long as the effect of the synchronizing current to load the leading machine is greater than that of the load current to load the lagging machine. On heavy inductive loads the machines may be thrown out of step. Capacity loads, on the other hand, tend to improve the stability.

Table 21. Approximate Performance Values of Alternating-current Generators

(From "American Electrician's Handbook," Terrell Croft)

Values vary with speed and other conditions. Those given are approximate only. A slow-speed machine, *S*, makes 100 to 200 r.p.m.; a medium-speed machine, *M*, makes from 200 to 300 r.p.m., and a high-speed machine, *H*, makes 300 to 1200 r.p.m.

Kva. output		Current at 1200 volts		Efficiency			Exciter capacity required, kw.
		Three-phase	Two-phase	½ load	¾ load	Full-load

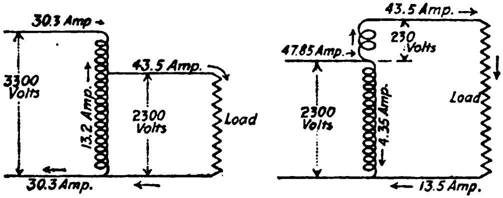
[1] Engine-type machines—efficiencies do not include friction of bearings.

Transformers, Converters, Rectifiers

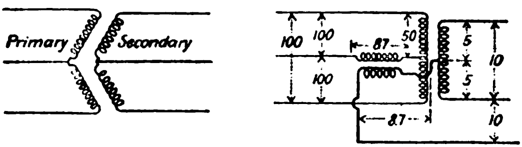
Transformers. Alternating currents may be transformed from one voltage to another by the use of a transformer consisting of a primary and a secondary electrical circuit, each linking with a common magnetic circuit. Since the same magnetic flux links both circuits the same voltage is induced per turn and therefore the voltages of the two coils are in proportion to the number of turns they contain. The **fundamental equation** of the transformer is $E = k \times 4\Phi_m f n 10^{-8}$, where E is the effective value of the impressed e.m.f. in volts, Φ_m the maximum value of the magnetic flux, f the frequency, n the number of primary turns, and k the form factor of the e.m.f. wave. When the e.m.f. is a sine curve, the equation reduces to $E = \sqrt{2}\pi f \Phi_m n 10^{-8}$. Transformers are built for a great variety of service and in capacities from a fraction of a kilovolt-ampere to 10,000 kva. and for voltages as high as 500,000. Ordinarily, transformers are used for the purpose of transforming constant voltage to another constant voltage. Assuming constant voltage applied to the primary, the secondary voltage will decrease slightly with increase of load due to the combined effect of resistance of the windings and the magnetic leakage, which, combined, make up the impedance of the transformer. The effect of the impedance is to cause a greater drop of voltage upon an inductive load than upon a non-inductive one, and a capacity load tends to counteract the effect of the impedance and may cause an actual rise of the secondary voltage with increased load. A load consisting of induction motors or other inductive apparatus having a low power factor, therefore, demands a lower transformer reactance than a non-inductive lighting load for the same percentage regulation. The energy **losses** involved in a transformer are the iron and the copper losses. The hysteresis losses constitute the major portion of the iron losses and are proportional to the 1.6 power of the maximum magnetic flux and directly proportional to the frequency. The eddy-current losses of the iron are proportional to the square of both the magnetic flux and the frequency. The maximum magnetic flux is directly proportional to the impressed voltage. The combined iron losses are approximately constant in **constant-potential transformers,** regardless of load. The copper losses are proportional to the square of the current. The efficiency of a transformer is best determined by measuring these losses and calculating the efficiency as the ratio of output/(output + losses). The iron losses are constant and may be measured by a wattmeter by applying normal voltage to the low-tension terminals and leaving the high-tension winding open. The copper losses can be calculated from the measured resistance of the windings, or they should be measured by applying to the high-tension terminals a low voltage sufficient to cause full-load current to flow through the short-circuited secondary. Low iron losses are especially important where, as in lighting loads, the transformer is only loaded for a few hours during the day, because the iron losses continue through the whole day. The **maximum efficiency** results when the iron losses and copper losses are equal. The all-day efficiency is the ratio of the total energy output for the day to the total energy input. It is customary to immerse the core and windings in oil, because of its greater dielectric strength and because the energy losses are more rapidly dissipated by oil, thus increasing the output without exceeding the safe limit of temperature. In the larger sizes the dissipation of heat is accelerated by a system of water circulation or by an air blast. Transformers for converting energy at constant potential to **constant current** are used for operating series arc-light circuits from constant potential circuits. This transformation is accomplished by having one of the coils movable with respect to the other and so balanced that the repulsion existing between the coils, due to their currents flowing in opposite directions, varies their distance apart and hence their mutual inductance. An **auto-transformer,** also called **compensator** or **balancing coil,** consists of a single coil linking with a magnetic circuit. Part of the energy is *transformed* and part flows through conductively. Suitable taps are provided so that if the primary voltage is applied to two of the taps, a voltage may be taken from any two taps which bears to the primary voltage the ratio of the turns included between the primary and secondary taps. It is desirable to install an auto-transformer when the ratio of transformation is not great. The ratio of energy transformed to total energy is $\frac{n-1}{n}$, where n is the ratio of transformation. This represents the saving over the ordinary transformer and is greatest when the ratio is small. Fig. 64(*a*) shows 100 kw. being transformed to from 3300 volts to 2300 volts; 30.3 kw. only are being actually transformed and the remainder of the power flows through conductively. Fig. 64(*b*) shows how an ordinary 10:1 10-kw. lighting transformer can be connected to boost 110 kw. 10 per cent. in voltage. The pressure may likewise be reduced by reversing the 230-volt coil. An auto-transformer should never be used when it is desired to keep dangerous primary potentials from the secondary. This type is used for starting induction motors and for a number of other similar uses.



(a.) (b.)

FIG. 64.

Polyphase Power Transformation. For the transformation of polyphase power single-phase transformers may be used. In the case of three-phase power it is frequently advisable to use three-phase transformers, for they cost less than an equal capacity in single-phase transformers. Trouble in one phase, however, means that all three phases must be shut down. The primaries and secondaries may be connected either in Δ or in Y; however, with a non-sine wave form it is important for satisfactory operation to use connections which will give similar secondary e.m.f.'s and current waves. For operation on high voltages the Y connection is frequently preferred, for the reason that the transformers need only be insulated to safely withstand $1/\sqrt{3} = 0.58$ times the line voltage when the neutral is grounded. In the



V-connection. T-connection.

FIG. 65.—Transformer Connections for Transforming Small Amounts of Three-phase Power.

case of high-tension transmission, the Δ connection possesses the advantage that if one of the transformers becomes disabled the other two will continue to carry the load until the third one can be replaced. For the transformation of small amounts of power from three-phase to three-phase, two transformers are frequently used as a permanent installation. Either the V- or the T- connection may be used. These are shown in Fig. 65. The capacities of these systems are only 58 per cent. of the capacity of the system using 3 similar transformers, one for each phase.

Table 22. Performance of Distributing Transformers

(From Croft's "Am. Electrician's Handbook")
Average values for 2200 to 220–110-volt, 60-cycle transformers

Kva.	Watts loss		Per cent. efficiency				Per cent. regulation				Per cent. exciting current

To transform from two- to three-phase or *vice versa*, the T-connection shown in Fig. 66 is used. To make the secondary voltages symmetrical a tap (called a Scott tap) is brought out at 87 per cent. ($\sqrt{3}/2$) of the primary winding of the auxiliary transformer as shown in Fig. 66. With balanced no-load

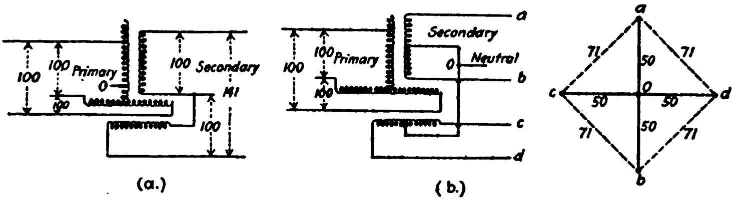

Fig. 66.—Connections for Transforming from Two-phase to Three-phase.

voltages the voltages become slightly unbalanced even under a symmetrical load, due to unequal phase differences in the individual coils. The three-phase neutral is ⅓ the distance along the auxiliary transformer from the junction.

Synchronous Converter. The synchronous converter is essentially a direct-current dynamo with the addition of collector rings connected to suitable points of the armature winding. This machine is generally used for converting polyphase alternating current to direct current. In large generating plants and where power is to be transmitted more than a few miles, alternating-current apparatus generally is employed and synchronous converters are used to transform the alternating current to direct current. The same machine may be used to convert direct current to alternating current or it may be used as a double-current generator to supply alternating and direct current simultaneously. It may be used as a three-wire direct-current generator by connecting the neutral wire to the center of an auto-transformer across the alternating-current end. The rotary converter is cheaper and much more efficient than a motor-generator set of the same capacity, as there is only one armature, one field, and the armature conductors need only carry a current equal to the *difference* of the motor and generator current. The capacity is increased materially by running six-phase, as shown in the following table:

Power factor	Continuous-current generator	Single-phase converter	Three-phase converter	Four-ring converter	Six-phase converter
100 per cent.	100	85	132	161	194
95.5 per cent.	100	78	120	145	170

Assuming a sine-voltage wave, the direct-current voltage is the peak of the diametrical alternating-current voltage waves. The voltage relations for sine waves are as follows: Direct-current volts, 141; single-phase, 100; two-phase, diametrical, 100; two-phase, adjacent taps, 71; three-phase, 87; six-phase, diametrical, 100; six-phase, adjacent taps, 50.

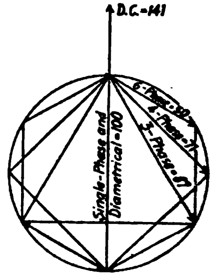

FIG. 67.

These relations are obtained by finding the sides of polygons inscribed in a circle having a diameter of 100 volts, as shown in Fig. 67. When used to convert alternating to direct current, the machine must be in synchronism with the alternating supply. Generally, the same methods of starting and synchronising are used as for synchronous motors, but occasionally the machine is brought to speed as a direct-current motor by supplying direct current to the commutator end. When operated inverted (direct current to alternating current) some centrifugal or electric device must be employed to prevent the rotary from running away, as it will if a highly inductive load is applied. To vary the voltage of the direct-current end, the applied alternating voltage must be varied or the wave shape must be altered. To vary the ratio of transformation by the latter method, special split-pole converters are built, in which the space distribution of the field magnetism is altered by subdividing the field poles into two or three sections. By varying the ampere-turns of the sections the wave form and ratio of transformation may be varied to a limited extent.

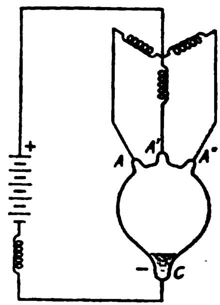

FIG. 68.—Mercury-arc Rectifier.

Rectifiers. In many cases, where only an alternating-current source of energy is available and it is desirable to use direct current of relatively small magnitude for special purposes, such as the charging of storage batteries, operation of arc lamps for projection lanterns, etc., it is found convenient to make use of some form of rectifying apparatus. The rectifiers available for this class of service which can be operated from an alternating source of supply and will deliver a rectified or direct current, are vibrating armature rectifiers, selective spark-gap rectifiers, and mercury-arc rectifiers. The **mercury-arc rectifier** makes use of the selective action of an arc in mercury vapor between mercury (—) and graphite or iron (+) electrodes, and consists (Fig. 68) of an evacuated glass bulb containing a pool of mercury, *C*, and as many graphite or iron electrodes, *A'*, *A″*, *A‴*, as there are leads in the supply circuit. The figure shows the circuits for a three-phase rectifier. These rectifiers may be had in capacities up to about 50 amperes direct current, with voltages of from about 5 to 110 volts direct current, and can be operated from 110- or 220-volt circuits. In Fig. 69 are given the performance characteristics of a General Electric 20-ampere rectifier set. The **Murphy rectifier** is a representative of a class of apparatus in which the rectifying action depends upon the selective characteristics of a particular kind of high-tension spark gap. The performance curves of a 10-ampere Murphy rectifier are given in Fig. 70.

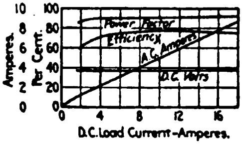

Fig. 69.—Performance of a 20-amp. G. E. Co. Rectifying Set.

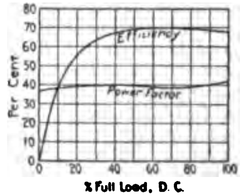

Fig. 70.—Performance of a 10-amp. Murphy Rectifier.

Alternating-current Motors

Induction Motor. In fundamental principle the induction motor is identical with the transformer. A two- or a three-phase e.m.f. is applied to phase windings displaced 90 or 120 electrical degrees from each other, depending upon whether the motor is two-phase or three-phase. A rotating magnetic field is set up which revolves at synchronous speed (r.p.m. = frequency × 60/number of pairs of poles) and cuts the conductors of the short-circuited secondary winding and produces a current therein. Since the secondary current finds itself in a magnetic field, torque is produced. The maximum e.m.f. is induced in the secondary at standstill or when the slip is 100 per cent. The motor can never attain full synchronous speed because at zero slip there is no induced secondary current. The torque is directly proportional to the magnitude of the rotating field and the component of the secondary current in phase with the field. The secondary has leakage reactance, and at the slower speeds and at starting the secondary frequency is high and the secondary current lags behind the secondary e.m.f., and the primary field, and consequently the torque, is ordinarily low under these conditions. The torque at starting can be improved by adding resistance to the secondary circuit so long as it increases the in-phase component of current. As the motor attains normal running speed the secondary resistance is reduced, for then the slip and secondary frequency are low. The induction motor is inherently a **constant-speed machine**, but where it is to be operated for variable-speed work it is customary to provide the secondary with slip rings so that the secondary resistance and power factor may be varied, and the maximum torque developed at all speeds. A great drawback to the induction motor is its poor power factor, necessitating added investment in machinery and distribution system to carry the reactive component of current. The effect of the poor power factor upon the voltage regulation of the system is an additional drawback. Its advantages are great simplicity and ruggedness, and it is finding extended application in a great variety of work in units of all sizes. The development of automatic controlling devices has considerably widened the field of application of induction motors.

Induction motors are made with two types of **rotors**, the **squirrel cage**, in which the inductors are copper bars embedded in longitudinal slots in the laminated steel rotor core and are connected in parallel to short-circuiting copper rings, one at each end of the rotor; and the **wound rotor,** in which the winding is polar, and the terminals of the windings are connected to a resistance carried on the rotor spider or through slip rings to an external controlling resistance, which resistance may be cut out when the proper speed is attained. Polyphase squirrel-cage induction motors are used for constant-speed service where starting and reversing are infrequent. Their starting torque is relatively small, and a large starting current (2 to 6 times the full-load current) is drawn from the lines if the motor must start full-load torque. Such motors have no moving electrical contacts (hence are sparkless) and are advantageous for use in places where exposed to inflammable gases or dust. By increasing the rotor resistance, small motors of this type may be built for high starting torque, rapid acceleration and frequent starting, for the operation of punches, presses and similar machinery, where simplicity is desirable. Motors with wound rotors and internal starting resistance give about 1½ times full-load torque with approximately 1½ times full-load current, making them suitable for use on lighting circuits and for other applications where a minimum starting current is desirable. They will develop a greater starting torque per ampere than those of the squirrel-cage type, but should not be applied to overcome great inertia or excessive static friction.

If, while an induction motor is connected to a source of power it is driven at a speed above synchronism, it becomes an **induction** or **asynchronous generator** and returns electrical energy to the line without any change of connections whatever, for, when driven above synchronous speed, the rotor conductors cut the lines of force of the rotating field in a direction opposite to that when the rotor speed is less than the speed of the field, and hence mechanical power applied to the shaft is converted into electrical power. The greater the negative slip, the greater is the load assumed by the induction generator, and for this reason practical application of the induction generator is sometimes made in connection with exhaust-steam turbines which are run without governors. In this way all the power available from the exhaust steam is converted to electrical energy by the induction generator, which is connected in parallel with the synchronous generators driven by the engines exhausting into the exhaust-steam turbine. Upon short-circuit, the induction generator has the desirable characteristic of not delivering any power. It must always be used in parallel with some synchronous apparatus. Induction motors are not infrequently **used in railway work,** especially in mountain electric railways, where it is advantageous to make use of the motors as induction generators on the down grades as electric brakes returning power to the circuit. When two motors are mechanically connected and the secondary of one motor is electrically connected through slip rings to the primary of the other motor, they are said to be **connected in concatenation or** in **cascade**; thus connected they operate efficiently at a little less than half speed, and if driven at more than half synchronous speed they return power to the circuit.

Single-phase Induction Motor. If from a polyphase motor which is running, one of the line wires is disconnected so that but one phase remains connected to the supply circuit, the motor will continue to run as a single-phase induction motor. If all the phases of another polyphase motor be connected to the terminals of the motor which is running as a single-phase motor, the second motor can be started as a polyphase motor. The first motor is in fact acting as a transformer, converting single-phase power into polyphase power, for the rotor currents of the single-phase motor combine with the supply current to produce a rotating magnetic field as in a true polyphase motor. The great drawback of the single-phase induction motor, aside from some disadvantage in the matter of weight, is the lack of any starting torque. This necessitates that the motor be started either as a polyphase motor by applying polyphase or split-phase power to it, or that it be provided with auxiliary windings to start it as a series or as a **repulsion motor.** All of these methods are used in practice, but the single-phase motor is only used in small sizes where polyphase power is not available.

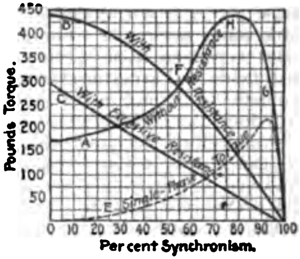

Fig. 71.—Torque Curves of an Induction Motor with Wound Rotor.

The torque curves of an induction motor with a wound rotor, from rest to synchronism, running both three-phase and single-phase with resistance and without resistance, are shown in Fig. 71. Curve *A* shows the torque from rest to synchronism without resistance in the rotor circuit. If resistance is inserted, curve *B* is obtained. Curve *C* indicates the torque where too much resistance is used in the rotor. Curve *E* illustrates the torque single-phase, which is zero at starting. An induction motor starts as shown on curve *B* until it reaches the point *F*, when the resistance is cut out and the motor adjusts itself to its operating position at *G*. Thus, if the torque required of the motor is greater than that shown at *H*, the motor will stall. With the resistance in the rotor, a starting torque *B* is available, but this load cannot be brought up to normal speed. The motor can only bring the torque represented by the point *F* up to normal speed. The torque is always zero at synchronism.

Table 23. Approximate Data on Standard Induction Motors
(220, 440 and 2200 volts,* two-phase and three-phase.—From "American Electricians' Handbook")

* 2200-volt motors are seldom made in capacities under 20 to 30 h.p.

† Efficiencies of 25-cycle motors are slightly lower than those of 60-cycle motors, due to their lower speeds.

The **starting current** for full-load torque varies from 2.7 to 3 times the full-load current for sizes up to 50 h.p., and from 3 to 3.5 times for sizes from 50 h.p. to 200 h.p. The **starting torque** at rated voltage averages from 1.3 to 1.5 times the full-load torque. The **pull-out torque** varies from 2.3 to 3 times the torque at full-load current.

Alternating-current Commutator Motors. A number of different motors have been developed for operation upon single-phase circuits. The use of alternating-current motors in railway work makes it feasible to transmit the power at high voltage and to use it without intermediate substations and the accompanying synchronous converters. In the smaller sizes, single-phase commutator motors are chiefly used where polyphase power is not available. For railway work series motors or a modification of the series type are used. Such motors have both fields and armature laminated, and the problems to be met in the motor design are to reduce the self-inductance and sparking to a minimum. This has been accomplished by using low frequencies, compensating windings to neutralize armature reaction and preventive leads to still further reduce sparking. Alternating-current commutator motors with shunt characteristics are available in small units. These are generally single-phase induction motors or modifications which have starting torque and are compensated also to give a high power factor. Fig. 72 gives the operating characteristics of a 5-h.p. motor of this type.

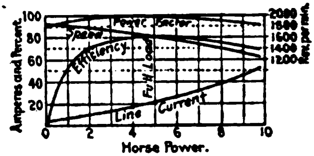

FIG. 72.—Characteristics of a 5-H.P. A.C. Commutator Motor.

Synchronous Motor. When alternating current is supplied to an alternator which is in synchronism with the supplied current, the alternator becomes a synchronous motor. Such motors find considerable application in power-transmission systems. They possess the disadvantage that they are not inherently self-starting, so that they have not been very generally adopted for ordinary power requirements. Their speed is constant regardless of load, which characteristic is often valuable. A characteristic which makes them particularly adapted to use in power-transmission systems is that their power factor may be controlled and varied through a wide range by varying the field excitation. Normal excitation which gives unity power factor produces a motor e.m.f. about equal to the applied e.m.f. Excitation below normal causes the machine to act like an inductive load and above normal causes it to act like a condenser in drawing a leading current. A synchronous motor may be started as an induction motor by opening the field circuit in several places and applying a reduced e.m.f to the armature until nearly synchronous speed is attained. The revolving field thus produced reacts upon the field poles to start the motor. The starting torque thus obtained is not high and a large inductive current is demanded. Another method is to use a small induction motor having one less pair of poles than the connected synchronous motor. If connected to a direct-current generator, this may be used as a shunt motor to start the synchronous motor.

Synchronous motors are often "floated" or run light, overexcited, at the end of transmission lines to balance the reactive current due to inductive loads. Under these conditions they are called **synchronous condensers.** The present long-distance lines require synchronous motors with field regulators at the load end to keep the line regulation within reasonable limits by supplying lagging or leading current.

Flywheel Equalizer. Conditions may be such that sudden overloads occur only intermittently some distance from the station, so that a large investment in copper is not justified as it would be if the maximum power were a steady load. If the load be intermittent and the copper loss of the transmission line large, the voltage regulation will be poor. If the load fluctuations are rapid, the regulation may be improved by the installation of a flywheel equalizer, which is nothing more than a shunt dynamo provided with a flywheel. At the periods of light load the voltage impressed upon the equalizer will be high and the speed will be accelerated. When the load is heavy the terminal voltage will fall and the equalizer machine will now return energy to the circuit at the expense of the momentum of the flywheel. Storage batteries floating upon the line would accomplish the same purpose, but, on account of their cost, are only superior to the flywheel method of storing energy when the fluctuations are so infrequent or of such long duration that the flywheel scheme becomes impracticable.

Rating of Electrical Apparatus—Efficiency

Rating. All electrical apparatus should be rated by output and not by input, and electrical power should generally be expressed in kilowatts. The rating of electrical apparatus is as a rule chiefly determined by the maximum temperature at which the materials in the machine, especially those employed for insulation, may be operated for long periods without deterioration. The effect of too great a temperature may also cause the hysteresis loss of the iron to increase permanently. The aging of iron and injury to the insulating materials usually employed in electromagnetic machinery begin at a temperature of about 85 deg. cent. Since the temperature does not rise immediately to its ultimate value, it is permissible, as far as temperature is concerned, to overload the apparatus so long as the safe temperature is not exceeded. Extracts from the Standardization Rules of the American Institute of Electrical Engineers, covering these matters, are as follows:

Temperature Limits. The highest temperatures attained in any machine corresponding to the output for which it is rated must not exceed the following values: For cotton, silk, paper and other fibrous materials, not so treated as to increase the thermal limit, 95 deg. cent.; for cotton, silk, paper and other fibrous material treated or impregnated and including enameled wire, 105 deg. cent.; for mica, asbestos or other material capable of resisting high temperatures, in which the previous materials, if used, are for structural purposes only, and may be destroyed without impairing the insulating or mechanical qualities, 125 deg. cent.; for fireproof and refractory materials, no limit specified. The limits of temperature rise permitted under rated-load conditions are found by subtracting 40 deg. cent. from the figures just given, whatever be the ambient temperature at the time of the test.

In commutator generators or motors the sparking limit may be below the heating limit under some conditions. Ordinarily, the sparking limit is higher than the heating limit, but in shunt motors, if the field strength is reduced to increase the motor speed, the sparking becomes excessive before the safe temperature limit has been exceeded. In distribution circuits the Underwriters' rules specify safe carrying capacities for the various sizes of conductors, see p. 1652. Except for very short circuits the voltage variation permissible on the receiving apparatus determines the size of conductors. Kelvin's law of economy (see p. 1651) is sometimes the determining factor in the size of conductor chosen.

Efficiency of Electrical Apparatus. The losses to be considered in electrical apparatus are iron losses, copper or I^2R losses, and, where there are revolving parts, friction losses. In constant-speed machinery or machinery operating under constant e.m.f., as is generally the case, the iron losses are constant regardless of load. The copper losses are proportional to the square of the load current. To determine the efficiency of electrical apparatus the method sometimes employed is to measure both output and input. This method is open to the objection that it is difficult to measure mechanical input or output with as great accuracy as electrical quantities may be measured. A more accurate and satisfactory method is to determine the efficiency by assuming different outputs and calculating the corresponding losses from simple measurements. In a dynamo the constant iron and friction losses may be measured by operating the machine as a motor upon the normal voltage and without load. The constant losses are bearing and brush friction, windage, field I^2R loss and armature hysteresis and eddy-current losses. From the measured resistance of the armature (including brushes and brush contact resistance), the armature I^2R losses may be calculated for any assumed output or input. The efficiency is then calculated from the ratio Output/(Output + Losses) if efficiency as a generator is being considered, and from the ratio Input/(Input − Losses) if motor efficiency is desired. The maximum efficiency occurs at the point at which the variable copper losses and the constant losses are equal.

Control of Direct-current Motors

Starting Direct-current Motors. The fundamental e.m.f. equation of the direct-current motor (see p. 1616) may also be written as

$$E = (\Phi ZN/10^8) + I_aR_a \qquad (1)$$

Since the armature resistance I_a is made as small as possible, in order to limit the heating effect in the motor and to maintain high efficiency, the quantity I_aR_a will be small and the counter pressure $\Phi ZN/10^8$ will be very nearly equal to the impressed pressure E. When the armature is not rotating, however, the counter pressure is zero, since the speed N is zero. If the motor is connected to the source of power under these conditions, the relation will be expressed by $E = 0 + I_aR_a$, and it is evident that the armature current I_a will necessarily be abnormally high until the armature has reached such a speed as to generate an appreciable counter pressure. It is, therefore, necessary to introduce additional resistance into the armature circuit of the motor while it is being started. This resistance is usually made up of several steps so that, as the speed of the motor increases, the total resistance can be decreased and gradual acceleration of the motor obtained.

In some motor applications it is desirable to have the starting operations automatically controlled or to have the motor started by pushing a button or closing a switch at some remote point. The two most important methods used in controlling the operations of **automatic motor starters** are (*a*) by a dash pot, and (*b*) by series or current relays. Automatic starters of the **dash-pot type** consist of a solenoid and dash-pot attachment applied to the starting arm of a common manually operated starting box. Closing the main switch energizes the solenoid, which is connected across the line in shunt with the motor, and causes its plunger to move the starting arm upward, cutting out the starting resistance. The rate at which the arm moves is controlled by the dash pot. When the main switch is opened, or the power supply is off, the starting arm falls to its zero position. If the motor is to be started from a distant point, it is not necessary to extend the main current carrying lines to this point. The solenoid circuit can be run to this point and an auxiliary switch installed to control it. This type of starter is used very frequently with motor-driven pumps controlled by float switches and motor-driven air compressors controlled by pressure gages.

The **control of a starter by series or current relays** is the method most generally used in the automatic starting of motors. In this scheme the operation of the switches is controlled by the current in the armature circuit of the motor. Fig 73 shows diagrammatically a controller of this type. The operation in starting is as follows: The power is supplied to the controller by the closing of the main switches S_2 and S_1. The closing of the master switch *MS* closes the circuit through the shunt field and through the electromagnet M_1. Electromagnet M_1 closes contactor 1, allowing current to flow through relay A_1, the total starting resistance, and the motor armature, and causing the motor to start. The plunger of relay A_1 is drawn up, due to the flow of armature current through its winding, and breaks contact at P_1. As the motor accelerates, the armature current decreases until it reaches a value that allows the plunger of A_1 to drop and close the contacts at P_1. This completes a circuit through contact P_4 and electromagnet M_2, and energizes this electromagnet so that contactor 2 is closed. The armature current now flows through relay A_2 and resistance R_2, the first step in the starting resistance being short-circuited. The plunger of relay A_2 is held up until the current again drops to the minimum value, which allows contact P_2 to be closed. The operation is repeated until the total starting resistance has been cut out of the circuit and the motor runs with its armature directly across the line. It will be noted that the armature current varies between maximum and minimum values, the maximum current being determined by the total resistance in the armature circuit at the instants that the contactors close and the minimum values by the adjustment of the series relays. To give the best starting conditions, the contactors should close for the same minimum value of current, and the different inrushes of current should reach the same maximum value. In practice, the relays are set to close at about full-load current, while the resistances are adjusted to give about 50 per cent. overload current. To stop the motor it is only necessary to open the master switch *MS*. It should also be noted that if the power mains become dead, the motor will stop and automatically start again, without any attention whatever from the operator, when the power returns. When a manually operated starter is used, the rapidity with which the starting resistance is cut out is left to the judgment of the operator. If the resistance is cut out too rapidly damage to motor or machine may result. On the other hand, if the resistance is cut out too slowly, there result waste of time and possibly burning out the rheostat.

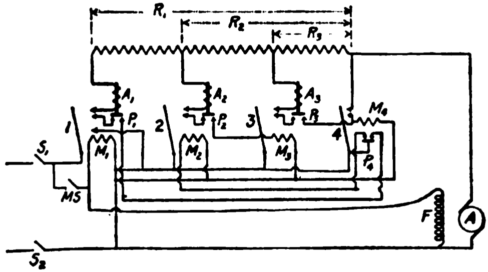

FIG. 73.—Automatic Starting Controller for D.C. Motor.

Speed Control of Shunt Motors. If Eq. (1) be solved for the speed N, the relation obtained is

$$N = 10^8(E - I_aR_a)/\Phi Z \tag{2}$$

From this equation it is evident that if either E, R_a, or Φ is changed the speed of the motor will be changed. There are three general methods of controlling the speed of a shunt (or compound) motor, depending upon which of these factors is changed.

Control by Armature Resistance. When the load I_a on a motor remains constant, the speed of the motor can be reduced by inserting resistance into the armature circuit. If the load on the motor varies, the speed of the motor changes, since the numerator of the above equation changes with each new value of I_a. If the speed of the motor is reduced to a low value while the motor is loaded, the speed will be very greatly increased when the load is thrown off. This makes this type of speed control unsuitable for motors which have fluctuating loads. Moreover, the method is very inefficient. The same amount of power is supplied at all speeds (assuming I_a constant), but at low speeds only a part of it is converted into useful work, the rest being wasted as heat. These objections are in part offset by the fact that speed reductions by armature resistance may be applied to any motor of standard design and require only the simplest speed-regulating rheostat. This method of control is often used to regulate the speed of motor-driven ventilating fans and in many cases where the power demand decreases rapidly with decrease in speed.

Control by Changing Field Magnetism. It is evident from Eq. (2) that the speed of a motor is inversely proportional to the magnetic flux Φ. The flux can be changed either by changing the shunt-field current or by varying the reluctance of the magnetic circuit. The insertion of resistance into the shunt-field circuit affords the simplest and most easily controlled of all methods of speed variation. The chief limitation to this method of control is the sparking at the commutator. More or less satisfactory operation of almost any standard shunt motor can be obtained by this method, providing that a speed ratio of not more than 1.5 to 1 is required. To attain greater ratios, it is necessary to have the motor equipped with commutating poles or interpoles (see p. 1619) which produce a magnetic field of the right polarity and intensity for commutation. Then each armature coil as its corresponding commutator bar passes under the brushes has induced in it an e.m.f. just sufficient to arrest the current in the coil and build up a current of the same strength in the opposite direction during the time the coil is short-circuited by the brushes. Commutating-pole motors are regularly manufactured with adjustable-speed ranges of 4 and 5 to 1. Another important characteristic of this type of motor is its excellent speed regulation with changes of load. The field rheostat can be manipulated to give the desired initial speed, and this speed will be maintained to within 5 per cent. when the load is varied from full load to zero. The only way of obtaining speed **control by varying the magnetic reluctance** of a motor is to mechanically move the iron parts so as to change the length of air gap or the effective area of the magnetic circuit. The Lincoln motor is designed so that both the length of the air gap and the effective area of the pole face are changed to give speed adjustments. The armature is movable in the direction of its axis, so that as it is withdrawn the area covered by the poles is decreased. Moreover, the armature is slightly tapered, so that the length of the air gap is increased simultaneously with the decrease of area. In both of these methods there are no distinct "steps" in the speed variations, all values of speed within the range of the motor being passed through in going from maximum speed to slow speed. Moreover, the only electrical controlling device necessary is the ordinary starting box. The regulation and efficiency of these motors is good at all speeds, but they are expensive.

Control by Changing Impressed Voltage. From Eq. (2) it is evident that the speed of a motor will be changed if its armature is connected to sources of power of different voltages. Speed control by this method is obtained by having current supplied over a number of mains (usually four) between which constant electrical pressures of different values are maintained by generators. The shunt field of the motor is generally permanently connected to one pair of mains and the armature circuit is provided with a controller which the operator can adjust at will to quickly connect the armature to any pair of mains. Such a system gives a series of distinct and widely separated speeds and generally necessitates the use of field-resistance control, in combination, to obtain intermediate speeds. This method, known as the "multi-voltage" method, has the disadvantage that the system is expensive, since it requires several generating machines, an elaborate switchboard, and a complicated system of wiring. The system is extensively used in machine shops.

Another application of variable armature voltage to motor speed control is found in the **Ward Leonard method.** This system makes use of an auxiliary motor-generator set which runs at constant speed from the supply mains. The field circuit of the generator is excited from the main power circuit and has a field rheostat which has sufficient resistance to vary the field current from its full value to nearly zero. The working motor which is to have its speed changed has its armature connected to the variable-voltage generator while its excitation is maintained constant from the supply mains. This arrangement gives any speed from zero up to full speed by the adjustment of the generator field current. On account of its cost and complications, the practical applications of this system are limited to very special conditions. It has been employed in the operation of large newspaper printing presses and the turning of gun turrets on battleships.

Speed Control of Series Motors. The series motor is fundamentally a variable-speed motor. Since the amount of current drawn from the lines by the motor depends upon the load which it is carrying, it follows that the strength of the fields will depend on the load, and, as the speed of the motor depends inversely upon the field strength, the speed of the series motor is inversely proportional to the load. Since the speed of the motor depends upon the voltage impressed upon its armature, the speed of a series motor may be controlled by introducing resistance in series with its armature. This method, which is practically the same as the armature resistance control method of shunt motors, has the same objections of low efficiency and poor regulation with fluctuating loads. It is extensively used, however, in controlling the speed of hoist and crane motors. At least two series motors, controlled by the **series-parallel system,** are usually used in traction work. The two motors are first placed in series with each other and with the starting resistance. The starting resistance is gradually cut out and the motors reach approximately half speed. On the next step the motors are placed in parallel with each other and again in series with the starting resistance. Full speed of the motors is then obtained by gradually cutting out the resistance. This scheme of putting the two motors in series at the start, allows the motors to be started on half the current it would take to start them if they were always connected in parallel to the line. The surges of current drawn from the trolley are thus less and the efficiency of starting higher.

Control of Alternating-current Motors

Starting Alternating-current Motors. Polyphase **induction motors of the squirrel-cage type** are generally started by means of an auto-transformer or compensator (see p. 1625). From the winding of each coil a number of taps are taken off to give a reduced potential at the motor terminals.

A double-throw switch is provided and so arranged that the motor, after it has been started, can be thrown onto the full line potential and the auto-transformer disconnected from the circuit. The double-throw switch, which is equipped with sliding, self-wiping contacts, is immersed in oil. Means are provided for compelling the operator to throw the switch first to the starting position and then to the running position. The taps are generally brought out from the windings so as to give potentials approximately equal to 40, 58, 70, and 80 per cent. of the line voltage. Approximately full-load starting torque will be developed in a motor at starting when 70 per cent. of the line voltage is used. In order to limit the current to as low a value as possible, the lowest taps that will give the motor sufficient voltage to supply the required starting torque should be used. As the torque of an induction motor varies as the square of the voltage, the compensator produces a very low starting torque.

A typical starting compensator is shown in Fig. 74. On starting, the switch cylinder contacts are connected to the corresponding ones on the front finger block. The three compensator coils are then connected in Y across the line and the motor voltage is tapped from some point on the coils. When the handle is thrown into the running position, the motor takes its power directly from the line through the fuses, and the compensator coils are entirely disconnected.

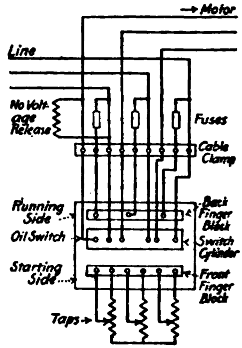

FIG. 74.—Typical Starting Compensator for A.C. Motor.

Resistances can also be used to start motors which have squirrel-cage rotors. These are inserted in each phase and are gradually cut out as the motor comes up to speed. These resistors are generally made of wire-type resistance units or of graphite disks inclosed within heat-resisting porcelain-lined iron tubes. The disadvantage of resistance starters is that the current is not limited. The handle operating the starter may be moved directly to the line contact before the motor reaches full speed, thus causing many times full-load current to flow, or the handle may be moved over so slowly that the resistor becomes very hot and possibly burns out. Resistor starters are less expensive than auto-transformers. Their application is to motors that start light loads at infrequent intervals.

The **wound-rotor type of induction motor** is always started by inserting resistance in the secondary circuit. In one type of this motor the resistances are mounted on the rotor in the space between the iron core and the shaft, and are controlled by operating a lever so placed as to engage a collar free to move longitudinally along the shaft. When the collar is moved in, the resistance is gradually cut out until the winding is short-circuited. Such a motor gives satisfactory operation where frequent starting is not necessary. Extreme heating occurs, however, if heavy loads are started at frequent intervals. For this class of service the windings of the rotor are connected to slip rings and the variable resistance is mounted externally to the machine. Putting resistance into the rotor of a polyphase induction motor at starting reduces the primary currents and increases the starting torque. Slip-ring motors are particularly adapted to starting heavy loads with a minimum amount of current.

Single-phase motors, as such, are not self-starting but require currents differing in time phase to produce a rotating field. This result is often accomplished by providing the stator with a two-phase winding and connecting these in parallel to the single-phase supply mains with a resistance or condenser in series with one of the windings. The currents in the two windings are sufficiently out of phase with each other to produce a revolving field which gives the required starting torque. After the motor reaches a moderate speed, one of the windings is disconnected and the machine operates as a single-phase induction motor. Such motors have very low starting torque, so are sometimes equipped with an automatic centrifugal clutch pulley which only allows the load to be applied after the motor has come up to a fairly high speed itself.

Another method of starting single-phase motors is to provide an armature of the ordinary direct-current drum type, so arranged that the commutator is short-circuited when nearly full speed is attained. During the starting period, carbon brushes which are electrically connected short-circuit the armature in one direction, producing a magnetic field in the rotor at an angle with the primary field in the stator. A high starting torque is thus developed due to the repulsion between the two fields. An automatic centrifugal device converts the machine into an induction motor just before full speed is reached. Such a machine can be adjusted to start with about twice normal full-load torque without requiring excessive current.

A **series alternating-current commutator motor** can be started by means of a rheostat placed in series with it, or by reducing the voltage impressed on its terminals by means of an auto-transformer. With the resistance method the efficiency of the system is low, but the cost of the controlling equipment is much less. Series motors operating cranes and hoists are generally controlled by rheostats, while such motors used in traction work are operated from the secondaries of auto-transformers.

Speed Control of Alternating-current Motors. The synchronous speed of an induction motor is given by the equation $S = 60f/P$, where f is the frequency of the supply and P the number of pairs of poles. Any change in the frequency of the applied voltage or in the number of poles on the motor, causes a change in the speed of the rotating field. No practical method has been developed whereby the frequency of the supply power can be varied. Induction motors are built, however, in which the stator windings are arranged so that they may be changed quickly from say a four-pole winding to an eight-pole winding by means of double-throw switches. In some motors, two independent windings, corresponding to different numbers of poles, each of which may be halved by a pole-changing switch, are provided so that four different speeds are available. When a speed ratio of only 2 to 1 is required, the connections of this type of motor are relatively simple, but if a greater number of speed ratios are necessary, and, especially if machines with wound rotors are used, the connections are very complicated. The power factor of this type of machine is not greatly affected by a change in the number of poles. This method of speed adjustment is very satisfactory as regards efficiency and constancy of speed. The disadvantages of the system are that the motor must be disconnected from the line to effect speed changes, and that the first cost is high.

The most common method employed in varying the speed of a polyphase induction motor is to introduce resistance into the rotor circuit. This method is essentially the same as that used in starting slip-ring motors. The introduction of non-inductive resistances in series with the rotor windings has the effect of reducing the speed while leaving the torque unaltered. At constant torque, the total power drawn from the line will be constant, and the loss of mechanical power due to reduced speed appears as heat dissipated in the regulating rheostat. This method, therefore, although giving any desired change of speed, is very wasteful, especially at the low speeds. Moreover, the speed changes over a wide range when the torque varies from full-load value to zero. This method is used where the periods requiring speed variation are comparatively short and when the motor runs at its normal speed most of the time.

Application of Motors

Alternating- or Direct-current Power. The question as to whether alternating- or direct-current power is more suitable to an industrial plant depends on the size of the plant and whether the kind of work the motors are to do requires adjustable speed. In large manufacturing plants covering a considerable area, alternating current is generally preferable because it permits the use of high voltage with the corresponding saving in copper in the distribution system. The chief disadvantage of the alternating-current system is that the motors do not have the adjustable-speed characteristics required in many machine-tool drives. In plants which consist of a few buildings grouped close together and where the saving in copper in the distributing system is not so important, the direct-current system, possessing the adjustable-speed possibilities, is more advantageously installed. Even where transmission from a distance makes the use of alternating current necessary, motor-generators are often installed to furnish direct current to the adjustable-speed motors. Where the installation uses direct-current power, the general practice is to distribute at a pressure of 230 volts, while with alternating current a three-phase transmission voltage of 2300 or 6600 volts is employed, and this is transformed down to 440 or 220 volts for distribution to the motors.

The application of motors to industrial plants depends upon their **operating characteristics,** and of these characteristics probably the most important is the speed-torque characteristic. Motors may be classified according to their speed-torque characteristics as follows:

(*a*) Motors with constant-speed characteristics.
(*b*) Motors with compound characteristics.
(*c*) Motors with variable-speed characteristics.
(*d*) Motors with adjustable-speed characteristics.

The **constant-speed** motor gives practically constant speed under all conditions of load. Shunt-wound direct-current and single-phase and polyphase induction motors are made which give a speed regulation of less than 5 per cent. when the load is varied from full load to no load. Constant-speed motors are used to drive line shafting to which a number of machines are belted, woodworking machines, lathes, boring mills, circular and band saws, milling machines, and in general in all cases where the work of cutting is continuous. Their characteristics also correspond to the requirements of fans, blowers, and air compressors.

The speed variation with change of load is greater in a **motor with compound characteristics** than that for a constant-speed motor and less than that for a variable-speed motor. Also the maximum starting torque is greater than that for the constant-speed and less than that for the variable-speed motor. The compound-wound direct-current motor is the only motor that has strictly compound characteristics, although polyphase induction motors can be made which have characteristics approaching those of the direct-current machine. The compound type of motor has good starting torque and at the same time gives average speed variations for different loads. It is, therefore, applicable for work requiring fairly heavy starting torque or frequent starting and reversing and also for operation at fairly constant speed for a certain length of time. Good examples of its application to this class of work are found in the electric-driven elevator and in rolling mills. The compound type of motor is also best suited to driving printing presses and reciprocating-motion machine tools, such as planers, shapers, slotters, etc. This type of motor is also used to operate shears and other tools having heavy flywheels. In such machines, when the motor slows down during the cutting stroke, the inertia of the flywheel aids in doing the work. Such a combination is especially useful in keeping down the rush of current from the line at the time of sudden heavy cutting.

Series-wound direct-current and single-phase series-wound alternating-current motors are **variable-speed motors.** At no load the field is very weak and the motor races and tends to run away, while under heavy load the field is strong and the speed is greatly reduced. This type of motor is never run without load. The characteristics of these motors are heavy starting torque and speed dependent upon the load. Polyphase induction motors can be made to have varying speed characteristics somewhat like those of the series-wound machine by the introduction of resistance into their rotor circuit, but the efficiency of the induction machine is considerably less. Variable-speed motors are used for work requiring frequent starts and large torques, such as hoisting, hauling, and traction work. In these fields they are superior to all other types of motors. They are also used for auxiliary purposes, such as raising the cross rails of planers and boring mills and traversing the carriages of large lathes.

An **adjustable-speed motor** is a machine the speed of which can be adjusted over a very wide range, and which, after being adjusted, remains practically constant for all changes of torque throughout its working range. Shunt-wound direct-current motors with commutating poles and motors in which the magnetic flux is varied by changing the reluctance of the magnetic circuit, fulfill these requirements. Such motors are **constant-power machines,** for, since the speed varies inversely and the torque directly with the field strength, the product of the two for the same armature current will be constant. The average class of machine tools, such as lathes, boring mills, etc., requires motors of such characteristics. When the tool is taking a light cut it is run at a high speed, and when taking a heavy cut the speed is low, thus requiring practically constant horse power throughout its working range.

The **choice of** the **correct size** of motor for a particular machine is of great importance. If the machine is already installed and is to be furnished with a new motor drive, it is customary to set up a test motor and make careful runs to determine the maximum and average loads. The motor is then generally selected on the basis of the average load, provided its overload capacity will take care of the maximum loads. All good motors have a 25 per cent. overload capacity for a period of at least 2 hr. When such a test is made, the efficiency of the test motor should be determined for the conditions under which it is working. It is not safe to make an estimate of this, for, as in the case of a large motor operating under light load, the efficiency may be rather low. In many instances the size of the motor required can be obtained from the builder of the machine, but it should be noted that many manufacturers recommend motors that are altogether too large. The expenditure of time and money in the accurate determination of the amount of power required for a machine installation is wisely made.

SWITCHBOARDS

Switchboards may in general be divided into two classes: direct-control and remote-control boards. On or near **direct-control boards** are mounted the switches, bus bars, meters, and other apparatus for handling directly the current supplied, while in the case of the **remote-control boards,** all bus bars, switches, etc., are removed to a distance and only the control-circuit apparatus finds place on the board. For low-tension circuits up to and including 750 volts direct-control panels are generally used. For circuits of 1100 volts and over, no "live" switch parts or apparatus should appear on the face of the board and all switches should be of the remote-control type. Most switchboard panels are now standardized as to **size** and thickness. Standard switchboards for central stations are usually 90 in. high and each panel consists of two or three slabs. The lengths of the General Electric Co. standard slabs for a two-piece panel are 62 in. and 28 in., respectively, for upper and lower slabs, while the corresponding dimensions for Westinghouse slabs are 65 in. and 25 in. **Marble** is extensively used for the slabs of switchboard panels, because of its appearance and high insulating qualities. For many installations slate is satisfactory and less expensive; it may be made moisture- and oil-proof by black enameling or by finishing in black marine.

Switchboards should be erected at least 3 or 4 ft. from the wall to permit of ready access to the connections at the rear. For panels supplying circuits of 750 volts or less the frames should be insulated from ground, while for higher voltages all frames should be grounded. For low-potential work, the **conductors** on the rear of the switchboard are usually made up of flat copper strip, known as **bus-bar copper.** The size required is based upon a current density of about 1000 amp. per sq. in. Where heavier currents are to be carried than can be accommodated by the sizes given in Table 24, a laminated bar is built up of thin strips insulated from each other to give a greater radiating surface.

* The current-carrying capacity is calculated on the basis of 50 per cent. load factor for densities which under average conditions of radiation would give a temperature rise of about 10 deg. cent. With a load factor of 100 per cent. the current densities given should be halved.

Switches. The current-carrying parts of switches are usually designed for a current density of 1000 amperes per sq. in. At contact surfaces, the current density should be kept down to about 50 amperes per sq. in. of contact surface. **Knife switches** are used on low-tension circuits, and in most cases are mounted on the front of the board. They should be mounted to "throw" vertically, with the blade side of the switch "dead" or disconnected from the source of power when open, to lessen the danger of accidental contact. **Plug switches** are used on high-voltage circuits where the current to be carried is small, as in the case of arc-lighting circuits. **Copper-brush switches** substitute a leaved copper brush with a wiping contact for the knife-blade contact and make use of an auxiliary break between carbon blocks to prevent burning of the copper leaves due to arcing. This type of switch is much used as a circuit breaker, being rendered automatic in its action by the addition of a tripping coil. **Oil-break switches** are used in high-voltage work where the oil is necessary to extinguish the arc.

Circuit Breakers. Any of the above switches equipped with a tripping device constitutes a circuit breaker. The tripping device usually takes the form of a solenoid which may be energized in various ways. In **overload circuit breakers** a solenoid coil connected

into the main circuit trips the breaker when the current exceeds a certain value. If the coil is either connected in series with or across the circuit and is designed to trip the breaker when the current decreases beyond a certain value, the arrangements are respectively known as underload and reverse-current circuit breakers. In the case of a switchboard panel for the control of a motor, where the load on the motor seldom or never exceeds its maximum rating, it is found satisfactory and less expensive to install **fuses** rather than a circuit breaker to protect the motor from overloads. **Wiring diagrams** are shown in Figs. 75–77.

Equipment of Standard Panels. Following are enumerated the various parts required in the equipment of standard panels for varying services:

Generator or Synchronous Converter Panel, Direct-current, 2-wire System: 1 circuit breaker; 1 ammeter; 1 handwheel for rheostat; 1 voltmeter; 1 main switch (3-pole s.t. or d.t.) or 2 s.p. switches.

Generator or Synchronous Converter Panel, Direct-current, 3-wire System: 2 circuit breakers; 2 ammeters; 2 handwheels for field rheostats; 2 field switches; 2 potential receptacles for use with voltmeter; 3 switches; 1 four-point starting switch.

Generator or Synchronous Motor Panel, Three-phase, 3-wire System: 3 ammeters; 1 three-phase wattmeter; 1 voltmeter; 1 field ammeter; 1 d.p. field switch; 1 handwheel for field rheostat; 1 synchronizing receptacle (4-pt.); 1 potential receptacle (8-pt.); 1 field rheostat; 1 triple-pole oil switch; 1 power-factor indicator; 1 synchroniser; 2 series transformers; 1 governor control switch.

Synchronous Converter Panel, Three-phase: 1 ammeter; 1 power-factor indicator; 1 synchronizing receptacle; 1 triple-pole automatic oil switch; 2 series transformers; 1 shunt transformer; 1 watthour meter (polyphase); 1 governor control switch.

Induction Motor Panel, Three-phase: 1 ammeter; series transformers; 1 oil switch.

Feeder Panel, Direct-current, 2-wire and 3-wire: 1 s.p. circuit breaker; 1 ammeter; 2 s.p. main switches; potential receptacles (1 four-point for 2-wire panel; 1 four-point and 1 eight-point for 3-wire panel).

Feeder Panel, 3-wire, Three-phase and Single-phase: 3 ammeters; 1 automatic oil switch (3-pole for three-phase, 2-pole for single-phase); 2 series transformers; 1 shunt transformer; 1 wattmeter; 1 voltmeter; 1 watthour meter; 1 handwheel for control of potential regulator.

Exciter Panel (for 1 or 2 exciters): 1 ammeter (2 for 2 exciters); 1 field rheostat (2 for 2 exciters); 1 four-point receptacle (2 for 2 exciters); 1 equalizing rheostat for regulator.

DISTRIBUTION AND WIRING

Distribution

Distribution Systems. The choice of a particular system of power distribution is determined by the nature of the load. It is more economical in copper to transmit electric energy at high voltage than at low voltage. To transmit a given power over a given distance with a given percentage power loss (I^2R), or a given percentage voltage drop (IR), the **amount of copper** required varies inversely as the square of the voltage between wires. Because of the danger to life and because of the requirements of lamps, motors, and other apparatus, this power may not in general be utilized at high voltage. Incandescent electric lamps cannot be built for economical operation at voltages higher than 110, while commercial power for direct-current motor service has found its most satisfactory operating pressure at about 500 volts. When power for lighting is to be distributed in a district where the consumers are relatively far apart, alternating current is ordinarily used at high voltage (1100, 2200 volts, or higher), and transformed to 110 volts at the consumer's premises. In congested city districts, where the draft of heavy currents necessitates the use of large cables, direct-current distribution from substations is advisable and necessary, as the use of heavy alternating currents is prohibited by the reactive voltage drop in the cables, which interferes with voltage regulation.

Series Circuits. Where the devices to be supplied with power are all of about the same capacity, are located relatively far apart, and are ordinarily used simultaneously, it is often more economical to supply power at **constant**

current than at constant potential. To operate at constant current, the power-consuming devices as well as the generator are all connected in series, as the same current passes through them all. In cutting any individual device out of service, an equivalent resistance must be inserted in its place to maintain the same current in the circuit, or else some means must be provided at the generator to adjust automatically the total voltage so as to maintain the constant current. If, in a series circuit of the kind under consideration, the resistance of each of the power-consuming devices is R_d, the resistance of the line is R, the current is I, the generator voltage when all of the devices are operating is E, and the number of the receiving devices is n, then $E = nIR_d + IR$, where $IR = e$ is the voltage consumed as resistance drop in the line. Now $e = \rho lI/A$, where ρ is the specific resistance of the material in ohms per mil-ft., l the length of the conductor in feet and A the sectional area of the conductor in circular mils. Having decided upon the permissible voltage drop e, the proper **sectional area of conductor to use** is

$$A = e/\rho lI$$

This method of distribution finds almost exclusive use in the case of arc-lighting systems for street illumination where the lamps are scattered over a large area. Here it is found more economical to connect the lamps in series and cause the constant-current transformer or other apparatus in the station to adjust the total voltage as the number of lamps in service changes. The high voltage used is not objectionable in this case, as circuits placed on poles or underground can be safely and satisfactorily operated at these voltages (1100 to 2300 volts per circuit).

Parallel Circuits. Power is usually delivered by the generator at constant potential, and all the devices or receivers in the circuit are connected in parallel, making a constant-potential system, as in Fig. 78. If conductors of constant cross-section are used, and all the lamps, L_1, L_2, etc., are operating, there will be a greater **voltage drop** or IR drop in the portion of the circuit AB and CD than in any other portion, and the voltages at the terminals of the different lamps will not all be the same.

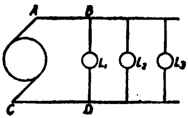

FIG. 78.
Parallel Circuit.

Loop Circuits. A more nearly constant voltage may be obtained by the use of the loop system of wiring shown in Fig. 79. The electrical distance from one generator terminal to the other through any receiver is the same as that through any other receiver, and the terminal voltage at the receivers may be maintained more nearly constant at the expense of additional conductor material.

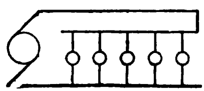

FIG. 79.—Loop Circuit.

Three-wire Circuits. In the operation of the incandescent electric lamp, power must be delivered at the lamp terminals at low voltage (110 volts) and with good voltage regulation, *i.e.*, small voltage fluctuation. For transmission to any considerable distance or for large loads per circuit, this necessitates a large investment in conductor material. In some special cases where it is permissible, lamps may be operated in groups of two in series as shown in Fig. 80. The voltage may thus be doubled, and, for a given number of lamps, the current is halved, the permissible voltage drop (IR) in conductors doubled, the conductor resistance quadrupled, and the amount of conductor material reduced by nearly 75 per cent.

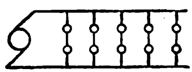

FIG. 80.

The lamps must be used in pairs. Independence in lamp operation, however, may be secured by the use of two generators and a third or **neutral wire** as shown in Fig. 81. When an equal number of lamps is burning on each half of the system, there will be no current flowing in the middle or neutral wire, and the condition is the same as that shown in Fig. 80. When there is a difference in the number of lamps in use on the two sides, the neutral wire will carry a current equal to the difference of the currents in the outside wires. Assuming each lamp to carry 1 amp., the currents in the various parts of the circuit would be as indicated by the ammeters in Fig. 81.

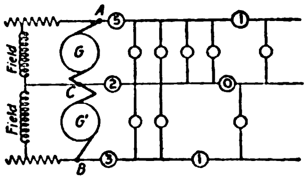

FIG. 81.—Three-wire Circuit.

Where there is a possibility of the load on one-half of the circuit being thrown entirely off, the neutral wire should be of the same size as the outside wires. In practice, it is usually possible so to lay out the circuits that the amount of unbalancing will never be very great, and the neutral wire is often made with one-half the sectional area of the outside wires. This is not always good practice, for if the fuse in one of the outside lines should open the circuit while the load were all on, the neutral wire would have to carry full-load current. Again, if the load were unbalanced, as for instance in Fig. 81, and the fuse or circuit breaker in the neutral wire should "blow," the voltage of the outside lines would be impressed across a combination of a group of 5 parallel lamps in series with a group of 3 lamps in parallel. This would give rise to an unbalanced voltage condition, whereby the lamps on the lightly loaded side of the system would be operated at an abnormally high voltage. For example, if the outside line voltage is 220, the resistance of each lamp is 150 ohms, and the fuse in the neutral wire has been accidentally "blown," the resistance of the lamp load between main A and the neutral wire will be 30 ohms and between main B and the neutral 50 ohms. The total voltage will be divided between the two halves of the load in proportion to the resistances, and hence the voltage across AC will be $(30/80) \times 220 = 82.5$ volts, while that across BC will be $(50/80) \times 220 = 137.5$ volts. Where the amount of unbalancing is slight, independence in the use of lamps may be obtained by the use of a third wire in the receiver part of the circuit only, as shown in Fig. 82. As the amount of unbalancing increases, this case becomes the one discussed above with the fuse blown in the neutral.

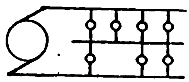

FIG. 82.

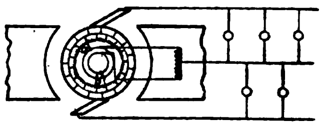

FIG. 83.—Three-wire Generator.

Three-wire Generator. Another method of obtaining a neutral point is by means of a three-wire generator. This machine consists of a direct-current generator wound for outside line voltage with points on the winding 180 electrical degrees apart connected through slip rings to the ends of a compensator or reactance coil, the connections being made as shown in Fig. 83. The **compensator** draws a small amount of reactive alternating current by way of the slip rings continuously. The mid-point of its winding is always at neutral potential with respect to the outside lines, and any unbalanced or neutral current will flow in the middle wire to the compensator and there divide in proportions depending upon the instantaneous position of the armature with respect to the field. Thus, when the slip-ring tap connections (a, b) are directly under the brushes, the pressure at the slip rings is a maximum and all of the unbalanced-load current flows through one-half of the compensator. With the same load conditions and the armature rotated through 180 deg., the neutral current flows through the other half of the compensator, while at intermediate positions in the revolution the current divides in the two halves in varying proportions. In some types of machines, to eliminate some of the slip rings, the reactance coil is mounted within the spider of the armature.

Motor-generator Balancer. Where close voltage regulation is desirable in a three-wire system, it can be obtained by providing a single generator supplying power at 220 volts and "floating" across the line a motor-generator set or balancer of sufficient current-carrying capacity to carry the maximum neutral or unbalanced current. (See Fig. 84.) The armatures of the two machines are connected in series across the line. When the system is balanced, the voltage across each machine of the balancer set is the same, and only enough energy is drawn from the line to supply machine losses and cause the armature to revolve. As the system becomes unbalanced the voltage on the side with the heavier load decreases, the voltage M becomes higher than that across G, M acts as a motor and drives G as a generator, which in turn supplies the additional current necessary on the heavily loaded side and thus maintains good voltage regulation. This method of balancing is most desirable where the amount of neutral current is not large and where it is not necessary to operate the generator continuously. On the other hand, there is a constant loss due to the energy required to drive the balancer set.

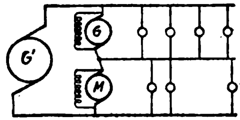

Fig. 84.—Motor-generator Balancer.

Feeders and Mains. Where power is to be supplied to a large district, improved voltage regulation is obtained by establishing **centers of distribution,** to which power is supplied by heavy circuits known as feeders and from which power is distributed to the consumers by circuits known as mains. As there are no load wires connected at any point on the feeders between the generating station and the centers of distribution, the voltage at the latter points may be kept very constant, and thus the consumer is supplied with power at better voltage regulation than would otherwise be possible. Pilot wires from the centers of distribution often run back to the station voltmeter so that the operator can keep the potential at the center constant.

Alternating-current Three-wire Distribution. With the exception of the congested districts of large cities, where power is more economically distributed as direct current, practically all energy for lighting and small motor work (such as dental motors, fan motors, etc.) is transmitted at 1100 or 2200 volts alternating current to the centers of distribution and from there to transformers which step the voltage down to 220 and 110 volts suitable for use in three-wire lighting systems. The transformers are so designed that the secondary or low-tension winding will deliver power at 220 volts and the middle or neutral wire is obtained by connecting to the center or mid-point of this winding.

Grounding. The neutral wire of the secondary circuit of the transformer should be grounded on the pole (or in the manhole) and at the service switch in the building supplied. If, as a result of a lightning stroke, the transformer primary circuit becomes grounded at *a* (Fig. 85) and the transformer insulation between primary and secondary windings is broken down at *b*, then, if there is no permanent ground connection provided in the secondary neutral wire as shown, the potential of wire No. 1 is raised 2200 volts above ground potential. The National Electrical Code requires the use of a ground wire not smaller than No. 6 B. & S. copper; on secondary circuits grounds should be provided at least every 500 ft.

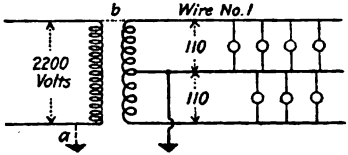

FIG. 85.

Wiring

Copper Requirements of Power Transmission Lines. The amount of copper required to transmit power by any given system, as a three-phase system, with a given percentage power loss, or a given percentage drop in voltage in the ohmic resistance, varies directly with the amount of power, directly as the square of the distance of transmission, and inversely as the square of the voltage used. The cross-sectional area of the conductors for transmitting power with a given percentage loss or voltage drop varies directly with the amount of power, directly with the distance of transmission, and inversely as the square of the voltage. If the percentage loss in transmission is not fixed but if the cross-sectional area of the copper is proportioned to make the annual expenditures for lost power plus interest, depreciation and taxes on the copper a minimum, the weight of the copper required varies directly with the amount of power, directly as the first power of the distance, and inversely as the first power of the voltage used. With the conductors proportioned for minimum annual expenditures, the cross-sectional area of the conductors varies directly with the amount of power and inversely as the voltage, and, for a given voltage, is independent of distance of transmission.

For two systems of the same length transmitting the same amounts of power at different voltages and with the same power loss for both systems, the cross-sectional area and weight of the conductors will vary inversely as the square of the voltage. The foregoing relations between the cross-section or weight of the copper and transmission distance and voltage hold for any system whatsoever, whether direct current, single-phase, three-phase, or quarter-phase.

The copper required at different voltages or by different systems is often determined by the use to which the circuit is put. In lighting mains, the drop in the conductors must not be allowed to exceed a small percentage (4 to 6 per cent.) of the total voltage, in order to maintain a fairly uniform voltage across the lamp throughout the length of the circuit. By reason of this fact, a conductor much larger than the most economical size must in many instances be used. When this is the case the amount of copper required varies inversely as the square of the voltage. In transmission lines and in feeders provided with means for regulating the voltage impressed across the feeders at the generator end, the drop is not limited to this low value and the conductors may be proportioned for economy.

In comparing the different systems for copper economy, the voltage across the load units should be assumed equal in each case. If the systems are high-oltage transmission systems, the line and station insulation may limit the oltage. The comparison of the amount of copper required by two systems hould be made in this case on the basis of equal voltage stress on the systems' isulation. The relative amounts of copper required in transmitting the same amount of power the same distance by different systems are shown in Table 25.

Table 25. Relative Amounts of Copper Required in Transmitting Power by Different Systems

(Power and distance the same in all systems. Table based on equal receiver voltage)

		Conductors proportioned	
		for same percentage of power loss in all systems	for economy or minimum annual expenditure
	Lighting Circuits	Per cent.	Per cent.
	2-wire (copper required taken as 100 per cent.)	100.0	100.0
	3-wire Edison:		
	Neutral same size as outer wire	37.5	61.3
	Neutral half size of outer wire	31.2	55.8
	No neutral	25.0	50.0
	Three-phase delta	75.0	86.6
	Inverted three-phase	56.2	75.0
	Three-phase 4-wire star, neutral full size	33.3	57.9
	Transmission Circuits (Based on same maximum stress on the insulation)		
	Single-phase, neutral grounded (Copper required taken as 100 per cent.)	100.0	100.0
	Three-phase, neutral grounded	100.0	100.0
	Single-phase, ungrounded, to operate with accidental grounds, as at *A*	400.0	200.0
	Three-phase, neutral ungrounded, to operate with accidental grounds	300.0	173.2

The **economical cross-section** may be determined from the curves of Figs. 86 and 87, relating to copper and aluminum, respectively. The ordinates of the curved lines are given in cents and give the value of power

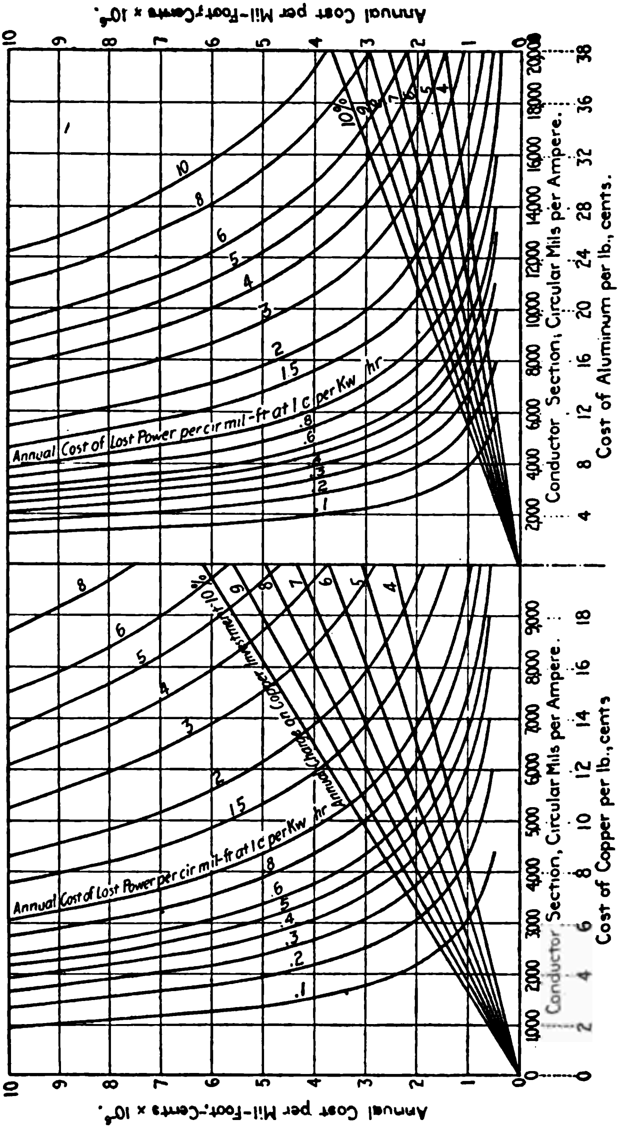

FIG. 86.

FIG. 87.

Charts for Determining the Economical Cross-sections of Copper and Aluminum Conductors.

lost annually in 1 circular mil-foot of conductor for each current density plotted as abscissæ (expressed in circular mils per ampere) when the value of power per kw.-hr. is that given on the curve. Each straight line gives for each of several interest rates the annual cost of interest, depreciation, taxes, etc., upon 1 cir. mil-foot of conductor for the various costs of conductor metal per lb. as abscissæ. The economical conductor is that at which the current density is such as to make the annual interest on the value of each circular mil-foot equal to the annual value of the power lost in each circular mil-foot (Kelvin's Law).

Example. To determine the economical size of copper conductor when power is worth 1 cent per kw.-hr., copper conductor is worth 16 cents per lb. and interest, etc., is equal to 7 per cent., refer to the 7-per cent. curve, where the annual interest is found to be 3.5×10^{-6} cents when copper is 16 cents. A horizontal line at this value intersects the curve giving the annual value of power loss in 1 cir. mil-foot at approximately 5250 cir. mils per ampere. This is the economical section to use. The value of current used in expressing current density in circular mils per ampere should be the square root of the mean square of the current ordinates taken over a year, that is, the **effective value.** With constant load this annual effective value would equal the average value of the current. With a varying load current, the annual effective value will be greater than the average value.

The maximum and minimum values of effective current for various load factors may be determined as follows: Assume a load current as shown by the area *OABC* in Fig. 88, which has a load factor of 50 per cent. A load having the same maximum value and the same average value and therefore the same load factor, is outlined in the figure as *ODEFG*. The rate of loss in the first case will be four times that of the second case, but for half the time; therefore, the loss for the total time period will be twice as great. The effective value of the current in the first case is then twice the average value. The **form factor,** which is the ratio of effective value to average value, is therefore two. In the following tables are set down the maximum possible form factors for various load factors, the minimum form factor being unity in each case:

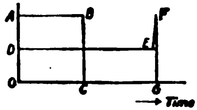

FIG. 88.

Load factor...........	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
Max. form factor......	10.0	5.0	3.33	2.5	2.0	1.66	1.428	1.25	1.11	1.0

Wiring Calculations for Direct-current Circuits. The determination of the proper size of conductor to use in supplying a certain electrical load with power is influenced by a number of factors. In general, it is not sufficient to use the minimum size of wire recommended by the National Board of Fire Underwriters in Table 26 based upon the maximum permissible current for the kind of insulation used, but the size of conductor must be so chosen that the voltage drop (IR) along the conductor is small. In the case of **feeders and branch circuits** for an incandescent lamp load, this **drop** may not be more than a small percentage of the voltage between wires. Good practice in interior wiring allows a drop of not more than 3 volts in feeder circuits from the main switchboard to the farthest tablet board, and a drop of not more than 1 volt from any tablet board to the farthest lamp.

The resistance of a mil-foot of copper is 10.8 ohms, and the resistance of a copper conductor may be expressed as $R = 10.8l/A$, where l is the length in feet and A the area in circular mils. Expressing the length in terms of the transmission distance d (since the two wires are usually run parallel), the voltage drop IR to the end of the circuit is

$$e = 21.6Id/A \qquad (1)$$

and the size of conductor in circular mils necessary to give the permissible voltage drop e is

$$A = 21.6Id/e \tag{2}$$

If e is expressed as a percentage of the voltage between conductors and this percentage is represented by P, then

$$A = 2160Id/P \tag{3}$$

Example. Find the size of conductor to supply a 10-h.p. 220-volt direct-current motor with power with 5 volts drop at 500 ft. from the switchboard. Assume a motor efficiency of 86 per cent. The motor will then require a current of [(10 × 746)/(0.86 × 220) =] 39.4 amperes. From Equation (2), $A = 21.6 \times 39.4 \times 500/5 = 85{,}200$ c.m. The next largest wire is No. 0 (B. & S.). Should a voltage drop of slightly more than 5 volts be permissible, No. 1 wire might be used.

Table 26. Permissible Currents for Different Sizes of Copper Wire*

(National Board of Fire Underwriters)

B. & S. gage No.	Area, circular mils	Amperes: Rubber insulation	Amperes: Other insulations	Area, circular mils	Amperes: Rubber insulation	Amperes: Other insulations

1	83,690	100	150	1,300,000	770	1,220
0	105,500	125	200	1,400,000	810	1,290
00	133,100	150	225	1,600,000	890	1,430
000	167,800	175	275	1,800,000	970	1,550
0000	211,600	225	325	2,000,000	1,050	1,670

* The current is limited by the deterioration of the insulation due to temperature rise. For insulated **aluminum wire** the safe carrying capacity is 84 per cent. of that given above.

The calculation of wire size for direct-current **three-wire circuits** is made in practically the same manner. With a perfectly balanced circuit no current flows in the neutral wire and the current in each outside wire will be equal to one-half the sum of the currents taken by all of the receiving devices connected between neutral and outside wires plus the sum of the currents taken by the receivers connected between the outside wires. Using this total current and neglecting the neutral wire, make calculations for the size of the outside wires according to equation (2). The neutral wire should be given the same sectional area as the outside wires.

Example. What size wire should be used for the 3-wire main of Fig. 89? Allowable drop is 3 volts and the distance to the load center 40 ft.; circuit loaded with two groups of receivers each taking 60 amp. connected between the neutral and the outside wires, and one group receivers taking 20 amperes connected across e outside wires. Solution: Load = (60 + 60)/2 20 = 80 amperes. Substituting in Equation), cir. mils = 21.6 Id/e = 21.6 × 80 × 40/3 = ,030 cir. mils.

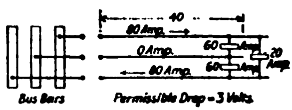

FIG. 89.

Referring to Table 26, 23,030 cir. mils correspond most nearly to No. 6 wire, which has an area of 26,250 cir. mils. This size wire would satisfy the voltage drop requirements, but rubber insulated No. 6 has a safe carrying capacity of but 50 amperes. The current in the circuit is 80 amperes. Therefore, with rubber-insulated wire No. 2 should be used, which will safely carry 90 amperes. The neutral wire is made the same size as the outside wires. For exposed wiring with slow-burning or weather-proof insulation, three No. 4 wires, each of which safely carries 90 amperes, could be used.

Wiring Calculations for Alternating-current Circuits. While these are essentially the same as for direct-current circuits, the problems are often complicated by other factors which have to be considered, such as power factor and line reactance. Skin effect becomes pronounced only when very large conductors are used for alternating current. For interior wiring, conductors larger than 700,000 c.m. should not be used, and many engineers will not use conductors larger than 300,000 c.m. For sectional areas larger than these conductor sizes, a number of smaller conductors in parallel should be used. At voltages under 2000 the effect of line capacity may be neglected.

In the case of ordinary **single-phase interior wiring,** where the effect of line reactance may be neglected and where the power factor of the load (incandescent lamps) is nearly 100 per cent., the calculations are made the same as for direct-current circuits. **Three-wire alternating-current circuits** of ordinary length with incandescent lamp loads are also determined as outlined for direct current.

When the electrical load is other than that of incandescent lamps, it is necessary to know the **power factor** of the load before commencing calculations. When the exact power factor cannot be determined, the following approximate values may be used: Incandescent lamps, 0 95 to 1.00; lamps and motors, 0.85; motors, 0.80. While not strictly accurate, the following equation may be used for the calculation of alternating-current circuits (single-phase) of moderate length where the effect of line reactance may be neglected:

$$I = \frac{\text{kw.} \times 1000}{E \times \text{p.f.}} \qquad (4)$$

where I is the current in amperes, kw. the kilowatts consumed by the load, E the load voltage, and p.f. the power factor of the load. The size of conductor to use is then determined by substituting this value of I in (2) or (3) above.

Example. In Fig. 90, load = 10 kw.; voltage of circuit = 220; power factor = 0.85; distance = 180 ft.; allowable drop = 4 volts. Substituting these values in (4), the current flowing = I = (10 × 1000)/(220 × 0.85) = 53.5 amperes. Substituting again in (2), cir. mils of conductor section = 21.6 × 53.5 × 180/4 = 52,000. The next larger standard size of wire is No. 3 (52,630 c.m.), will safely carry 80 amperes (see Table 26), and is therefore ample for 53.5 amperes.

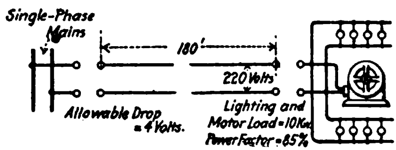

FIG. 90.

For **three-phase three-wire alternating-current circuits** where line reactance may be neglected, the following equations may be used:

$$I = \frac{\text{kw.} \times 1000}{E \times \text{p.f.} \times \sqrt{3}} = \frac{\text{kw.} \times 580}{E \times \text{p.f.}} \qquad (5)$$

and

$$A = \frac{10.8 \times I \times d \times \sqrt{3}}{e} = \frac{18.7 \times I \times d}{e} \qquad (6)$$

Example. In Fig. 91, load = 10 kw.; voltage of circuit = 220; power factor = 0.85; distance = 180 ft.; allowable drop = 4 volts. Substituting in (5), $I = (10 \times 580)/(220 \times 0.85) = 31$ amperes. Substituting in (6) to find the conductor size, $A = 18.7 \times 31 \times 180/4 = 26{,}100$ c.m. The next larger standard size wire is No. 6 (26,250 c.m.), will safely carry with rubber insulation 50 amperes and with other insulations 70 amperes (Table 26), and is therefore ample in section for 31 amperes. Three No. 6 wires would be used for this circuit.

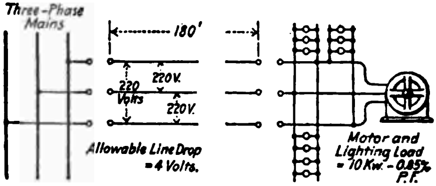

Fig. 91.

Practically all alternating-current circuits have some line reactance The **effect of line reactance** is to cause a drop in voltage somewhat similar to that caused by resistance. Where all of the wires of a circuit, two wires for a single-phase, four wires for a two-phase and three wires for a three-phase circuit, are carried in the same conduit or where the wires are separated less than an inch between centers, the effect of line (inductive) reactance may ordinarily be neglected. Where circuit conductors are large and widely separated from one another and the circuits are long, the effect of inductive reactance may increase the volts line loss considerably over that due to resistance alone. Every such case should be investigated with the Mershon diagram. With aerial circuits on pole lines, where the wires are widely separated, the effect of inductive reactance may be too large. Line reactance decreases somewhat as the size of wire decreases, and decreases as the distance between wires decreases.

The **inductance per mile of single conductor** in henrys is $L = \left(0.74 \times \log_{10} \dfrac{D - R}{R} + 0.0805\right) \times 10^{-3}$; R = radius of conductor, cm., D = distance between centers, cm. R is usually small compared with D and in the numerator may be neglected. The reactance $X = 2\pi fL$, where f is the frequency.

Line or circuit reactance with a conductor of given area can be reduced in two ways. One of these is to diminish the distance between wires. The extent to which this can be carried is limited, in the case of a pole line, to the least distance at which the wires are safe from swinging together in the middle of a span. In inside wiring, knob or cleat work, it is limited by the separation distances required by the underwriters. In conduit work the conductors lie so close together that there is very little effect from inductive reactance under ordinary conditions. The other way of reducing reactance is to divide the copper into a greater number of circuits. Voltage drop in lines due to inductive reactance is best diminished by subdividing the copper or by bringing the conductors closer together. It is little affected by changing the size of conductor.

The **Mershon diagram** (*Am. Elecn.*, June, 1897) offers a "cut and try" method of ascertaining voltage drop. The distance between the wires and the frequency being known, a conductor of the size that appears to be about right selected for trial. With the known current owing, the volts line loss in this conductor can be determined with the diagram. If the volts line loss with this conductor is found to be excessive, a conductor of different size is tried.

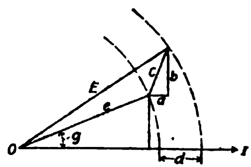

Fig. 92.

Fig. 93 is simply an extension of the vector diagram in Fig. 92, giving the relations of the e.m.f.'s of line, load, and generator. In Fig. 92, *E* is the

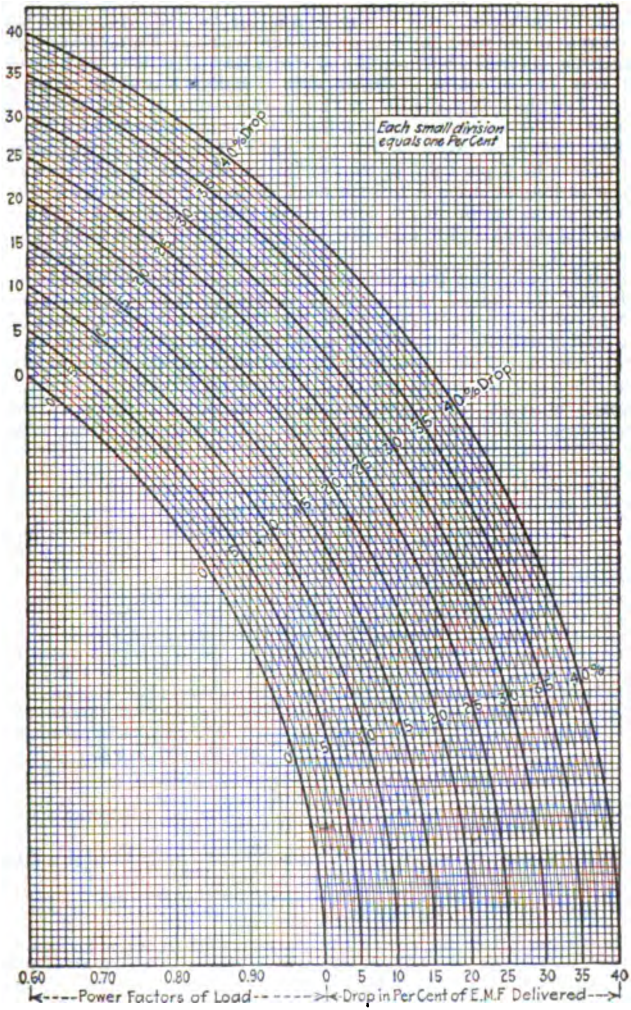

Fig. 93.—Mershon Diagram for Determining the Voltage Drop in A.C. Circuits.

generator e.m.f., *e* the e.m.f. impressed upon the load, and *c* that component of *E* which overcomes the back e.m.f. due to the impedance of the line. *c* is

made up of two components at right angles to each other. One is a, the component overcoming the IR or back e.m.f. due to the resistance of the line, and is in phase with I. The other is b, the component overcoming the reactance e.m.f. or back e.m.f. due to the alternating field set up around the wire by the current in the wire, and is in quadrature with I. Numerically, the drop is the algebraic difference between E and e, or d the radial distance between two circular arcs, one of which is drawn with a radius E and the other with a radius e. The chart is made by striking a succession of circular arcs with 0 as a center. The radius of the smallest circle corresponds to e, the e.m.f. of the load, which is taken as 100 per cent. The radii of the succeeding circles increase by 1 per cent. of that of the smallest circle, and as the radius of the last or largest circle is 140 per cent. of that of the smallest, the chart answers for drops up to 40 per cent. of the voltage delivered. Thus, since the vector e is chosen as 100 per cent., the cosine of the angle g represents the p.f. of the load, and knowing the value of this p.f., the vector position of e is determined by projecting from this p.f. value on the horizontal axis to the 0 arc. Having determined the values of resistance drop and reactance drop in per cent. of load voltage (a and b in Fig. 92), these values are laid off horizontally and vertically respectively as shown, which locates the vector of generator voltage. This value may be read off from the series of arcs and gives the generator voltage in per cent. of the load voltage.

Example. What size wire should be used for the branch to the 50-h.p., 60-cycle, 250-volt, single-phase induction motor of Fig. 94? The name-plate current rating of the motor is 195 amperes and its full-load power factor is 0.85. The wires are run open and separated 4 in.; length of circuit, 600 ft. The volts line loss must not exceed 7 per cent. or 0.07 × 250 = 17.5 volts.

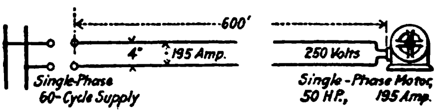

FIG. 94.

Solution. To ascertain approximately what size the conductor must be, substitute in (2), giving cir. mils = 21.6 × 195 × 600/17.5 = 144,500. Referring to Table 27, the next larger standard size wire is No. 000 or 167,800 cir. mils. This size would be ample if there were no line reactance, but as it is known that there is line reactance, select a larger conductor and find what the volts loss with it will be, using the Mershon diagram (Fig. 93). Find the resistance and reactance drops in the line, using the values from Table 27 for a 250,000-cir. mil conductor for 60 cycles and a 4-in. separation. From the table, *resistance volts* = 0.085 and *reactance volts* = 0.139.

$$\text{Resistance drop} = \frac{I \times \text{resistance volts} \times d}{1000} = \frac{195 \times 0.085 \times 600}{1000} = 9.9 \text{ volts}$$

$$\text{Per cent. of resistance drop} = \frac{\text{resistance drop}}{\text{receiver volts}} = \frac{9.9}{250} = 3.96 \text{ per cent.}$$

$$\text{Reactance drop} = \frac{I \times \text{reactance volts} \times d}{1000} = \frac{195 \times 0.139 \times 600}{1000} = 16.3 \text{ volts.}$$

$$\text{Per cent. of reactance drop} = \frac{\text{reactance drop}}{\text{receiver volts}} = \frac{16.3}{250} = 6.5 \text{ per cent.}$$

Now, in Fig. 93, follow the vertical line corresponding to the power factor, 0.85, upward until it intersects the smallest circle. From this point lay off horizontally the percentage resistance drop, 3.96. From this last point lay off vertically the percentage actance drop, 6.5. This last point lies about on the 7-per cent. circle, indicating that e volts line loss in this circuit with 195 amperes flowing will be 0.07 × 250 = 17.5 volts. e conditions of the example are satisfied by a 250,000-cir. mil. conductor. Actually, e line loss will be somewhat less than 7 per cent., as the last point does not quite touch e 7-per cent. circle. Inasmuch as this is a motor branch, the code rules require that

its safe carrying capacity be sufficient for a 25 per cent. overload. Therefore the conductor should be capable of safely carrying 195 × 1.25 = 244 amperes. Referring to Table 26, a 300,000-cir. mil. conductor, rubber-insulated cable would be required to safely carry this 244 amperes. In a problem in practice one would, therefore, immediately try a 300,000 conductor for volts line loss.

Table 27. For Calculating Drop in Alternating-current Lines with the Mershon Diagram—60 Cycles*

B. & S. gage and size of wire (cir. mils)	Resistance volts in 1000 ft. of line (2000 ft. of wire) for 1 amp.	Reactance volts in 1000 ft. of line (2000 ft. of wire) for 1 amp. at 60 cycles per sec. for the distance given in inches between centers of conductors.

* For other frequencies the reactance will be in direct proportion to the frequency.

In the calculation of **three-phase three-wire circuits** where line reactance must be considered, the Mershon diagram may also be used. After a conductor of the most economical section has been determined by following the procedure indicated in Table 28, the drop along each of the three conductors may be considered separately, as follows: Assuming a line pressure *E*, the pressure between any line and the neutral or imaginary zero point will

Table 28. Illustrative Tabulation of Relative Economies of Conductors of Different Sizes

be $e = E/\sqrt{3}$. Knowing the line resistance (r) and reactance ($2\pi fL$) per conductor and the current per wire, the resistance and reactance drops may be computed and laid off on the Mershon diagram as for a single-phase circuit. Using the value e as a base pressure, the pressure value found from the Mershon diagram will be the phase or neutral pressure at the generator end of the line, whence the line pressure at the generator end will be $E' = e'\sqrt{3}$.

National Electrical Code. The rules governing the installation of electric wiring vary in different parts of the country, but the rules and requirements of the National Board of Fire Underwriters, as published in the National Electrical Code, should be followed in all cases where they are not modified by existing requirements. The rules are revised biennially and a copy of them may be obtained gratis from the Underwriters' Laboratories. A list of **approved fittings,** a supplement to the Code, is revised semi-annually, and only fittings therein recommended should be used. The approved methods of wiring are given below.

Rigid conduit consists of standard sizes of iron, gas or water pipes which have been galvanized or covered with an insulating enamel ("loricated"). It is recommended for all classes of work and fills the requirements of a mechanically strong, waterproof and fireproof duct for electrical conductors. It is installed as a complete system with iron outlet boxes for all switches and fixtures before the wire is drawn in. In the case of defective wiring, the conductors may be withdrawn at any time and new ones inserted. In cases where it is embedded in concrete in modern fireproof buildings, the fact that it may in time corrode and disintegrate is no objection, since the duct left in the concrete is still satisfactory for electrical conductors. Double-braid rubber-covered wire must be used in rigid conduit. Table 29 shows the proper sizes of conduit to use with the various sizes of wire. **Flexible conduit** consists of a continuous flexible steel tube composed of concave and convex metal strips wound spirally upon each other in such a manner that their concave surfaces interlock, thus leaving smooth interior and exterior surfaces. While it is not waterproof, it possesses great mechanical strength and is ventilated, and due to its flexibility may be installed easily and cheaply in places where it would be impossible to install rigid conduit. It is particularly well adapted to the wiring of old buildings. It can be obtained in coils of from 50 to 200 ft. in length, depending upon the diameter. **Armored cable** consists of either one or two insulated wires with the steel strips used in flexible conduit permanently wound upon them. For alternating current, a pair of wires or "twin conductor" must be used to avoid inductive effects. When installed in old or completed buildings, it is not necessary to draw in the conductor after the conduit is installed. **Flexible tubing** is being used less as a conduit every year, because, as this tubing (or flexible loom, as it is also known) is made up of cotton and fiber, it may not be used where there is a possibility of the presence of moisture. It is much cheaper than any of the other kinds of conduit. **Knob and tube work** is used mostly in houses of frame construction where first cost of the installation is the controlling factor in the choice of a system. The wires are run concealed under floors and in partitions, mounted on porcelain knobs, and where the conductors pass through beams they are insulated by means of porcelain tubes. This method is not to be recommended strongly, because, unless properly installed, there is much danger due to the possibility of mechanical injury, sagging of wires between supports, and gnawing of the insulation by rats and mice. **Cleat work** for open wiring is much used in factories and similar places, and when properly installed has much to recommend it. The wires are supported in porcelain cleats or holders, and where necessary these cleats may be mounted in tiers to economize space. When mounted in a dry place excellent insulation and ventilation are secured. **Wooden moldings** with grooves to receive the wires are often used for exposed and ceiling work, although the general tendency in practice is away from this method of wiring. Wooden moldings may not be installed where there is the possibility of the presence of moisture, but they have the advantage of the protection of wires from mechanical injury and present a neater appearance than open wiring.

Table 29. Sizes of Conduits to be Used with Different Sizes of Wires and Cables*

* Allowance has been made in the table for the easy pulling of wires around three elbows, so that in straight, short runs conduits a size smaller may be used, excepting that ½ in. is the smallest size permitted by the underwriters' rules.

Costs of Wiring. The **cost of installing a system** of wiring based upon the number of outlets for various systems of wiring is given below (Whitehead, "Lectures on Illuminating Engineering," vol. 1, p. 266, 1911.) The values given represent the costs for work done for all classes of buildings in the larger cities of the eastern part of the United States, and it is believed that the values stated will be subject to but little variation.

	Per Outlet
Exposed wiring	$1.50 to 1.60
Wooden molding	2.00 to 2.50
Concealed knob and tube work	2.50 to 3.00
(Add $1.00 for each switch outlet)	
Iron conduit in new building	$4.50 to 5.00
Iron conduit in concrete buildings	5.00 to 6.00

Switch and base board plugs are considered outlets when the iron box is included.

These values cover that portion of the work from the source of supply at the building line to all outlets, but include no switches, lamps, or fixtures.

According to Knox ("Electric Light Wiring," p. 40), the **relative costs** (approximate) of the various methods based upon the cost of installing a rigid conduit system as 100, are as follows:

Rigid conduit...........	100	Armored cable........	70	Flexible tubing.......	40
Greenfield flexible conduit	80	Molding (hardwood)..	65	Cleat work...........	40
Molding (fireproof wood)	80	Molding (soft wood)..	50	Knob and tube work..	35

Rubber-covered Wire consists of a copper conductor, either solid or stranded, covered with one or two layers of rubber and then protected from abrasion by one or two layers of woven cotton sleeving. Rubber-covered wire is required by the Code for all interior wiring, except in places subject to high temperature. For permissible current-carrying capacities, see Table 26. The values there given for rubber-covered wire are based upon a temperature rise of 15 deg. cent.

Weatherproof Wire. The insulation on this wire consists of two or more layers of cotton braid impregnated with asphaltum or some similar compound. Weatherproof wire is recommended for use out of doors only where it withstands weather conditions better than rubber-covered wire, even though it absorbs more moisture. Weights of weatherproof wire are given on p. 1588.

Slow-burning or Underwriters' Wire. The insulation on this wire is made up of cotton braid impregnated with a heat-resisting compound containing white lead or zinc oxide and chalk. It is used for interior wiring in places where high temperature prohibits the use of rubber-covered wire.

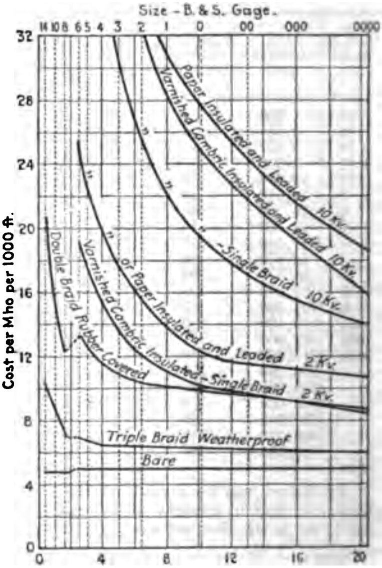

Fig. 95.—Costs of Wires and Cables. (Based on bare copper conductor at 15 cents per lb.)

Cost of Wire. Bare copper wire is sold by the pound, based on the market quotation on bar copper (usually from $0.13 to $0.21) with about 1 cent advance for drawing solid wires and ½ cent additional for stranding. Fig. 95 shows the costs of various kinds of wire and cable based upon a quotation of 15 cents per lb. for bare conductor. In sizes larger than No. 6 (B. & S.), conductors are stranded. To use Fig. 95, proceed as follows: Assume for instance that it is desired to determine the cost per 1000 ft. of a No. 0 triple-braid weather-proof wire. Referring from No. 0 on the horizontal axis to the T.B.W.P. curve, the cost per ohm per 1000 ft. is found to be $6.40. From the copper wire table on p. 1588 the resistance of 1000 ft. of a No. 0 wire is found to be 0.0981 ohm, which means a conductivity of 1/0.0981 or 10.19 mhos. The cost per 1000 ft. will thus be 10.19 × 6.40, or $65.22.

Systems of Wiring. A diagrammatic scheme for laying out the lighting circuits for a building for both a two-wire system and a three-wire system

is shown in Fig. 96. Here the power is brought through the main fuse

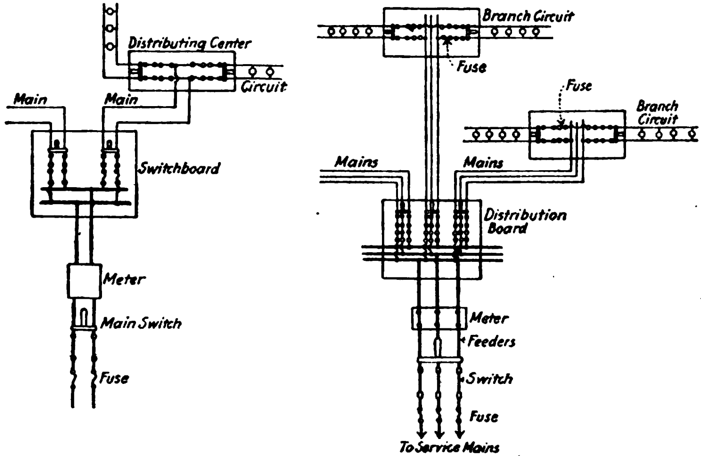

FIG. 96.—Layouts of Two-wire and Three-wire Lighting Circuits for Buildings.

block, switch, and meter to the main switchboard or distribution board as shown. The power is fed through feeder switches and fuses to the distribution panels or tablet boards on the various floors, from which it is supplied to the load on the branch circuits through branch-circuit switches and fuses. The only difference in the wiring for the two systems is that in the latter three wires are carried through to the tablet boards instead of two, and this for a given load permits of the use of a smaller wire for the feeders. Care must be taken, however, to connect the load so that it is divided as evenly as possible between the two halves of the system.

Location of Switches. Although single-pole wall switches are used in most installations for the control of lighting fixtures, double-pole switches (those which open both sides of a circuit) should be used, especially on grounded three-wire systems, unless special precautions are taken to place the single-pole switches in the outside wires.

Multi-switch Control. Where a group of lamps is to be controlled independently from two points, two three-way switches must be used as shown in Fig. 97, while if control is to be had from more than two points, the end switches of the series must be three-way

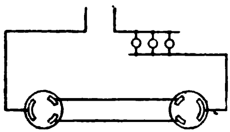

FIG. 97.

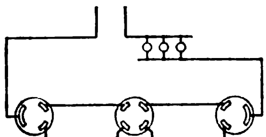

FIG. 98.

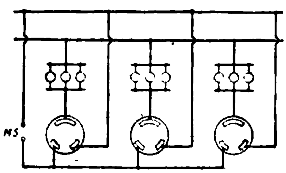

FIG. 99.

FIGS. 97–99.—Switch Control of Lamp Groups.

switches and all others four-way switches, as shown in Fig. 98. Fig. 99 shows a "burglar" circuit, by means of which, through a master switch located at some convenient point, all of the lamps in the building may be thrown on. The diagrams are self-explanatory.

Fuses. Fuses are ordinarily placed in the circuit where power is drawn from the feeders, and also at the main cut-out where the service wires enter the building. They consist of strips, rods, or tubes of some easily fusible metal, so proportioned that they will melt and thus open the circuit at some predetermined value of current. Fuses exposed to the air are known as **open fuses**; fuse links enclosed in insulating cartridges filled with porous or powdered insulating material are known as **enclosed fuses.** With open fuses and heavy currents, the explosive force at the instant of rupture is dangerous, and the location of the fuse block should be such that the possibility of fire is eliminated. For currents of 1000 amperes and over, **copper fuses** are often used. There is objection to using copper as a fuse due to its high melting point. At 75 per cent. of their rated capacities, copper fuses often become so hot as to greatly heat the connecting blocks to which they are attached. **Commercial fuses** are stamped or rated at 80 per cent. of the maximum currents which they will carry continuously, thus allowing for about a 25 per cent. overload. Table 30 gives the diameters of wires of various materials which will fuse with a current of given strength.

Table 30. Diameters of Wires of Various Materials Which Will Fuse with a Given Current (Preece)*

Amperes	Diam. in mils						Amperes	Diam. in mils			
	Copper	Aluminum	Platinum	German silver	Iron	Lead		Copper	Aluminum	Platinum	German silver
1	2.1	2.6	3.3	3.3	4.7	8.1	70	36.0	44.0	56.8	56.4
2	3.4	4.1	5.3	5.3	7.4	12.8	80	39.4	48.1	62.1	61.6
3	4.4	5.4	7.0	6.9	9.7	16.8	90	42.6	52.0	67.2	66.7
4	5.3	6.5	8.4	8.4	11.7	20.3	100	45.7	55.8	72.0	71.5
5	6.2	7.6	9.8	9.7	13.6	23.6	120	51.6	63.0	81.4	80.8
10	9.8	12.0	15.5	15.4	21.6	37.5	140	57.2	69.8	90.2	89.5
15	12.9	15.8	20.3	20.2	28.3	49.1	160	62.5	76.3	98.6	97.8
20	15.6	19.1	24.6	24.5	34.3	59.5	180	67.6	82.6	106.6	105.8

35	22.7	27.7	35.8	35.6	49.8	86.4	250	84.1	102.8	132.7	131.7
40	24.8	30.3	39.1	38.8	54.5	94.4	275	89.7	109.5	141.4	140.4
45	26.8	32.8	42.3	42.0	58.9	102.1	300	95.0	116.1	149.8	148.7
50	28.8	35.2	45.4	45.0	63.2	109.5	$k =$	10,244	7585	5172	5230
60	32.5	39.7	51.3	50.9	71.4	123.7					

* The values in the table have been calculated by means of the equation $d = (I/k)^{2/3}$. Values of k for different materials are given in last line of table for values of diameter d in inches. For iron, $k = 3148$; for lead, 1379.

COST OF ELECTRICAL APPARATUS

The data given in this article are based upon the average retail prices, f.o.b. factory, to small consumers or to small central stations. Jobbers, large central stations and other large consumers usually obtain contract prices averaging about 10 per cent. less. All the following cost values, however, are necessarily approximate, and variations of as much as 20 or 25 per cent. may be expected. The cost of rotating electrical machinery varies inversely as the speed, and hence the curves in Figs. 100, 101 and 102 are plotted with machine ratings as abscissæ against costs per unit of rating at a speed of 100 r.p.m., *i.e.* [cost in dollars per kilovolt-ampere (kva.), kilowatt, or horse power of rating × 100's of r.p.m.], as ordinates in order to obtain smooth curves. A **general rule**, therefore, is: Cost of generator or motor = rating of apparatus in kilovolt-amperes, kilowatts or horse power (K) × cost reading from curve (k) × 100/speed of machine in r.p.m. (N), or

$$\text{Cost of generator or motor} = 100Kk/N \tag{1}$$

For example, the cost of a 750-kva. low-speed waterwheel-type alternator will be 100 × 750 × \$14.90/150 = \$7450, where \$14.90 is the cost reading (curve XI, Fig. 100) for a rating of 750 kva., and 150 is the number of r.p.m. assumed as standard for an alternator of this size and type. Were a different speed demanded, say 200 r.p.m., the cost would be lower, namely, 100 × 750 × \$14.90/ 200 = \$5587. All costs for three-phase machinery apply also to two-phase machinery.

Costs of Polyphase Alternators, 250 to 2300 Volts

Turbo-alternators. For 60-cycle alternators (3600 r.p.m.) below 800 kva. rating, take value of k from curve I of Fig. 100 and **multiply it by 100** before insertion in formula (1). For larger sizes use the following **net** values of k:

Rating of alternator in kva.	750	1000	1500	2000	2500	5000	7500
	Values of k						
60-cycle { 3600 r.p.m. below 2500 kva. / 1800 r.p.m. above 2500 kva. }	\$660	590	510	450	220	200	190
60-cycle { 1800 r.p.m. below 1500 kva. / 900 r.p.m. above 1500 kva. }	\$560	540	270	230	210	170	...
25-cycle (1500 r.p.m.)	\$360	320	270	240	220	190	170

Up to 750-kva. rating the costs include a direct-connected exciter.

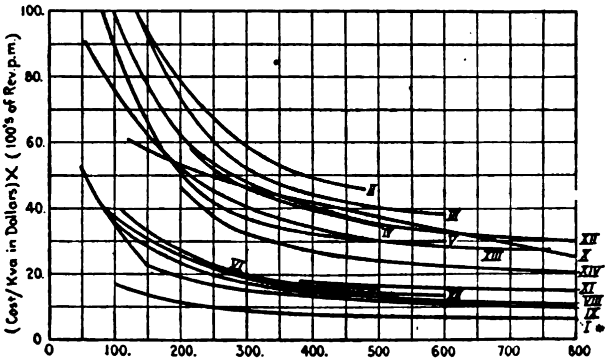

FIG. 100.—Costs of Polyphase Alternators.
(*Multiply cost by 100)

Belted-type Alternators. Costs include bed plate, rails, belt tightener and pulley for exciter, but not the exciter. Obtain value of k in formula (1) from the curves of Fig. 100, using

Curve II for 25-cycle, high-speed (750 r.p.m. below 300 kva. and 500 r.p.m. above).
Curve III for 60-cycle, high-speed (1200 r.p.m. below 300 kva. and 600 r.p.m. above).
Curve IV for 25-cycle, low-speed (500 r.p.m. below 300 kva. and 375 r.p.m. above).
Curve V for 60-cycle, low-speed (600 r.p.m. below 300 kva. and 300 r.p.m. above).
Curve V for 60-cycle, low-speed (900 r.p.m. below 150 kva.).

Thus, a 400-kva. 25-cycle high-speed alternator (500 r.p.m.) would cost (see Curve II) 100 × 400 × \$49/500 = \$3920.

Engine-type Alternators. Costs include brushes and holders and field rheostat, but do not include bed plate, shaft or exciter. The irregular point in Curve IX is due to a sudden drop in the rated speed. Obtain value of k in (1) from Fig. 100, using

Curve VI for 25-cycle, high-speed (150 r.p.m. above 300 kva.).
Curve VII for 60-cycle, high-speed (150 r.p.m. above 400 kva.).
Curve VIII for 25-cycle, low-speed (125 r.p.m. above 300 kva.).
Curve IX for 60-cycle, low-speed (100 r.p.m. above 150 kva.).

The costs for low-speed alternators (25 or 60 cycle) are practically the same at 1000-kva. ratings as at 800 kva.

Waterwheel-type Alternators (60-cycle). Costs do not include exciter. For ratings up to 800 kva., obtain value of k in formula (1) from Fig. 100, using Curve X for high-speed (600 r.p.m. up to 800 kva.; 510 r.p.m. to 1000 kva.); Curve XI for low-speed (150 r.p.m.).
For larger sizes use the following values of k:

Rating of alternator in kva.	1000	1200	1400	1500
High-speed (400 r.p.m. above 1000 kva.).	\$20	18	17	16
Low-speed (150 r.p.m.)	\$15	14	13	11

Direct-driven-type Alternators. Costs include bearings with supporting base and pulley for exciter, but do not include exciter. Obtain value of k in formula (1) from Fig. 100, using

Curve XII for 25-cycle (750 r.p.m. below 300 kva.; 500 r.p.m. above).
Curve XII for 60-cycle, high-speed (600 r.p.m.).
Curve XIII for 25-cycle (500 r.p.m. below 300 kva.; 375 r.p.m. above).
Curve XIV for 60-cycle (450 r.p.m. below 300 kva.; 300 r.p.m. above).

For higher ratings use the following values of k:

Rating of alternator in kva.	1200	1400	1600	1800	2000
25- and 60-cycle, high speed	\$29	27	24	21	18
60-cycle, low-speed	\$20	18	16	13	10

Costs of Direct-current Generators and Motor-generator Sets

Turbo-generators for Exciters, Etc. (125 to 250 volts). Obtain value of k from Curve VI of Fig. 101 and **multiply it by 100** before insertion in formula (1). k is constant from 180- to 250-kw. ratings. Speeds (r.p.m.): 4500 below 25 kw.; 3600 below 75 kw.; 2400 below 125 kw.; 2000 above 125 kw.

Belted-type Generators, Compound-wound (125 to 250 volts). Costs given are for 2-wire generators and include slide rails, pulley and field rheostat. 250-volt 3-wire generators cost from 12 to 15 per cent. more. For high-speed generators (1950 to 980 r.p.m., inversely as size), obtain k from Curve V of Fig. 101; for low-speed (1650 to 720 r.p.m., inversely as size) from Curve VII of Fig. 101.

Engine-type Interpole Generators. Costs include field rheostat, but do not include bed plate, sole plate, bearings, shaft or turning tool. Obtain value of k in formula (1) from Fig. 101, using

Curve I for high-speed (330 r.p.m. down to 200 r.p.m. above 300 kw.).
Curve II for low-speed (300 r.p.m. down to 100 r.p.m. above 200 kw.).

At higher ratings use the following values of k:

Rating of generator in kw.	200	300	400	500	700	1000
High-speed	\$23	19	17	15	...	....
Low-speed	\$19	14	12	11	8	6

Motor-generator Exciter Sets (125 to 250 volts). These consist of 60-cycle polyphase induction motors (220-2200 volt) direct-connected to 125- to 250-volt compound-wound direct-current generators. Costs are for complete sets. Speeds range from 1130 r.p.m. down to 840 r.p.m. Obtain value of k in (1) from Fig. 101, using

Curve III for 2200-volt alternating-current motors.
Curve IV for 220–440-volt alternating-current motors.

Generating Sets (Gasoline and steam-engine). Costs given are for combinations of engines and generators, but without switchboards. The gasoline-engine sets up to

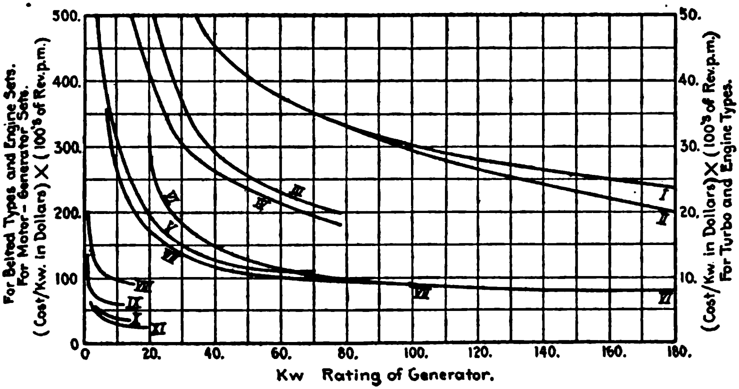

FIG. 101.—Costs of Direct-current Generators and Motor-generator Sets.

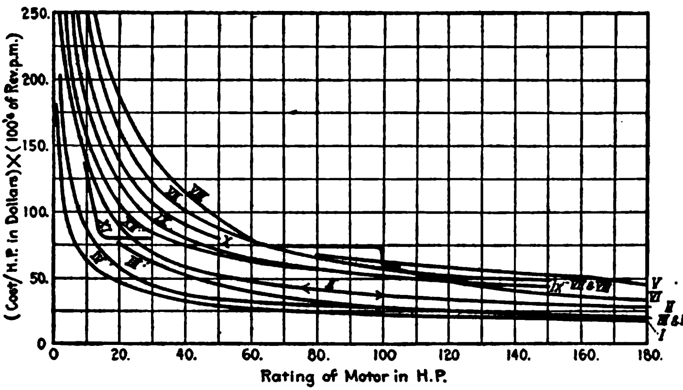

FIG. 102.—Costs of Electric Motors.

7.5 kw. are furnished with cooling tanks and 110-volt generators. The steam-engine sets comprise a standard-type automatic engine direct-connected to a 125- or 250-volt generator. Obtain value of k in (1) from Fig. 101, using

Curve VIII for direct-connected gasoline-engine sets.
Curve IX for belted gasoline-engine sets.
Curve X for low-speed direct-connected steam-engine sets.
Curve XI for high-speed direct-connected steam-engine sets.

Costs of Alternating-current Motors

Belted-type Polyphase Motors, 25-cycle. Costs are for open-type machines with squirrel-cage rotors, and include bed plate, pulley and auto-starter, except for sizes under 5 h.p., where no starter is required. Obtain value of k in formula (1) from Fig. 102, using

Curve I for 110–220-volt, low-speed (360 r.p.m.).
Curve I for 2200-volt, low-speed (360 r.p.m.) above 75 h.p.
Curve II for 110–220-volt, high-speed (720 r.p.m.) above 100 h.p.
Curve XII for 110–220-volt, high-speed (1440 r.p.m.) below 30 h.p.
(For 110–220-volt, high-speed (1440 r.p.m.) between 30 h.p. and 100 h.p., average value of k = $75).
Curve II for 2200-volt, high-speed (720 r.p.m.) above 75 h.p.

Belted-type Polyphase Induction Motors, 60-cycle. Costs include same equipment as for 25-cycle above. Obtain value of k from Fig. 102, using

Curve III for 2200-volt, low-speed (575 r.p.m. below 100 h.p.; 500 r.p.m. above).
Curve IV for 220–550-volt, low-speed (575 r.p.m. below 100 h.p.; 500 r.p.m. above).
Curve V for 2200-volt, high-speed (1730 r.p.m.) between 80 and 180 h.p.
Curve VII for 2200-volt, high-speed (1730 r.p.m.) between 30 and 80 h.p.
Curve XII for 220–550-volt, high-speed (1730 r.p.m.) up to 40 h.p.
Curve VI for 220–550-volt, high-speed (1730 r.p.m.) between 100 and 180 h.p.
(For 220–550-volt, high-speed (1730 r.p.m.) between 40 and 100 h.p., the average value of k is $70.

Costs of Direct-current Motors

Shunt-wound Motors. Costs are for open-type motors and include pulley, starting box and rails. Compound-wound motors cost from 1 to 3 per cent. more. Obtain value of k in formula (1) from Fig. 102, using

Curve VII for 110-volt, high-speed (1300 down to 450 r.p.m.).
Curve VIII for 550-volt, high-speed (1400 down to 430 r.p.m.).
Curve IX for 110-volt, low-speed (400 down to 300 r.p.m.).

Series-wound Motors (Open-type 550-volt motors for indoor service only). Costs of enclosed motors for crane service are not greatly different. Obtain value of k in formula (1) from Curve II of Fig. 102. Speeds decrease from 800 r.p.m. at 10 h.p. to 425 at 75 h.p.

Adjustable-speed Motors (Speed ratio, 1 : 2). Costs are computed from normal or minimum speeds and do not include starting or field rheostats. Obtain value of k from Fig. 102, using

Curve X for 110-volt, high-speed (average 1100 r.p.m. below 20 h.p.; 550 r.p.m. above).
Curve X for 550-volt, high-speed (530 r.p.m.).
Curve XI for 110-volt, low-speed (average 550 r.p.m.) above 10 h.p.
Curve XII for 110-volt, low-speed (average 550 r.p.m.) below 10 h.p.

Adjustable-speed Motors (Speed ratio, 1 : 4). Costs are for 220-volt motors only and do not include starting or field rheostats. Obtain value of k from Curve II, Fig. 102, up to 20 h.p. Minimum speeds average 500 r.p.m. below 5 h.p., 400 between 5 and 15 h.p., and 300 above 15 h.p.

Costs of Transformers

Pole-type Transformers (25- and 60-cycle). Pole-type lighting and power transformers up to 50-kva. ratings are available in two classes, a high-efficiency type and a standard type costing from 75 to 90 per cent. of the former, for use where high core loss is of no great moment. The costs below are for the high-efficiency type, 2300 volts primary, 110/220 secondary, and single-phase unless otherwise stated.

Rating of transformer in kva	2.5	5	7.5	10	15	30	50
Cost per kva. of rating:							
60-cycle, three-phase	$26	18	15.0	13.5	11.5	9.5	8.0
60-cycle, single-phase	15	12	10.5	9.5	9.0	7.5	6.5
25-cycle, 2300-volt	26	18	15.0	13.0	11.5	10.0	8.0
25-cycle, 6600-volt	40	26	20.0	17.5	14.5	11.5	10.0

Oil-insulated Self-cooled Transformers (Single-phase). High-duty power transformers are built as standard apparatus up to 66,000 volts. Cost data are given for 2200- and 44,000-volt transformers, and those for intermediate sizes may be obtained roughly by interpolation. For the smaller sizes the secondary winding is usually designed for 110, 220 or 440 volts; in the very large sizes for 220 or even 660 volts.

Rating of transformer in kva.	80	125	150	200	300	400	500	750
Cost per kva. of rating:								
44,000-volt, 25-cycle	$11.5	8.7	7.9	6.9	5.9	5.2	4.7	...
44,000-volt, 60-cycle	$ 9.6	7.2	6.6	5.8	4.8	4.1	3.6	...
2200-volt, 25-cycle	$ 6.3	5.0	4.7	4.2	3.8	3.5	3.3	3.1
2200-volt, 60-cycle	$ 4.8	3.7	3.5	3.2	2.8	2.6	2.5	2.3

Oil-insulated Water-cooled Transformers (single-phase) are less expensive than self-cooled transformers, as they do not have to be as liberally designed. About ¼ gal. of water per kw. of loss is made to pass through a cooling coil immersed in the oil, which results in a temperature rise of about 15 deg. cent. in the cooling water.

Rating of transformer in kva.	100	150	200	300	400	750	1000
Cost per kva. of rating:							
44,000-volt, 25-cycle	$8.7	6.7	5.8	4.8	4.0	3.2	2.7
44,000-volt, 60-cycle	7.0	5.3	4.6	3.8	3.2	2.4	2.2
2,200-volt, 25-cycle	4.5	3.8	3.4	3.0	2.6	2.2	2.0
2,200-volt, 60-cycle	3.4	3.0	2.8	2.5	2.3	2.0	1.8

Oil-insulated Water-cooled Transformers (Polyphase). Costs given below are for delta connection; for star (Y) connection they are 3 to 4 per cent. less.

Rating of transformer in kva.	125	175	250	300	400	700	1000
Cost per kva. of rating:							
44,000-volt, 25-cycle	$15.7	12.3	8.9	7.8	6.4	4.8	4.4
44,000-volt, 60-cycle	11.7	9.3	7.0	6.2	5.0	3.6	3.0
2,200-volt, 25-cycle	6.2	5.2	4.4	4.0	3.6	3.0	2.2
2,200-volt, 60-cycle	4.5	3.8	3.3	3.0	2.8	2.4	2.0

Air-blast Transformers (polyphase) are ordinarily used only in the larger sizes. No oil is provided either for cooling or insulation, a reasonable operating temperature being obtained by forcing a blast of air through the windings (about 150 cu. ft. per min. per kw. of loss). Costs below are for delta connection; those for Y connection are about 4 per cent. less.

Rating of transformer in kva.	220	400	600	800	1200	2200
Cost per kva. of rating:						
33,000-volt, 25-cycle	$10.4	6.5	4.9	4.1	3.6	3.1
33,000-volt, 60-cycle	8.7	5.6	4.3	3.5	3.0	2.4
2,200-volt, 25-cycle	5.5	4.2	3.5	3.2	2.7	2.3
2,200-volt, 60-cycle	5.1	3.6	2.9	2.6	2.2	2.0

Cost of Electrical Machinery in Cents per Pound

Name of machine	New or second-hand	Values of kw. ÷ r.p.m. 0.001	0.01	0.1	1.0	10.0
Direct-current generators and motors	New	65	35	27	25	......

Approximate values of *cost per pound* of electrical machinery are given in the table just preceding (see L. A. Doggett, *El. Wld.*, vol. 66, p. 746, Oct. 2, 1915). It will be noted that the average cost of all the new machinery tabulated is 32 cents per pound while that for second-hand machinery is 17 cents per pound, indicating a depreciation of about 50 per cent. for such machinery when in good condition and not obsolete.

Depreciation of Electrical Apparatus, Equipment and Distribution Systems. The values employed by the Railroad Commission of Wisconsin in making appraisals of estimated life in years and minimum service value in per cent. (the latter in parentheses), are as follows:

Generators, motors and rotaries, modern type, 20 (20), obsolete type, 15 (15); static transformers, including regulators and compensators, station type, 20 (40); steam turbo-generators, 20; switchboard and wiring complete, modern type, 20 (45), obsolete type, 15 (35); switchboard instruments alone, modern type, 20 (80), obsolete type, 15 (60); storage batteries, (35); lightning arresters, station type, 10 (50).

Electric Shock and Resuscitation

The effects of the passage of electrical currents through the human body vary with almost every individual case. Generally speaking, 1/10 ampere may be considered dangerous and 1/2 ampere of current prohibitive. With the same conditions, it is probable that alternating current is less dangerous than direct current. With high-frequency alternating currents, it is found that above 50,000 cycles per sec. no muscular contraction or pain is experienced. (Kennelly and Alexander, *El. Wld.*, July 21, 1910.)

Resuscitation from Electrical Shock. If the victim of electrical shock is still in contact with the line conductors, he should be freed at once by cutting off the power, if that is possible. Pulling him off by grasping the clothing is usually dangerous and should be attempted only as a last resort. If the patient is unconscious, the work of **artificial respiration** should be commenced at once, as a few seconds delay may be fatal. The prone pressure method of artificial respiration should be practised, as follows:

1. Place the patient upon his stomach with face turned to one side so that the mouth and nose do not touch the ground.

2. The operator should kneel, straddling the patient's hips, or kneel by either side of the hips, facing the patient's head.

3. The operator should place his spread hands upon the lower ribs of the patient and throw his body and shoulders forward so as to bring his weight heavily upon the lower ribs of the patient. The downward pressure of the hands should take about 3 sec., when the pressure should suddenly be released. This act should be repeated at the rate of 12 times a minute, and should be continued regularly. Rapid and irregular operations are of no avail. Continue for at least 1 hr. or preferably longer, even though the patient is apparently dead.

4. Send for a physician. Have patient's tight clothing loosened, keep him warm and provide plenty of fresh air. Do not give patient liquids by mouth until he is fully conscious.

Cases are on record where the victim has been revived after 2 hr. of artificial respiration treatment.

TEMPERATURE MEASUREMENTS

Instruments for measuring temperature are classified in the following table, which also gives the temperature range and the degree of accuracy usually obtainable.

	Range, deg. fahr.	Probable accuracy, deg. fahr.
1. Mercury thermometers:		
(a) Ordinary type	− 38 to + 575	From 1 deg. in common instruments up to 0.01 deg.
(b) Jena glass, capillary tube filled with nitrogen	− 38 to +1000	Higher ranges accurate to 1 deg.
(c) Quartz glass, capillary tube filled with nitrogen	− 37 to +1500	Higher ranges accurate to 1 deg.
2. Alcohol or petrol ether	− 325 to + 100	Accurate to 1 deg.
3. Electrical resistance ("bridge" and galvanometer)	− 400 to +2200	Accurate to 0.01 deg., for range 0–500 deg.
4. Thermo-electric	− 400 to +3500	Reliable to nearest 5 deg.
5. Metallic (mechanical)	+ 300 to +1000	Uncertain.
6. Vapor (usually recording)	+ 95 to +1350	Reliable to nearest 2 to 10 deg.
7. Radiation:		
(a) Thermo-couple (in focus of mirror—Féry)	+ 300 to +4000	Reliable to about nearest 20 deg.
(b) Bolometer	− 400 to Sun	Reliable to about nearest 20 deg.
8. Optical	+1100 to Sun	Reliable to about nearest 20 deg.
9. Seger cones	+1100 to +3600	Reliable to about nearest 20 deg.

Mercury Thermometers. The ordinary type has a vacuum in the capillary tube above the mercury and is generally applicable to about 575 deg. fahr. (300 deg. cent.). For higher temperatures the capillary is filled with nitrogen or carbonic acid gas under high pressure, making the thermometer serviceable up to 1000 deg. fahr., and if quartz glass is used it is applicable up to about 1500 deg. fahr. **Quartz thermometers** are much stronger than those of glass but are too expensive for ordinary commercial uses. The lower limit for mercury thermometers is −38 deg. fahr. (−39 deg. cent.). For lower temperatures alcohol and other thermometers are used.

When the thread of mercury in the stem is not at the same temperature as the bulb, as in the case of partial immersion of the stem in a thermometer cup, a **correction for "stem exposure"** must be added. In practice, this correction K is generally calculated from the equation $K = 0.000088D \times (t - t')$, where D is the number of degrees on the scale exposed, t the observed reading, and t' the temperature observed by an auxiliary thermometer having its bulb about 4 in. away from and on a level with the mid-point of the exposed stem (all in fahr. deg.). The work of Reimbach (*Zeit. f. Inst.*, vol. 10, 1900) shows that this equation is not very accurate for short stem exposures. His determinations are given in deg. fahr. for Jena glass thermometers with degree intervals about 1/30 in. long in Figs. 1 and 2. Fig. 1 is for thermometers with the ordinary type of solid stem, that is, with the scale on the stem. Fig. 2 is for "sleeve" thermometers with a capillary tube enclosed in an outer glass tube, which covers also the scale. Beyond the limits of the curves the equation given above should be used.

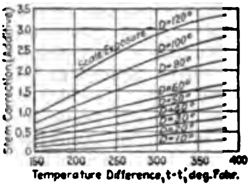

FIG. 1.

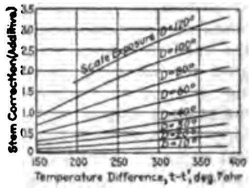

FIG. 2.

Stem Exposure Corrections.

When the **temperature of superheated steam** is to be determined, care must be taken that the thermometer cup is well protected with some non-conducting covering. It is desirable to insert the thermometer into a cork stopper fitting the thermometer cups. Calibrations of the scales of thermometers are usually made by comparing them with mercury thermometers which have been standardized by comparison with a primary standard. The freezing point is usually tested in melting ice, and calibrations above the boiling point of water can be readily made by comparing the readings of the thermometer with the temperatures of saturated steam as given in steam tables for observed pressures.

Electrical-resistance Thermometers are based on the increase of electrical resistance of certain metals with the temperature. Platinum is usually selected because for a given temperature it has a very constant resistance and does not deteriorate at high temperatures. A resistance thermometer is made of a coil of pure annealed platinum wire wound upon a mica framework. The variation of resistance is measured by a small Wheatstone bridge. Commercial instruments are usually arranged so that the galvanometer indicates the temperature in degrees. Up to 1000 deg. fahr. the error should be less than 1/50 deg. and at 2400 deg. fahr. not more than 1/2 deg. A delicate galvanometer is required so as to be sensitive for small currents. For many classes of work, particularly where there is liability to rough usage, the platinum coil must be protected by a porcelain or iron tube, which introduces a time lag. The junctions of the platinum wire of the thermometer with the wires going to the resistance-measuring device, must be placed in the cooler part of the circuit, where the temperature should be the same as when the instrument was calibrated; or compensators may be used. Electric-resistance thermometers are readily calibrated for temperatures of melting ice, steam at varying pressures (212 to 350 deg. fahr.), and boiling sulphur (832.5 deg. fahr.) Intermediate temperatures are computed (*Bulletin* No. 7, U. S. Bureau of Standards).

Thermo-electric Thermometers, or Pyrometers, measure temperatures by the electric current generated in a "couple" made by joining two different metals. The voltage of this current increases as the temperature to which the couple is subjected. A sensitive galvanometer or voltmeter, usually graduated in degrees of temperature, measures the voltage. For thermo-couples to be used not above 1500 deg. fahr., a wire of nickel is usually the positive element and an alloy of nickel and chromium the negative. A couple made of one wire of pure platinum and another of 90 per cent. platinum and 10 per cent. rhodium is not injured at 3500 deg. fahr. There are two general types of such instruments, (1) high-resistance and (2) low-resistance. The **high-resistance type** has a couple formed of wires of small diameter of platinum and an alloy of platinum and rhodium. To protect the wires against breakage and also because platinum deteriorates when acted on by various hot gases, the couples of the high-resistance type are always protected by porcelain or iron tubes. If the temperature does not exceed 1500 deg. fahr., iron tubes are satisfactory. For higher temperatures, porcelain tubes are used, but they must be handled more carefully. Formerly iridium was used for alloying, but it volatilizes rapidly at over 1500 deg. fahr., causing a gradual lowering of the voltage produced. **Base-metal or low-resistance types** of couples are usually made of alloys of nickel, iron and copper. A couple used very largely in America is made of nickel steel and copper. Such couples made of cheap metals can be made of larger rods and at less cost than those of the high-resistance type. They are not quite as accurate, but are generally preferred for industrial work. There is also the advantage that a broken couple can be readily replaced by two rods of nickel steel and copper fused together at one end, and a calibration curve for the couple can be quickly made to be accurate enough for most practical purposes. The principal consideration in selecting rods for such couples is to get them of uniform chemical composition. They should be annealed preferably in an electric furnace at a temperature higher than that to which they are to be exposed. If rods in a couple are not of uniform composition, parasitic currents are produced which oppose that produced by the couple at the junction. Since these wires can be made comparatively large, usually about 3/32 in. in diameter, the current generated will be large compared with that in the high-resistance types and its change in resistance with change in temperature will be small, so that a cheaper low-resistance galvanometer can be used.

Low-resistance couples are usually protected by an iron tube, mainly because steel deteriorates in the presence of sulphur gases, and the asbestos insulation needed for separating the rods along their full lengths is likely to last longer with this protection. Low-resistance pyrometers often have the leads of the same metals as the couples, so that the so-called **"cold junction"** is at the terminals of the galvanometer, and the leads are usually long enough to permit the instrument being placed where the temperature can be maintained at about normal "room" temperatures. Variation in the "cold-junction" temperature from the calibration temperature produces more error in low-resistance than in high-resistance types. Correction is best made with compensators placed in the circuit at the "cold junction." When iron is a constituent of a couple, it should not be used for temperatures above 1300 (to 1400) deg. fahr., as this temperature is a "transition point" for this metal, and its physical and also its thermo-electric properties are changed.

Thermo-couples of platinum and platinum-nickel alloy produce twice the voltage of a platinum-rhodium combination, but should not be subjected to temperatures above 2000 deg. fahr. Thermo-electric couples are particularly adaptable for measuring temperatures in restricted spaces. The couples can be made thin enough to be inserted into spaces less than 1/50 in. wide. They are adaptable also for indicating temperatures of objects at a distance from the observer.

Metallic or Mechanical Pyrometers consist of two rods made of substances having different rates of expansion connected by gears and levers to rotate a pointer on a graduated dial. Generally the rods are made of iron and brass, or of graphite and iron. Although the use of such instruments is quite common, they are generally very unreliable and should never be used for temperatures above 1000 deg. fahr. There is always a tendency for the zero of the instrument to get higher with use, even at moderate temperatures. Beckert and Weinhold found that in a number of cases the zero changed 200 to 400 deg. fahr. in two months. In order to obtain readings corresponding with the graduations, the entire length of the tube enclosing the rods should be placed in the chamber of which the temperature is being measured.

Recording Thermometers. The greater number of recording thermometers operate by the expansion of the vapor of ether, mercury or other liquids confined in a bulb and capillary tube connected to a pressure-measuring device. When the bulb is heated the vapor tension increases and actuates the pressure-recording device. The following **liquids are used,** depending on the range of temperature (deg. fahr.): Liquid sulphur dioxide (SO_2), 15 to 200; ether (free of water), 95 to 250; water, 212 to 450; heavy hydrocarbons, 410 to 700; mercury, 650 to 1350. The capillary tube may be made 100 ft. long, and such instruments are suitable for "**distant reading,**" but varying the temperature of the capillary tube by exposure will alter the observations. The whole length of the bulb must be exposed to the temperature to be measured.

Thermometer Cups should be filled with cylinder oil or mercury. If cylinder oil is used the cups must be kept free from water, as the steam that forms will produce explosions violent enough to throw out the thermometer. The thermometer should be kept from contact with the sides of the cup by wrapping it with a little waste or fitting a cork loosely over it.

The Féry Radiation Pyrometer and the **Wanner optical pyrometer** are instruments devised to measure temperature by means of the radiation from incandescent bodies. In the Féry instrument heat rays are focused upon a miniature thermo-couple and the temperature is indicated by the use of a sensitive galvanometer. These instruments are particularly serviceable for determining the temperature of a bed of fire and of the parts of the settings of boiler furnaces. Optical and radiation pyrometers are calibrated in terms of the radiation from a so-called "black body," which is approximately realized by a uniformly heated enclosure. It is only for "black bodies" that the temperature is exactly proportional to the radiation. Observations made with such pyrometers of incandescent bodies or gases do not give the true temperature. It is generally assumed, however, that they can be used to measure fairly accurately the temperature of heated chambers when focused upon the walls, because of the reflection going on in all directions. In most cases the flame temperature can be taken as the same as that of the surrounding walls. A relatively large area is usually required to sight Féry pyrometers. The distance from the telescope to the hot body can be as much as 30 times the diameter of the hot body, and the telescope can be taken as much nearer as desired without changing the reading of the instrument. Both the Féry and Wanner pyrometers have a satisfactory range from 800 to 4000 deg. fahr. At the lower temperature the average error of such instruments is about 3 deg. fahr., and the maximum error at temperatures above 3000 has been shown to be not more than 20 deg. fahr.

Furnace Temperatures (in deg. fahr.) can be determined approximately from the values corresponding to the color of the fire; see p. 290.

High-reading thermometers and pyrometers are best calibrated by comparison with the known melting points of tin, lead, zinc, antimony, silver, gold, nickel and platinum. Seger cones may also be used.

Seger Cones are pyramids about 2 in. high made of several different oxides mixed to give a definite melting point. Melting points range from 590 to 2000 deg. cent. by steps of from 20 to 30 deg., each having a definite number. The temperature corresponding to a number has been reached when the tip of the cone turns over and touches the surface on which its base is resting. Following are the Centigrade and approximate Fahrenheit temperatures corresponding to a few numbers (These cones indicate only the maximum temperature):

No.	Deg. cent.	Deg. fahr.	No.	Deg. cent.	Deg. fahr.	No.	Deg. cent.	Deg. fahr.
022	600	1110	7	1270	2320	30	1670	3040
016	750	1380	15	1435	2615	35	1770	3220
010	950	1740	20	1530	2790	39	1880	3420
02	1110	2030	26	1580	2880	42	2000 (about)	3600

Relative Accuracy of Thermometers. Mercury thermometers are usually preferred for low-temperature work. They can be made of any degree of accuracy and cost. Electric-resistance thermometers can be used for low and fairly high temperatures and can be made for observing at a distance. Accurate thermometers of this type are, however, expensive; but with them temperature *differences* can be determined much more accurately than with mercury thermometers. Thermo-electric pyrometers are generally more sensitive than those of the optical and radiation types.

Prices of Thermometers and Pyrometers. Mercury thermometers, \$0.50 to \$35, depending largely on accuracy and number of graduations. Ether-bulb recording thermometers, \$40 to \$60; electric-resistance thermometers, \$100 to \$300 (Leeds & Northrup Co., Philadelphia); thermo-electric pyrometers, \$50 to \$100 (Bristol Co., Waterbury, Conn. and Hoskins Instr. Co., Detroit, Mich.); Féry optical pyrometer, \$350 (Taylor Instrument Co., Rochester, N. Y.); Seger cones, 2 to 3 cents each (Eimer & Amend, New York).

The Bureau of Standards, at Washington, D. C., makes a charge of \$0.50 for two points and 10 cents for each additional point for calibrating mercury thermometers. A certificate of calibration is provided by the Bureau for each instrument. Charges for calibrating pyrometers are also nominal.

PRESSURE MEASUREMENTS

Mercury Barometers are ordinarily used for measuring atmospheric pressure. Standard barometric pressure for comparison is usually taken as 30 in. at 32 deg. fahr. Some observers have adopted 62 deg. fahr. instead of 32 as a standard for the brass scale.

Vacuum measured with a mercury manometer must be corrected to standard temperature conditions (see p. 1675, 1). To correct observations of vacuum to **equivalent vacuum** compared to (or "referred to") 30-in. barometer, the difference between the corrected barometer and 30 in. is *added* to the observed vacuum when the barometer is less than 30 in., and is *subtracted* when greater than 30 in. Temperature corrections are avoided when the barometer and the vacuum manometer are hung very near each other. Furthermore, if there is much difference in level, mercury columns should be corrected also for elevation. The correction (to be subtracted) is 1.15 in. per 1000 ft. (see p. 1748).

In using mercury barometers and vacuum gages it is necessary to correct for temperature, gravity (g) and capillarity if the height of the mercury column must be known closer than 2 or 3 mm. The method of correcting the mercury barometer is as follows:

Let h be the observed height of the mercury column at t deg. read on a brass scale which has an expansion coefficient of b, a be the latitude (in degrees) and H be the elevation of the barometer above sea level. Then,

1. If the scale be graduated into millimeters and temperatures are in deg. cent., subtract 0.000182 ht to correct for the density of the mercury, and add 0.000019 ht to correct for the scale.

If the scale is graduated into inches and fractions and temperatures are in deg. fahr., subtract 0.000101 $h(t - 32)$ to correct for the density of the mercury, and add 0.0000105 $h(t - 32)$ to correct for the scale.

2. To correct for capillary depression of the mercury column, add the amount in the accompanying table corresponding to the known internal diameter of the tube and the observed height of the meniscus of the barometer.

Capillary Depression of Mercury for Tubes of Different Diameters, and for Different Meniscus Heights
(Kohlrausch, 1910)

Diam. of tube, mm.	Height of meniscus in millimeters							
	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8
5	0.47	0.65	0.86	1.19	1.43	1.80	....	....
6	0.27	0.41	0.56	0.78	0.98	1.21	1.43	....
7	0.18	0.28	0.40	0.53	0.67	0.82	0.97	1.13
8	....	0.20	0.29	0.38	0.46	0.56	0.65	0.77
9	....	0.15	0.21	0.28	0.33	0.40	0.46	0.52
10	....	....	0.15	0.20	0.25	0.29	0.33	0.37
11	....	....	0.10	0.14	0.18	0.21	0.24	0.27
12	....	....	0.07	0.10	0.13	0.15	0.18	0.19
13	....	....	0.04	0.07	0.10	0.12	0.13	0.14

3. Pressure of mercury vapor: The correction is less than 0.01 mm. for temperatures under 40 deg. cent., and hence may be disregarded.

4. To correct for latitude and elevation: Multiply height of the column by $g_a/g_{45} = (1 - 0.0026 \cos 2a - 0.0000002H)$, H being in meters (see p. 84).

Aneroid Barometer. Atmospheric pressure is sometimes measured by an aneroid, which is a very delicate and portable pressure gage. Aneroids are frequently used in power-plant testing and for determining elevations. They must be frequently calibrated by comparison with a mercury barometer.

Prices: Mercury barometers, $15 to $35. Aneroids, $4 to $25, according to size, finish and accuracy.

Pressures are usually measured with **Bourdon gages**, consisting of an elastic brass tube of oval cross-section, bent into an arc. In another type of gage the pressure is applied to a diaphragm or plate in place of the Bourdon tube. The tube type is generally considered the more accurate. Gages of the tube type can be used for determining the pressure of steam, water, air, ammonia, etc. For ammonia, steel must be used instead of brass. For low pressures, **U-tubes** filled with water, mercury, gasoline, or other liquids are often used. A light liquid, such as gasoline or water, permits a greater degree of accuracy than mercury. For accurate work, vacuum is nearly always measured with a U-tube, although Bourdon and diaphragm gages are also adapted for measuring vacuum. Gages of either the Bourdon or diaphragm types when arranged for measuring on the same dial both pressure and vacuum are called **compound gages.**

Bourdon gages must never be exposed to temperatures over 150 deg. fahr. If the tube is heated above this limit it is likely to lose some of its temper. Above this temperature some form of siphon or water seal must always be used to prevent the heated fluid from entering the gage. Hydrostatic pressure must be taken into account. If the gage is located below the surface of the water in a boiler, it will read too high; the error being the pressure equivalent to the head of water between the surface in the boiler and the center of the gage. The correction in lb. per sq. in. is 0.433 times the head in feet.

When a **water column** accumulates on top of a mercury column, the length of the mercury column must be corrected. This **correction** is most conveniently made by dividing the length of the water column by the specific gravity of mercury (13.6) and adding this equivalent length to the mercury column on which the water rests. For capillarity corrections, see above. Mercury columns should be read at the top of the meniscus and water columns should be read at the bottom. Except in very small tubes, the errors due to capillarity may then be regarded as negligible.

Draft in flues and chimneys, as well as that produced by **fans** when the velocity of the air exceeds 2000 ft. per min., is conveniently measured with a U-tube manometer filled with water or some very light oil. The difference in level of the liquid in the two legs, expressed in inches of water, is the conventional measure of the force of the draft. Draft gages with inclined tubes can be read with greater accuracy than those with vertical tubes.

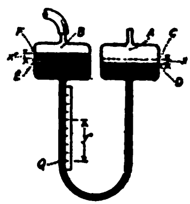

FIG. 3.—Draft Gage.

A very delicate **draft gage** can be made by connecting two glass vessels A and B by a glass U-tube of small diameter, as in Fig. 3. Water is put into A and oil into B, with the surface of separation at Q when A and B are both subjected to the same pressure. When B is connected to a vacuum chamber the levels are changed from E to F in B (x in.) and from C to D in A (also x in.), and the surface of separation moves y in. If s = specific gravity of the oil, then the change of pressure p in in. of water in A and B is $p = x + sx + y(1 - s)$. If the areas of A and B are equal and are n times the area of the connecting tube, then $y = nx$, and $p = \frac{y + sy}{n} + y(1 - s) = y\left[\frac{1 + s}{n} + 1 - s\right]$.
The smaller the factor in the brackets the greater will be the magnification or sensitiveness. The value of n should therefore be made as large as possible, say about 100, and the two liquids should be preferably nearly of the same specific gravity. Gasoline and brandy are frequently used for the two liquids. They are of nearly the same specific gravity and the line of separation is readily observable. If S_b is the specific gravity of the brandy and S_g that of the gasoline,*

$$p = y\left[\frac{S_b + S_g}{n} + S_b - S_g\right].$$

Another method of using the same apparatus is illustrated on p. 285.

Calibration of Gages. Gages are commonly calibrated either by comparison with a **test gage** or by use of the **gage tester.** Test gages must be calibrated from time to time with some standard apparatus to insure their accuracy. A vacuum gage is usually calibrated by comparison with a mercury column. The gage and column should both be connected to the suction of an air pump or to an aspirator.

Prices of Gages and Testers. Pressure and vacuum gages of good quality and of standard makes cost from $5 to $75, according to size and finish. Gages with a 6¾-in. dial—a suitable size for use on small engines—cost from $8 to $10; with 10-in. dial, from $15 to $25. Standard test and ammonia gages cost about twice as much. Recording gages cost from $40 to $75. (Bristol Co., Waterbury, Conn., Precision Instrument Co., Detroit, and Schaeffer & Budenburg, Brooklyn, N. Y.) Dead-weight gage testers, intended for the usual boiler pressures, cost about $50. (Crosby Steam Gage & Valve Co., Boston, Mass.) Ellison's differential pressure and draft gages (modified U-tubes) cost from $10 to $15. (American Steam Gauge and Valve Mfg. Co., Boston, Mass.)

DETERMINATION OF THE MOISTURE IN STEAM

The Throttling Calorimeter is most generally used for determining the moisture in steam. It consists of a vessel C (Fig. 4), into which steam enters through a small orifice O. If there is not too much moisture in the steam this throttling produces superheating. Temperature and pressure after expansion are indicated by a thermometer T and by a manometer attached to the cock V_2. Many throttling calorimeters are made with a large free opening on the exhaust side so that the pressure in the calorimeter is atmospheric. The valve V_2 may then be omitted. All the connecting piping and valves between the calorimeter and the steam main should be as short as possible and carefully covered with non-conducting material to reduce radiation to a minimum. For the usual range of boiler pressures throttling calorimeters cannot be used to determine the moisture in steam when it amounts to more than from 3 to 5 per cent. By connecting the vessel C to a condenser this range may be extended. The sampling pipe A should be made, as recommended by the American Society of Mechanical Engineers, of ½-in. pipe, extending to within ½ in. of the opposite side of the steam pipe, and should be closed at its end. At least twenty ⅛-in. holes (uniformly distributed and preferably drilled in spiral rows) are to be provided for the entrance of steam into the sampling tube. The first of these holes is to be not less than ½ in. from the wall of the pipe.

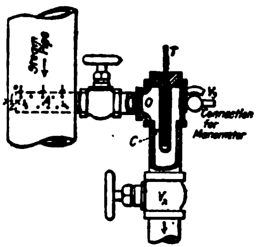

Fig. 4.—Throttling Calorimeter.

The **quality or relative dryness of wet steam** may be easily calculated from the following formula. Let p_1 = steam pressure in main, lb. per sq. in., abs.; p_2 = steam pressure in calorimeter, lb. per sq. in., abs.; t_c = temperature in calorimeter, deg. fahr.; l_1 and h_1 = heat of vaporization and heat of liquid corresponding to pressure p_1, B.t.u.; H_2 and t_2 = total heat (B.t.u.) and temperature (deg. fahr.) corresponding to pressure p_2; c_p = specific heat of superheated steam (assume 0.47 for approximately atmospheric pressures existing in calorimeters); x_1 = initial quality of steam; and $1 - x_1$ = initial moisture in steam; then $x_1 = [H_2 + 0.47(t_c - t_2) - h_1]/l_1$.

Chart for Moisture Determinations. The diagram in Fig. 5 provides a convenient and accurate means for determining the quality of steam without using the formula given above. Horizontal lines represent the process in a throttling calorimeter. As an example of its use, let initial pressure of the steam be 165 lb. per sq. in. abs., the temperature in the calorimeter 270 deg. fahr. and the pressure therein 15.2 lb. per sq. in. abs. Starting at the intersection of the temperature line for 270 deg. fahr. with the 15.2-lb. pressure line and going across the chart horizontally to the 165-lb. pressure line, the "lines of constant quality" indicate that the quality for this case is 0.979.

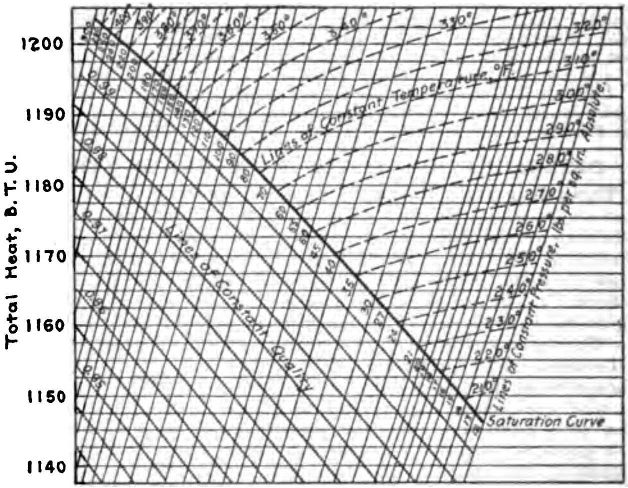

FIG. 5.—Chart for Determining the Quality of Steam.

A throttling calorimeter may be easily made up of pipe fittings, inserting a flat disk with a 3⁄32-in. hole for an orifice. The cost of an instrument made in this way should not be more than $5.

Separating Calorimeters may be used for determining the quality of steam which contains more moisture than can be determined by a throttling calorimeter. A simple form is shown in Fig. 6. The moisture is removed from the sample of steam by mechanical separation just as in the ordinary steam separator installed in the steam mains of a power plant. Steam enters at *A*, passes down through the vertical pipe into the perforated basin *B*, from which the dry steam escapes through a narrow slot near the top into the jacket *J*, while the moisture is deposited at the bottom of the vessel *V*. The volume or weight of the moisture can be determined from the height of the water in the gage glass *G*. Dry steam from the jacket *J* is discharged from the orifice *O* and must be condensed and weighed in a vessel containing cold water. The percentage of moisture is found by dividing the weight of water collected in the vessel *V* by the sum of the weight of steam condensed and the weight of water collected in *V*.

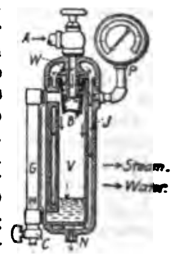

FIG. 6.—Separating Calorimeter.

Combined Separating and Throttling Calorimeters. The separating calorimeters already described are effective in removing practically all of the moisture in steam when the pressure is not lower than 25 lb. per sq. in.

gage pressure. For lower pressures, such calorimeters may not take out more than 80 per cent. of the moisture (*Trans. A. S. M. E.*, 1910, p. 76). Consequently, for determinations of moisture in low-pressure steam, a throttling calorimeter should be attached to the discharge of the separating calorimeter. A throttling calorimeter discharging into the atmosphere has very little capacity when used with low steam pressures. By making it discharge into a receiver in which a high vacuum is maintained, the throttling portion of the calorimeter will evaporate 2 to 3 per cent. of moisture. A combination separating and throttling calorimeter for low-pressure steam is shown in Fig. 7. The ½-in. brass nozzle of the sampling tube is directed against the flow of the steam. The lip of this nozzle is filed to a knife-edge to reduce the disturbance of the current to a minimum. This sampling orifice should be located at a distance of one-sixth of the diameter of the pipe from its side. The lever cock between the separating and the throttling calorimeters produces the necessary throttling action. In the throttling portion steam is condensed in a vacuum receiver, from which it flows to a volumetric measuring tank. A spyglass is used for observing whether moisture is passing through. As the spyglass is not large enough to carry all the steam, a by-pass connection is provided. All parts are covered with magnesia covering 2 in. thick. Radiation can be made less than 0.1 per cent.

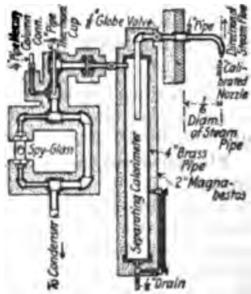

FIG. 7.—Combined Separating and Throttling Calorimeter.

Calculation of Percentage Moisture for Combination Separating and Throttling Calorimeter. The quality of steam x_1 is calculated for a combination calorimeter as follows: Let w_1 = weight of moisture collected in the separating calorimeter in a given time, lb.; w_2 = weight of dry steam condensed after passing through the throttling calorimeter, lb.; and x_2 = quality of steam discharged from separating portion as determined by the throttling calorimeter. Then, without sensible error, $x_1 = w_2x_2/(w_1 + w_2)$.

If radiation is appreciable and R is weight of condensation due to radiation in pounds in a given time corresponding to the other units, then $x_1 = (w_2 + R)x_2/(w_1 + w_2)$.

Superheating Calorimeters. A number of different types of calorimeters have been devised which depend for their action on superheating the steam by heat from an external source. The most successful of these uses electrical heating. Such an apparatus is serviceable for steam of high quality as well as low. Throttling calorimeters are usually preferred on account of greater simplicity, lower cost and because electric current is often not available where tests are to be made.

MEASUREMENT OF AREAS

The areas of irregular figures such as indicator diagrams are generally determined either by measuring the lengths of ordinates drawn on the figure and inserting their values in certain formulæ or "rules," or from readings of planimeters.

In the **ordinate method**, the figure (Fig. 8) is divided by parallel lines into an even number of strips of equal width w, and the ordinates $y_0, y_1, y_2 \ldots\ldots y_n$ measured.

FIG. 8.

Letting n = number of strips (the greater the value of n the greater the accuracy of the method), the area A may be approximately determined by using one of the following formulæ:

(1) **Trapezoid Rule:**

$$A = w(\tfrac{1}{2}y_0 + y_1 + y_2 + \ldots\ldots\ldots y_{n-1} + \tfrac{1}{2}y_n)$$

(2) **Durand's Rule:**

$$A = w(0.4y_0 + 1.1y_1 + y_2 + y_3 + \ldots\ldots\ldots y_{n-2} + 1.1y_{n-1} + 0.4y_n)$$

(3) **Simpson's Rule** (see also p. 106):

$$A = \tfrac{1}{3}w(y_0 + 4y_1 + 2y_2 + 4y_3 + \ldots\ldots + 2y_{n-2} + 4y_{n-1} + y_n)$$

The various lengths required by the foregoing methods can be conveniently added by laying them off with dividers one after the other along a straight line and finally measuring the total length of the line.

Planimeters are instruments for measuring areas. The **Amsler planimeter** (Fig. 9) consists of two arms pivoted at O. At the end of one arm is a tracing point T, and at the end of the other a "fixed point" P. Attached to the tracing arm is a small graduated wheel W. In using the instrument, mark a starting point for the tracing point T on the contour of the figure to be measured and observe the reading of the graduated wheel W. If the figure is traced in a **clockwise** direction, back to the starting point, the area measured is found by subtracting the first reading from the last; but if the tracing point is moved around in a **counter-clockwise** direction, the last reading must be subtracted from the first. The foregoing applies to small areas of only a few square inches, such as indicator diagrams, etc. For large figures the area of the zero circle of the instrument enters into the calculation of areas. This correction has to be added whenever the fixed point is inside the area which is being measured. Its value can be determined by measuring a circle or other figure of known area. The difference between the known area and that recorded by the instrument is the area of the zero circle. The area of the zero circle is stamped conspicuously on many planimeters. For measuring figures of indefinite length and limited breadth, **roller planimeters** must be used. They are expensive and are not much used in America.

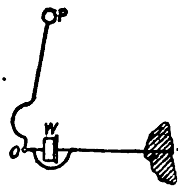

Fig. 9. Planimeter.

Integrators for Circular Charts. Instruments have been developed for measuring the mean ordinate of circular charts having a constant radial scale. Such instruments are made by the Bristol Co.

Prices of Planimeters. Amsler's "polar," \$7 to \$25 (Keuffel & Esser Co., and Eugene Dietzgen Co., New York); Coffin's "averager," \$20 to \$35 (Ashcroft Mfg. Co., New York); Coradi's roller, \$25 to \$50; Bristol-Durand integrator, \$15 to \$25 (Bristol Co., Waterbury, Conn.).

INDICATORS AND REDUCING MOTIONS

Indicators. Outside-spring indicators are coming into general use, and are particularly desirable for use with steam at high temperatures and for internal-combustion engines. In this type of indicator the elasticity of the spring cannot be affected by the steam temperature and the springs can be readily changed without removing parts of the indicator usually uncomfortably heated.

The **essential requirements for a good indicator** are (1) an accurately calibrated and elastic spring; (2) a light piston; (3) a small and light pencil mechanism and drum; (4) a "free" and practically frictionless movement of the pencil on the paper. The **scale or "number"** of a spring indicates the pressure in lb. per sq. in. producing a vertical movement of .1 in. at the pencil point. For high-speed engines the makers of the Thompson indicator recommend the following scales:

Maximum pressure, lb. per sq. in.	6	12	20	30	45	60	70	80	100	125	150	180	200	250
Scale or "number" of spring....	12	16	20	24	30	40	50	50	60	80	100	120	150	175

For slow-speed Corliss engines the following scales may be used:

Maximum pressure, lb. per sq. in..	8	12	18	30	40	50	70	90	125	150	200
Scale or "number" of spring.....	8	10	12	16	20	24	30	40	50	60	80

For engines operating at not over 200 r.p.m. the Crosby Co. recommends the selection of a spring making the height of the diagram for the maximum steam pressure at the engine about 1¾ in. For high-speed engines it is desirable to take smaller diagrams to avoid excessive inertia effects of the indicator piston and pencil mechanism. It is also recommended that the length of the diagram should not exceed 2½ to 3 in.

Indicator **springs** are never quite accurate for all heights of diagrams, even when new, so that for accurate work, as for example the making of guarantee tests of engines, the springs should be calibrated before and after a test. Calibrations of indicator springs that are good enough for rough checking in ordinary service can be made by comparing the vertical pencil movement with an accurate "test" steam gage at about 5 "steps" of pressure above and 3 below the atmospheric line. For accurate work comparison must be made with the indications of a mercury column or of some other special calibrating device.

There are other **errors** in indicator **diagrams. The drum** of the indicator is usually moved by means of a cord, the stretch of which varies throughout the reciprocation. When steel wires are used instead of a cord, errors due to stretching are rendered negligible; but the wire has the disadvantages of being stiff and easily tangled, while its weight introduces an objectionable element. The **indicator cord** used should be of the very best quality and its length should be made as short as possible. For lengths greater than 3 ft., wire should be used. The stretching of the cord is due to (1) inertia of the drum, causing the tension in the cord to be variable and the indicator diagram too long; (2) friction of the drum, causing stretching of the cord so as to make the position of points in the diagram lag behind the true position by an amount equal to the stretch.

Errors due to varying tension in the cord caused by inertia can be made very small by using a drum spring of a stiffness suitable for the speed of the engine. For indicating a high-speed engine a very stiff drum spring is required. The distortion and variation in length of the indicator diagram can be shown by turning the engine over by hand and taking the length of the stroke of the drum when inertia is negligible, and afterward running the engine at various speeds and taking diagrams. Such tests will show the suitableness of a drum spring for high speeds. If there is a large variation, a stiffer spring should be obtained. This error is also proportional to the length of the diagram, so that shorter diagrams are advisable at high speeds.

Drum friction and its effect in stretching the cord have been shown by Prof. O. Reynolds (*Proc. Inst. C. E.*, vol. 83) to have an appreciable effect on the calculated value of indicated horse power. He shows that the error in mean effective pressure is proportional to the stretching of the cord caused by drum friction, and that the least amount of stretch in a good indicator cord is 0.4 per cent. of its length. In the case of a cord 3 ft. long, the stretching under the best conditions would be about 0.14 in.

The errors due to inertia and friction have opposite effects, the one making the diagram longer and the other making it shorter. The indicated horse power at moderate speeds should be not more than 2 or 3 per cent. in error if the indicator drum spring and quality of cord are properly selected for the pressure and speed, assuming that the piston and drum move freely and are well lubricated (*Proc. Inst. M. E.*, 1905, pp. 785–788) and the piston spring has been carefully calibrated. At speeds exceeding 300 to 350 r.p.m. the probable error increases rapidly.

Automobile, aeroplane and other engines operating at speeds exceeding 500 to 600 r.p.m. require special indicators. The best known is the **manograph** or diaphragm type, in which the pressure in the engine cylinder deflects a diaphragm which in turn moves a small mirror about an axis in a vertical plane, while a somewhat complicated reducing motion deflects the mirror about an axis in a horizontal plane. A beam of light reflected from the mirror traces the diagram on a ground glass or a photographic plate. An instrument of this kind shows practically no inertia effects and there is no cord used to cause errors by its stretching. It is liable to very large errors. Another type of **optical indicator** devised by Prof. Hopkinson is also used in England. It differs essentially from the manograph in having a piston instead of a diaphragm. It can be made to give excellent results.

Precautions in the Use of Indicators. Unless an engine indicator is carefully handled the diagrams taken with it may be in error from 5 to 10 per cent. The following are the most important considerations:

1. Springs must be calibrated frequently.

2. The tension of the spring in the drum should be adjusted so that the drum revolves without slackness in the cord on the return stroke. If the cord sags on the return stroke the error may be considerable, but if the tension of the cord does not vary a great deal, errors due to stretching of cords of ordinary lengths are not serious.

3. Before an indicator is used all working parts should be cleaned and oiled. The piston and its rod should be examined before attaching the spring to determine by lifting the pencil lever and letting it fall whether these parts move easily. Attach the spring firmly and observe carefully that there is no lost motion. This precaution is most important in indicators having a bead on the spring for making a ball-and-socket joint. To put this kind of spring in place properly, the piston rod should be screwed tightly into the piston when the lower adjusting nut is loose. Then screw up this nut just tight enough to permit a slight movement. If the nut in the piston has been properly adjusted there should be no lost motion between the rod and the piston, and still there should be flexibility in this joint permitting the piston to adjust itself in the indicator cylinder.

4. Oil the piston with cylinder oil every time it is taken from the cylinder. Many careful engineers oil the piston regularly after taking about ten diagrams. A new piston usually requires more lubrication than one that is well worn.

5. Adjust the handle on the pencil motion so that when the pencil is sharp it will draw a very fine line. If the pencil presses heavily on the paper, friction and shifting of the paper may distort the diagrams. Prepared metallic paper if used with blunt brass points increases pencil friction considerably above what it is when sharp lead pencils or ordinary "household" pins are used.

6. Adjust the length of the indicator cord. If too short, it will be broken when the engine is started and may also injure the indicator; and if too long, the drum will strike against its stops and give a deformed diagram. After adjusting the length of the cord the engine should be turned over by hand to make sure the cord is of proper length.

7. Immediately after a diagram has been taken it should be examined and any irregularities or faults noted and corrected.

8. Mark diagrams plainly as regards head and crank ends of double-acting engines, the time, scale of spring, and name or initials of the person taking them.

9. Best results are always obtained with an indicator at each end of the cylinder of a double-acting engine. Tests show that sharp bends, long pipes and restrictions of bore may cause errors in indicator diagrams as great as 20 per cent. (W. F. M. Goss, *Trans. A. S. M. E.*, 1896.) This is a particularly important consideration in air and ammonia

compressors having very small clearance, and in long-stroke engines where the piping for a 3-way cock for a single indicator would add considerably to the clearance.

10. The indicator cock should be kept closed and the cord to the reducing motion should be unhooked except when a diagram is being taken.

Prices of Indicators. Crosby, $80 (Crosby Steam Gage & Valve Co., Boston); Thompson, $50 to $75 (American Steam Gauge and Valve Mfg. Co., Boston, and Trill Indicator Co., Corry, Pa.); Tabor, $65 (Ashcroft Mfg. Co., New York); Manograph (optical), $300 (Hugo C. Gibson, W. 135th St., New York); Hopkinson's (optical), $100 (Dobbie-McInnes Co., Ltd., Glasgow and London).

Reducing Motions

To obtain the conventional indicator diagram the drum of the indicator must be moved so as to give on a smaller scale an exact reproduction of the motion of the piston. A device accomplishing this is called a perfect reducing motion. Many devices used quite generally do not give a perfect motion.

The Pantagraph (Fig. 10) is a theoretically perfect device, and is actually accurate so long as there is no slackness at the numerous pinned joints. The point of attachment of the indicator cord *B* must be in the straight line joining the fixed point *C* with the connection on the cross head *A*. Fig. 11 is a simple reducing motion that is nearly perfect when properly laid out. The pin *D* is attached to the cross head *C* and the link *BD* connects the cross head to the oscillating arm *AB*. To convenient points, as 1, 2, or 3, the indicator cord is attached. If the arc *XY* in its extreme positions at the ends of the stroke reaches as much above the center line of motion of the pin *D* as it does below, the movement of the drum will be almost an exact duplicate of that of the piston. If the indicator motion is taken from the heavy dotted circular segment *G* instead of from a pin, the motion is more accurate. Fig. 12 is also a simple device and is fairly accurate if *AB* is made equal to *BC*. The cord is attached to *D*.

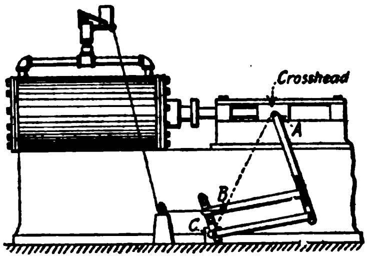

Fig. 10.—Pantagraph Reducing Motion.

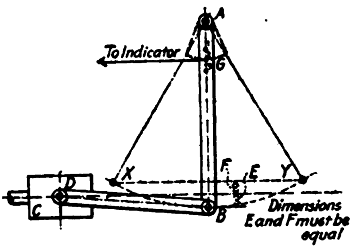

Fig. 11.

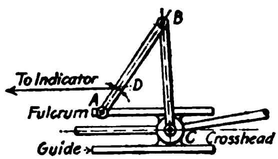

Fig. 12.

Simple Indicator Reducing Motions.

The method illustrated in Fig. 13 consists merely in attaching the indicator cord to a pin on the crank shaft and then changing its direction by passing it over a pulley not far from the shaft. In such an ar-

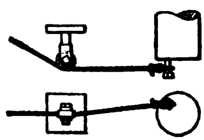

Fig. 13.

rangement the motion of the drum will not be even approximately proportional to that of the engine piston. Indicator diagrams taken with this device will be very much in error unless the pulley changing the direction of the cord is located at a considerable distance from the shaft. To reduce the error due to a long cord, wire should be used in such cases. Fig. 14 shows an accurate and simple reducing motion for attachment to the crank shaft. The ratio of the lengths of the connecting rod and stroke of this device must be the same as the corresponding ratio in the engine. A similar device is shown in Fig. 15.

FIG. 14.

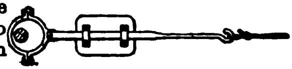

FIG. 15.

Reducing Wheels are coming into very general use. They may either be attached to the drum of the indicator or to some convenient part of the engine. Fig. 16 shows a typical device. The large wheel receives the cord direct from the cross head and the cord on the small wheel is connected direct to the drum of the indicator. Ratio of diameters gives the reduction. Each reducing wheel is provided with a nest of rings to be put on the small wheel to increase its diameter so that various reductions are possible to suit the stroke of the engine. The indicator drum is started and stopped by turning the knurled nut on top of the small wheel. The large wheel has a spring at its center to bring it back on the inward stroke. In engine testing for long periods it is desirable to disconnect the cord connecting the large pulley with the cross head during the intervals between taking diagrams. Hooks like those shown in Figs. 17 and 18 are very convenient for this purpose, particularly if attachment of the cords can be made to a pin on the cross head. The Trill hook (Fig. 17) is intended to be held between the thumb and finger, about an inch from either end of the stroke, so that the pin or standard on the cross head strikes the straight part of the hook, and immediately the pin or standard will be caught. The hook shown in Fig. 18 is used in the same way. The hook is of spring brass and is held so that the pin or standard *A* of the cross head strikes the crotch when about 1 in. from the end of its stroke and opens the hook and assumes the dotted position when in operation. In disengagement the hook is slipped off the end of the pin. Unless some special form of hook is used, as described, it is difficult to connect the cord when a diagram is to be taken, and the cord is likely to get tangled in moving parts of the engine or to be broken. Such difficulties can often be avoided, particularly in the case of such devices as Figs. 14 and 15, by continuing the cord from its point of attachment to the reducing motion closely past the indicator drum to a pipe or simple bracket that may serve as a stationary support. Between the indicator and this last support a spiral or helical spring of rather light wire or a heavy rubber band is attached to the cord, and will keep it taut and in motion. If now a ring is attached to the cord close to the indicator and between it and the reducing motion, this ring will be continually in motion but it will not be difficult to hitch into it the hook on the portion of cord

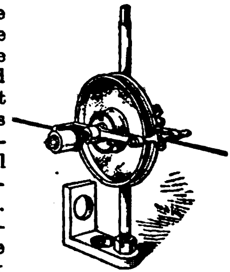

FIG. 16.—Reducing Wheel.

FIG. 17.

FIG. 18.

connected to the indicator drum. This method is particularly recommended in every case where wire is used instead of cord.

Some indicators are provided with a detent, or device for engaging a pawl in teeth on the circumference of the drum near the bottom and stopping the drum. Obviously, the pawl must engage when the cord is pulled out to the end of its stroke. On the return stroke the cord will flap about and possibly catch on something and be broken on the next outward stroke. The best way to prevent this is to keep the string always taut by using a helical spring or rubber band attached to some fixed point, as explained above. In all types of reducing motions except those in which the cord is taken off on a tangent to an arc of a circle, the direction of the cord as it moves back and forth at its point of attachment to the reducing motion must be parallel to the movement of the engine piston. Reducing motions are sometimes made inaccurate by not locating auxiliary pulleys properly to give the cord its proper direction.

WEIGHING DEVICES

The following devices are ordinarily used in engineering work to determine weight:

	Usual capacity, lb.	Probable sensitiveness, lb.
Platform scales	100 to 2,000	1/16 to 1/4
Spring balances	5 to 200	1/16 to 1
Torsion balances	10	1/32 to 1/4
Automatic scales:		
1. Pendulum type	50	1/32
2. Spring type	200	1/16
Chemical balances	50 (grams)	1 in 100,000

Platform Scales are best suited for most weighing operations. This type is quite sensitive when new, but its original sensitiveness is soon lost if the knife edges are allowed to become rusty from exposure to dampness, or become dulled from careless and excessive loading. All scales should be tested with standard weights and adjusted whenever used in important work. **Spring and torsion balances** are usually not very reliable and are used chiefly because they are easily portable and compact. Zero reading is not dependable. Careful calibrations are essential. **Automatic indicating scales,** particularly of the pendulum ("Toledo") type, are the best for weighing the fuel consumption of oil engines. A pointer on a dial indicates continuously the weight, so that observations can be made rapidly and without balancing. Devices of this type, operating with a spring mechanism, are subject to the same faults as the usual types of spring balances. **Automatic scales** for coal bunkers are filled under the chute from the bunker till a predetermined weight has accumulated. The supply is then shut off, and the scoop trips and discharges. Such devices are usually integrating, while automatic scales for weighing fuel being conveyed to power houses and furnaces are recording (see p. 1183).

Prices of Scales. Small platform (portable, for floor use), $15 to $50; (for counter use) $7 to $25; (for weighing wagon and car loads) $125 to $500; spring balances, $0.50 to $10; automatic pendulum scales, $50 to $100 (Toledo Scale Co., Toledo, O.); chemical balances, $25 to $100; integrating scales for coal bunkers, etc., $200 to $1000 (Fairbanks Co., New York and Chicago; or Streeter-Amet Co., Chicago).

MEASUREMENT OF POWER

Dynamometers, or instruments for measuring force or "power," are in general of two kinds: (1) Those **absorbing** the power by friction and dissipating it as heat; (2) those **transmitting** or passing on the power they measure, and wasting only a small part in friction. Devices for measuring power may be classified for convenience as follows:

Type	Approx. limit of speed, r.p.m.	Usual power limit, h.p.	Probable error, per cent.
Prony brakes:			
Block	1,000	10	1
Band	1,000	5	1
Wooden cleats on bands	1,000	100	1
Rope (¾-in.) with wooden cleats	1,000	50	1
Fluid friction dynamometers:			
Froude (ordinary "water" brake)	2,500	500	1
Westinghouse (turbine)	4,000	5,000	0.2
Alden	300	3,000	1
Fan brake	2,000	200	1 to 5
Electric eddy-current brake	2,000	100	1
Electric generator	750 to 4,000	30,000	0.2
Transmission dynamometers:			
Torsion	1,000 to 3,000	50,000	2 to 5
Emerson	300	50	2 to 5
Kenerson	1,500	100	2

The speed limits given above are approximately the highest allowable. Limits of horse power refer to the largest sizes made commercially. Any of these types (with the exception of the Westinghouse turbine) are made in sizes to absorb from 1 h.p. up. The probable error stated is very approximate and refers to the apparatus in fair adjustment.

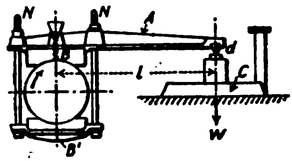

Fig. 19.

Absorption Dynamometers

A Prony Brake consists of a lever A (Fig. 19) and blocks, B, B' supported on a revolving drum or pulley. The blocks are held in place and tightened by the thumb nuts N, N. The tendency of the arm A to revolve is prevented by the resistance of a platform scales C as shown, or by weights attached. If the pressure on the pedestal at d due to its own weight and that of the lever arm A is W_0 lb. (determined by the weight on the scales when the brake block is supported at B on a three-cornered prism or on a small rod of circular section), the gross weight at the end of the brake arm with load is W lb., the length of the brake arm in ft. is l, and the number of revolutions per minute is n, then brake horse power (b.h.p.) $= 2\pi ln(W - W_0)/33{,}000$.

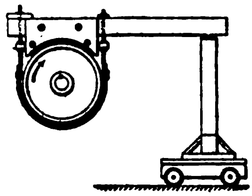

Fig. 20.

According to Bach, suitable **dimensions for a brake** of this type are given by the formula $bd =$ b.h.p. $\times 12/k$, where d is the diameter of the brake pulley in in., b the breadth of the brake blocks in in. (usually about 1.5 times the diam. of the shaft), and $k = 1/2$ for air cooling and varies from 2.5 to 5 for water-cooling as

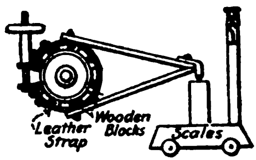

Fig. 21.

Fig. 19–21.—Types of Prony Brakes.

the speed increases. F. A. Halsey (*Am. Mach.*, April 4, 1912) states that the brake drum surface for a water-cooled Prony brake should not be less than 0.09 sq. ft. per b.h.p., to avoid the danger of the blocks taking fire.

In Fig. 20 the lower block in the preceding figure is replaced by two steel bands and narrow cleats of maple or oak attached by wood screws inserted from the outside through the bands; the upper block is lined with similar cleats, the screws being countersunk. At least ¼-in. spaces should be allowed between cleats for air circulation. In all such constructions for dynamometers, screws and nails should not touch the friction surface, as they are likely to cause the friction to be variable and the sound produced is objectionable. Grooves may be cut in the inside surface of a few of the cleats, and these grooves filled with grease to provide a little lubrication. A similar brake is shown in Fig. 21, where maple cleats are screwed to a leather belt. This type is more easily adjustable to different sizes of pulleys than the preceding designs, but it is not as durable. Washers should be placed on the heads of the screws fastening the cleats to the belt. If a brake wheel similar to Fig. 22 is used so that it can be satisfactorily cooled with water on its inside surface, the cleats should provide 5 to 10 sq. in. of friction surface per b.h.p. according as the speed ranges from low to high.

Fig. 22.

Band and Rope Brakes are also frequently used. The simplest form is shown in Fig. 23. If P is the reading of the spring balance in lb., r the wheel radius in ft., Q the applied weight in lb. (both P and Q must be net), and n the r.p.m., then b.h.p. = $2\pi rn(Q - P)/33{,}000$. This type of brake is very **accurate** and **sensitive**, but it is suitable only for low powers. About the same friction surface must be allowed as given for wooden blocks by Bach's formula (see Prony Brakes, *ante*). A convenient type of **rope brake** with "stay" cleats is shown in Fig. 24, the rope being passed around the circumference of the pulley. In this arrangement the cord or rope supporting the spring balance must have some point of attachment overhead. It is advisable to provide an anchoring rope or wire securely attached to the weights P, and its weight (or that part of it suspended) must then be added to P. Similarly, the weight of the rope between the spring balance and the point where it touches the pulley should be deducted from the readings of the spring balance. Usually 4 to 6 cleats are used on rope brakes. These cleats are often attached to the ropes by strong copper wire passed through a strand of the rope and over the backs of the cleats. The best arrangement is to place the rope on

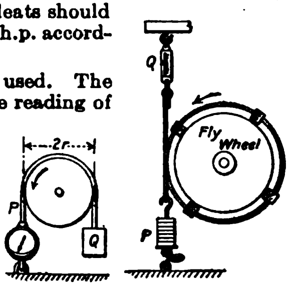

Fig. 23. Fig. 24.
Rope Brakes.

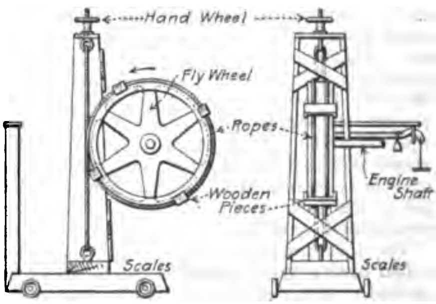

Fig. 25 Rope Brake.

the wheel double. In Fig. 25 an arrangement is shown in which both ends of the rope are attached to a rigid frame supported on weighing scales. The reading of the scales (corrected for the weight of the frame) gives $Q - P$ directly. A double rope ¾ in. in diameter with 6 cleats each of about 12 sq. in. on the "friction" side will absorb 50 b.h.p. For engines of smaller power ½-in. rope with 4 cleats is used. By steeping the rope in a mixture of melted tallow and graphite the frictional properties are improved. Manila or cotton ropes are used.

Fluid Friction Dynamometers are of the absorption type. There are three kinds. One arrangement is similar in principle to a centrifugal pump, the casing being balanced and supported on the pump shaft. An attached brake arm supported on scales measures the turning moment. This is the **Froude** or ordinary **"water" brake,** which differs from a centrifugal pump in that the runner is made with deep recesses to increase the resistance. The tendency is to carry the casing around in the direction of rotation. If $(W - W_0)$ is the net pressure at the end of the brake arm and l is the length of the arm, then the brake horse power is calculated in the same way as for a Prony brake (see *ante*). The **Westinghouse turbine hydraulic dynamometer** is a second type. It is essentially a double-flow steam turbine with blades shaped to produce great resistance to flow. The casing is balanced on the shaft and provided with a brake arm in the same way as the Froude dynamometer. Power is also calculated in the same way.

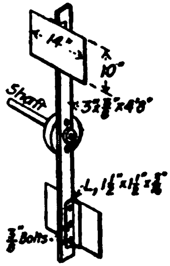

Fig. 26.—Fan Brake Dynamometer.

Alden's Dynamometer has for its rotor simply a flat cast-iron disk which revolves between two flexible copper plates attached to the inside of the casing. The iron rotor revolves in heavy cylinder oil. There is a small clearance on each side between the ends of the cylindrical casing and the copper plates, and water under pressure is forced into these spaces. By increasing the pressure the copper plates will be brought nearer the rotor and the friction will be increased. The turning moment is measured with a lever arm resting on a platform scales. (For a more detailed description of absorption dynamometers, see Royd's "Testing of Motive Power Engines," pp. 89–98; Moyer's "Power Plant Testing," pp. 127–131.) If the temperature of the water is raised 50 deg. fahr., dynamometers of this type require about 50 lb. water per b.h.p. per hour; but if the water is entirely evaporated, only about ⅒ as much.

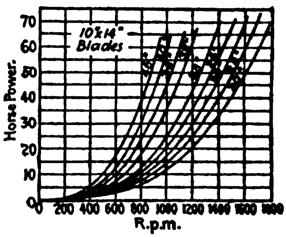

Fig. 27.—Power Absorbed by Fan Brake Dynamometer.

For the approximate determination of the horse power of high-speed engines a **fan brake dynamometer** consisting of two fan plates (Fig. 26) to be attached to the shaft is very convenient but is less reliable than any of the other methods described. The power is absorbed by the "fan" action of the plates on the surrounding air, which depends on the size of the plates, their distance from the center of rotation, and upon the cube of the r.p.m. Fig. 27 shows curves for determining the b.h.p. for varying speeds of a fan with rectangular blades 10 in. wide in a radial direction, 14 in. wide axially, and ¼ in. thick. These curves are for atmospheric pressure of 14.7 lb. per sq. in. and a temperature of 70 deg. fahr. Errors are introduced by other pressures and temperatures. The numbers on the curves indicate inches from the center of one plate to the center of the other. This distance is varied by shifting the bolts. This is probably the simplest as regards construction and most compact of all the types of dynamometers.

Eddy-current Brakes are made with a number of electromagnets and one or more copper disks. Either the electromagnets may be rotated with the shaft while the copper disks are held stationary, or *vice versa*. Eddy currents generated by rotation with the magnets excited produce a resistance, of which the moment is measured by a lever arm and scales as with similar forms of dynamometers. (For further information regarding the design of this type see "Eddy-current Brakes," *Jour. Inst. E. E.*, vol. 35.)

Dynamos as Power Dynamometers. One of the most convenient means for measuring the power of high-speed engines and turbines is to connect an electric generator to the main shaft. Then, if the efficiency of the generator is known at the particular speed and output at which it is operated, a very accurate method of measuring the power of the engine or of any other type of motor becomes readily available. For direct-current generators, b.h.p. = (volts × amperes)/(746 × efficiency of generator).

The load on the generator should be maintained uniform by absorbing electrical output in lamp or wire resistances, but for larger powers a water resistance (see p. 1593) is generally used. In some places the dynamo has been used as a brake, by supporting the dynamo frame on its shaft and measuring the resulting torque by a lever arm and scales.

Transmission Dynamometers

Torsion Dynamometers. When a shaft is subjected to a twisting moment an angular twist is produced which is proportional to that moment. Thus, if the angle of twist is produced by a twisting moment T in in.-lb. and n is the r.p.m., then b.h.p. $= 2\pi Tn/(12 \times 33{,}000)$.

Torsion meters, although applicable to large as well as small powers, have their most important applications for measuring shaft horse power of marine turbines and engines. (For descriptions of various types of transmission dynamometers, see Carpenter and Diederichs, "Experimental Engineering," pp. 293–318.)

Prices of Dynamometers. Prony brake, \$5 to \$25; rope or band brakes, \$2 to \$5; electric brakes (50 h.p.), \$1000 to \$2000 (Sprague Electric Co., New York; Diehl Mfg. Co., Elizabethport, N. J.); water brakes (25 h.p.), \$200 to \$500 (Standard Motor Co., Jersey City, N. J.; Michigan Motor Specialty Co., Detroit, Mich.); Kenerson torsion dynamometer, \$150 to \$400 (Builders' Iron Fdy. Co., Providence, R. I.); Emerson power scales (Florence Machine Co., Florence, Mass.).

MEASUREMENT OF FLUIDS

The following tabulation serves to indicate the methods used for the measurement of the volume, weight, or velocity of fluids:

	Measurement	Permissible velocity, ft. per sec.	Probable error, per cent.
Gas meters:			
"Wet" meter	Volume	(100 r.p.m.)	½
"Dry" meter	Volume		5 to 10
Pitot tube	Velocity	8 to 400	1
Anemometer	Velocity	1 to 40	1 to 5
Electric meter	Weight	3 to 500	½
Receiver	Volume	Unlimited	1
Orifice	Weight	Unlimited	2
Venturi tube	Velocity	Unlimited	1
Steam meters:			
Pitot tube	Velocity	10 to 400	1
Orifice	Weight	Unlimited	½
Float	Volume	50 to 200	2
Water meters:			
Impulse wheel	Velocity	5 to 100	1
Rotary disk	Volume	(100 r.p.m.)	1
Piston	Volume	(150 strokes per min.)	1 to 5
Rectangular weir	Volume	Unlimited	½ to 1
V-shaped weir	Volume	Unlimited	½ to 1
Flow-proportional-to-head weir	Volume	Unlimited	½ to 1
Automatic tank	Volume	(Up to 20 lb.)	1
Venturi tube	Velocity	Varying	½
Pitot tube	Velocity	10 to 400	1

Gas Meters

"Wet" Gas Meters are used when accurate determinations of volume of gas are required. A meter of this kind consists of a drum somewhat resembling a paddle wheel revolving on a horizontal axis in an enclosed cylindrical casing partly filled with water. The principle of operation is shown in Fig. 28. There are four compartments *A*, *B*, *C*, and *D*, and passages *a*, *b*, *c*, and *d* at the center are made to operate as valves by the water seal, admitting gas to the compartments out of the water. Gas is discharged through similar valves *a′*, *b′*, *c′* and *d′* at the periphery. Smallest rates of flow are accurately measured. It is essential that the water level be maintained at the standard level of its calibration and that the apparatus be properly adjusted by the spirit levels. Fluctuations of velocity can produce errors only when large enough to cause surging of water level so that the valves are not at all times sealed. If the flow is intermittent, as in the suction line of an engine or compressor taking gas under pressure, a gas bag is generally used as a regulator. When as in suction-producer plants there is a vacuum in the suction line, a regulator consisting of a diving bell hung on springs is used.

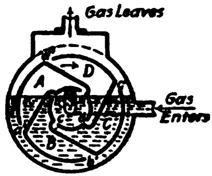

Fig. 28.—Wet Gas Meter.

"Dry" Gas Meters are used for the usual "house metering" of gas. No high degree of accuracy is claimed, but they are more adaptable for such service than the "wet" types because a water level need not be maintained. Such meters consist of two chambers separated by a vertical partition, each chamber containing an interior measuring receiver having a flexible shell. Gas is admitted to these measuring receivers alternately and automatically by means of slide valves. Reciprocating movements of filling and emptying these receivers actuate the counting mechanism.

Pitot Tubes (see pp. 255 and 285) are the most satisfactory devices for measurement of gas in large volumes. Let p = velocity pressure, in inches of water; v = velocity of flow, ft. per sec.; h = equivalent height (head) in ft. of a column of air to produce p; w_w = weight of 1 cu. ft. of water, lb. (62.4 nearly); w_a = weight of 1 cu. ft. of air at conditions of test; then $h = (p/12)(w_w/w_a) = 5.02p/w_a$, and $v = 18.3\sqrt{p/w_a}$. Tables of the weight of air for varying temperatures and humidities are given on p. 1512.

In **fan testing** the B. F. Sturtevant Co. employs a Pitot tube similar to that shown in Fig. 45, p. 285, in which the concentric brass tubes are ¼ in. and ⅜ in. in diameter and the overall dimension from nozzle tip to heel is 10 in. In place of the small holes in the outer tube of Fig. 45, however, there are two $1/16 \times 2\frac{1}{4}$-in. diametrically opposite slots beginning 3¾ in. back from the nozzle top and extending toward the heel. The form shown in Fig. 45, with small holes in the outer tube, indicates a greater volume and less static pressure than does the slit-tube type.

For finding average velocity in a circular pipe, see p. 286. For a pipe of radius R divided into 5 rings, the "stations" or points of observation would be at the following distances from the center: (1) $0.316R$, (2) $0.548R$, (3) $0.707R$, (4) $0.837R$, (5) $0.949R$. Ducts of square or rectangular section are usually divided up similarly into a series of elementary squares or rectangles.

A detailed discussion of the relative accuracy of different types of Pitot tubes is given in *Trans. A. S. M. E.*, vol. 33, p. 1137 (1911).

Anemometers are used for approximate work in measuring the velocity of air and gas. These instruments consist of a light vane wheel fixed on a shaft to which a counting mechanism is attached. Readings of the counter are taken at the beginning and end of a suitable time interval, usually ½ to 1 min. The axis of rotation must be in the direction of the flow of air. Upper and lower velocity limits beyond which they should not be used are generally stated on the cases of the better grade of these instruments. They are delicate and require frequent calibration and careful handling. Above a velocity of 2000 ft. per min. their use is not advocated. For the higher velocities a Pitot tube is the best means for calibration, and for low velocities a "wet" type of gas meter can be used. A common method of calibration, having many objections on account of the difficulty in preventing eddy currents, is to mount the anemometer at the end of a rotating arm. In such tests the anemometer records a higher value than when used for measuring a "straight-line" flow.

Prices of Meters, Pitot Tubes, and Anemometers. "Wet" gas meter (small laboratory sizes), $25 to $65 (American Meter Co., Philadelphia); "dry" meters (20 "lights"), $15 to $20 (Helme and McIlhenney, Philadelphia); Pitot tubes, $15 (B. F. Sturtevant Co., Hyde Park, Mass.; American Blower Co., Detroit), Burnham, $20 (C. F. Gebhardt, Chicago); anemometers, $18 to $35 (Keuffel & Esser Co., New York).

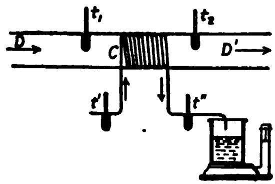

Fig. 29.

Measurements of Flow by Heating or Cooling. This method depends on taking from or adding to the gas to be measured a quantity of heat and observing its change in temperature. Fig. 29 shows a typical arrangement in which a coil C for either heating or cooling is well distributed over the section of the duct DD'. Thermometers are arranged as shown. Initial and final temperatures of the air are t_1 and t_2. Entering and leaving temperatures of the heating or cooling medium are t' and t''. If W_a = weight of air flowing per sec., lb.; W_e = weight of heating or cooling medium per sec., lb.; and s = specific heat of this medium, then $sW_e(t' - t'') = 0.2375\ W_a(t_2 - t_1)$, where 0.2375 is specific heat of air at constant pressure.

The **Thomas meter** employs this method of measuring gas. The gas flows past a series of electrical resistances enclosed in a pipe and the temperature of the gas is raised a few degrees. Temperature before and after heating is measured by resistance thermometers arranged to record temperature difference on a chart. If the electrical energy used for heating be kept constant and if the specific heat of the gas does not vary, the flow is inversely proportional to the rise in temperature.

Receiver Method of Measuring Air. None of the preceding methods are adaptable for measuring the volume of air at high pressures, as in the case of measuring the discharge in tests of air compressors. Pumping air into a suitably strong receiver is a method often used. The compressor is made to pump against any desired pressure, which is kept constant by a regulating valve on the discharge pipe.

Let P_1 and P_2 = absolute initial and final pressures for the test, lb. per sq. in.; T_1 and T_2 = mean absolute initial and final temperatures, deg. fahr.; W_1 and W_2 = initial and final weight of air in the receiver, lb.; and V = volume of receiver, cu. ft. Then, as $P_1V = W_1RT_1$, and $P_2V = W_2RT_2$, where R is the constant 53.3 for air, weight of air pumped $= W_2 - W_1 = (V/53.3)\ (P_2/T_2 - P_1/T_1)$.

In accurate laboratory tests the humidity of the air entering the compressor should be measured in order to reduce this weight of air to the corresponding equivalent volume at atmospheric pressure and temperature (see p. 339). The principal errors in this method are due to a difficulty in measuring the average temperature in the receiver. Whenever practicable, the final pressure should be maintained in the receiver at the end of the test until the final temperature is fairly constant.

Flow of Air Through an Orifice. Discharge from compressors at high pressure is also frequently measured by observing the pressures and temperatures on the high- and low-pressure sides of the orifice, see p. 353.

Durley (*Trans. A. S. M. E.*, vol. 27, 1905) gives the following coefficients for discharge into the atmosphere for circular orifices with sharp corners in a plate 0.057 in. thick where there is appreciable contraction:

Coefficients of Discharge for Sharp-edged Orifices

Diam. of orifice, in.	Pressure Difference on the Two Sides of Orifice (In inches of water column) 1	2	3	4	5
5/16	0.603	0.606	0.610	0.613	0.616
1/2	0.602	0.605	0.608	0.610	0.613
1	0.601	0.603	0.605	0.606	0.607
2	0.600	0.600	0.600	0.600	0.600
3	0.599	0.598	0.597	0.596	0.596
4	0.598	0.597	0.595	0.594	0.593
4 1/2	0.598	0.596	0.594	0.593	0.592

For accurate work the orifice should be carefully calibrated, measuring the discharge for the range of pressures at which it is to be used. For coefficients for orific meter disks in 8-in. and 10-in. pipe lines see Hickstein, *Jour. A. S. M. E.*, March, 1916. (For a discussion of nozzle and orifice coefficients for the flow of fluids, see pp. 353 to 357; also "Steam Turbines" (3d

Ed.), by J. A. Moyer, pp. 29–53, and Bendemann, in *Mitteilungen über Forschungsarbeiten*, No. 37.)

Steam Meters

Pitot-tube Steam Meters are made by the General Electric Co. The nozzle plug which is inserted into the steam pipe has two sets of holes, each set connecting into a separate pipe which is joined by unions to an indicator or recorder. The "leading" set of holes is subjected to velocity plus static pressure, and the "trailing" holes to velocity pressure less static. The principles of operation are essentially the same as for the measurement of air by Pitot tubes.

The Orifice Steam Meter (Fig. 30) requires the insertion into the steam pipe of a special flanged fitting F in which there is an orifice as shown. Pressure difference between the two tubes t_1 and t_2 located in this flange (produced by velocity) is measured by a differential mercury manometer. Without changing the orifice the apparatus is not adapted to a large range in the rate of flow. The spiral coils C_1 and C_2 are inserted for maintaining by condensation constant water levels in each of the legs of the manometer, irrespective of variations of pressure.

Float Steam Meters are designed so that a float (usually a disk or a cone) moves against a constant resistance in a passage in which the unrestricted area for the flow of steam varies with the height of the float. This principle is applied in the St. John and Sargent meters, in each of which there is a conical float connected to the registering device showing the rate of flow. In the St. John meter (Fig. 31) the float V rises with increased flow, carrying with it the arm N connected to the registering device. The accuracy of steam meters is usually not greater than ±.5 per cent.

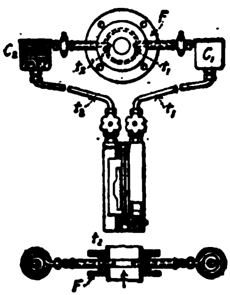

FIG. 30.—Orifice Steam Meter.

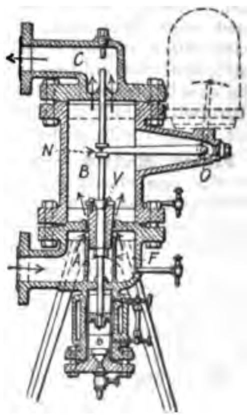

FIG. 31.—St. John Float Steam Meter.

Prices of Steam Meters: "G. E" Pitot tube, \$50 to \$165 for indicating types, \$260 to \$270 for recording type (General Electric Co., Schenectady, N. Y.); St. John recorder, \$250 for 2-in. pipe, \$550 for 6-in. pipe (G. C. St. John, New York); Sargent, \$200 for 2-in. pipe, \$450 for 6-in. pipe (Pittsburgh Supply Co., Pittsburgh, Pa.).

Water Meters

Impulse-wheel or "Velocity" Meters (Fig. 32) are arranged to receive the water at one end, where it passes through a screen, is deflected downward, and a central baffle plate distributes the water horizontally and radially into the row of guide vanes leading the water to the vanes on the rotating impulse wheel which is connected to the counting mechanism of the meter. After discharging from the vanes of the wheel the water flows out as indicated by the arrows. This type is particularly suitable for measuring large quantities at low pressure. A comparatively large flow is required to start such a meter.

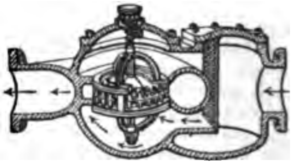

Fig. 32.—Impulse-wheel Water Meter.

Rotary-disk Meters (Fig. 33) have a measuring chamber which is divided into two equal compartments by a hard rubber disk, as shown. While one compartment is filling the other is emptying. There is thus an unbalanced water pressure always moving the disk and giving the pin *P* at the center a circular motion which is transferred to the counting mechanism. This type is not suitable for irregular flows because of excessive leakage, nor for use with hot water, as the rubber disk is likely to be cracked; but it is probably used more than any other in America. For a fairly constant flow it is generally quite accurate. Such meters should be calibrated frequently under the exact conditions of flow, pressure, and temperature with which they are operated. They should not be used with water above 105 deg. fahr.

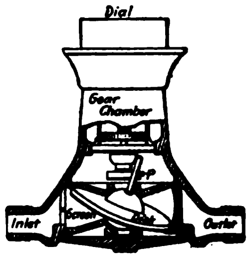

Fig. 33.—Rotary-disk Water Meter.

Piston Meters have two pistons side by side. In the one shown in Fig. 34, water is admitted alternately at the two ends by a slide valve moving on seats in the bottom plate *P*, containing the inlet and discharge ports. One of the pistons moves the counting mechanism by means of a lever. Piston meters are not as reliable as those of the disk type, but they can be used for measuring hot feed water, for which work the rubber-disk type is useless.

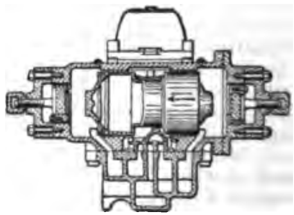

Fig. 34.—Piston Water Meter.

Weir Meters. For a general discussion of the flow of water over weirs, see pp. 263 to 268. Rectangular weirs are generally used for large quantities and "notch" weirs of various shapes for small quantities. The instrument used for measuring the head should be not less than 2 ft. from the crest. The distance from the crest to the bottom of the weir tank should be not less than three times the head. For a tank with two contractions the width of the tank should be not less than three times the width of the weir. Baffle plates, preferably of perforated sheet metal, should be judiciously located to eliminate ripples.

V-notches (see p. 265) are used in many services for measuring water. The head is usually measured by means of a float attached to a vertical shaft. In the **Lea recorder** the rise and fall of the water in a tank provided with a V-notch actuates a float which operates a drum in the recording mechanism through a rack and pinion. This drum has a helical groove whose constantly changing pitch varies with the amount of water flowing over the weir. An arm sliding on a rod parallel to the drum carries on one end a stylus engaging with the drum groove and on the other a pencil the point of which rests on a paper record wound around a clockwork-actuated drum. The groove is so cut that the ordinates of the record drawn by the pencil are proportional to the flow of water over the weir. In **Moyer's weir meter** one side is without contraction and the other is a logarithmic curve of a shape to give a flow proportional to the head. Charts for both the Lea and the Moyer recorders are graduated in lb. of water flowing per hour. This is made possible by an automatic temperature correction: for a given weight of flow, as the temperature varies the head varies correspondingly, but at the same time the displacement of the float changes so as to compensate the change in head. Error due to temperature variation is always less than ½ per cent. No weir device is very accurate for low rates of flow.

The Wilcox Tank Meter is a cylindrical vessel divided by a horizontal partition into two chambers. Water enters the top chamber, which, when filling, compresses air in a trip valve designed to open and discharge the water into the lower chamber after a given weight has accumulated. The discharge from the lower chamber is through a siphon-shaped pipe which is always water-sealed. A weigher of this kind is easily calibrated by weighing several fillings, and it can be used with as great a degree of accuracy as can be expected with rapid weighings in tanks on platform scales. An error of not more than 1 per cent. should be expected if the tank has been calibrated with water at the temperature prevailing in service.

For **Venturi Meters,** see p. 262.

Prices of Water Meters. Velocity, rotary or disk types (3 in.), $80 to $90; Worthington piston meter (3 in.), $125; Lea's V-notch recorder, $400 to $500 (Yarnall-Waring Co., Philadelphia); Moyer's weir recorder, $90 to $125 (J. C. Moyer & Co., Philadelphia); Wilcox tank weigher, $150 to $600 (Wilcox Co., Battle Creek, Mich.); Venturi meter, recording, $250 to $1000 (Builders' Iron Foundry, Providence, R. I.).

APPARATUS FOR FLUE-GAS ANALYSIS

For the analysis of flue gases in a power plant by chemical means an **Orsat apparatus** is generally used. It consists of a graduated tube or burette surrounded by a water jacket to receive and measure the volume of the gas. This burette is connected by a manifold of glass or hard rubber to "pipettes" containing the liquids for absorbing CO_2, O_2 and CO. The pipettes are each a little more than half filled with the absorbing liquid. Water well saturated with CO_2 is ordinarily used for displacement of gases. For accurate work brine or mercury should be used. To absorb CO_2 the gases are first passed into a pipette containing a solution of one part by weight of KOH (caustic potash) in two parts by weight of water. Free oxygen is similarly absorbed by a mixture of pyrogallic acid and KOH, prepared by pouring 5 grams of powdered pyrogallic acid into the pipette and then adding 100 c.c. of the KOH solution as prepared for the first pipette. Some engineers use solutions containing a much larger proportion of pyrogallic acid to make the absorption more rapid, but this is not recommended, as stronger solutions are likely to evolve CO in the presence of free oxygen. Phosphorus sticks may be used in the place of pyrogallic acid for absorbing oxygen. Phosphorus acts more rapidly than the pyrogallic solution; it must be always handled under water and should be at a temperature of about 100 deg. fahr.

The solution for absorbing CO is cuprous chloride (Cu_2Cl_2), which should be made in a glass bottle having a well-fitting glass stopper, greased to made it air-tight. It can be made by pouring 25 grams of copper oxide into the bottle and adding about 500 c.c. of commercial hydrochloric acid (sp.

gr. about 1.1, being obtained by adding *to water* an equal volume of chemically pure acid). To this solution is added from 150 to 200 grams of copper wire cut in lengths to extend from the bottom to the top of the bottle. The solution is then allowed to stand in the bottle till clear, when it is ready for use in gas analysis. By filling the bottle from time to time with acid and adding copper wire as needed to replace that dissolved, a supply of the solution will always be on hand. The KOH solution will absorb 40 times its volume of CO_2 before requiring renewal, while the pyrogallic solution will absorb efficiently only twice its volume of oxygen, and cuprous chloride only an equal volume of CO. The solution for absorbing oxygen, therefore, requires very frequent renewals.

The most common **errors** in the use of gas apparatus are **due to leakage.** The apparatus should be carefully tested before starting an analysis by filling each pipette with the solution up to a mark on its capillary tube, and then, after closing all stoppers and pinch cocks, carefully observing the volume of gas at atmospheric pressure on the scale of the burette. The water bottle is then placed on top of the case so that the gas in the burette and in the yoke will be under pressure for about 5 min., after which the volume of gas is again measured. If there is no leakage the volume will remain constant. If there is leakage a drop of water should be put at each place where there might be leakage. Bubbles of gas will indicate where the apparatus is not air-tight. Extreme care should be taken in arranging for and in collecting the samples of flue gas for analysis. A continuous sample should be collected at a uniform rate during the whole period of the test. Many engineers use for a collecting tube a ½-in. pipe open at the end, which is carefully located so that the open end will be in the unobstructed flow of the gases. Others prefer a perforated pipe closed at the end. The latter method will generally give a more nearly average sample. A small steam or water jet "ejector" or aspirator may be used for securing a continuous flow of gas into the collecting vessel. In most cases it is most convenient to collect the gas over water, which must be saturated with the gas in order to avoid differential absorption of the constituents of the gas.

If by accident a little of the KOH or pyrogallic solution has been drawn into the manifold and into the water in the burette, the analysis is not necessarily spoiled but may be continued by flushing out the tubes with water and adding a few drops of HCl to the water in the bottle. To make sure that all the gas has been absorbed by each reagent, the process should be repeated until readings agree within $^1/_{10}$ per cent. With fairly fresh solutions 2 to 3 min. are required to absorb all the CO_2 or CO, while from 5 to 7 min. may be required to determine the oxygen. It is desirable to replace the pyrogallic solution frequently. One type of automatic apparatus in common use absorbs CO_2 continuously and registers the percentage content. In practically all such apparatus KOH is the absorbent. Another type depends for its action on the difference between the specific weight of air and of flue gas, which is approximately proportional to the percentage by volume of CO_2 in the gas ("econometer" method). Of the two methods, that of absorption is the better.

Prices of Apparatus. Fisher's Orsat, $30 to $50 (Eimer & Amend, N. Y.); Allen & Moyer's, $25 (Bausch & Lomb Co., Rochester, N. Y.); "Sarco" CO_2 recorder, $300 (Sarco Co., 90 West St., N. Y.); "Precision" CO_2 recorder, $250 (Precision Instrument Co., Detroit); Uehling's "composimeter," $350 (Uehling Instrument Co., Passaic, N. J.) Arndt's "econometer," $100.

TACHOMETERS AND SPEED COUNTERS

Hand Speed Counters consist of a small steel shaft pointed at one end and geared to operate the counting device. If handled carefully and well made, these are the most reliable type of instrument, particularly for speeds of from 200 to 2000 r.p.m. To prevent slipping of the head at high speeds, a rubber tip is sometimes provided.

Continuous Speed Counters consist of a series of gears operating a set of dials indicating, by the successive digits, totals of revolutions. Such instruments, although operating by a reciprocating motion, can be arranged ɪo **rotary** motion by any simple "crank" or eccentric device. :s **are not suited** for speeds much over 250 r.p.m.

ers give the instantaneous speed of a machine. At any instant **shown by** an indicating dial in r.p.m. In the operation of **ents rotating** parts usually connected to the shaft by gearing **es which,** reacting against a spring, or in some cases against **.ace the indicating** device in proportion to the speed. Utiliza- **entrifugal force** of rotating masses, eddy currents in a magnetic **e pumping** of liquids so as to indicate the speed by the height **› discharge** rises in a glass tube, are the most common means **. instruments.**

Resonance Tachometer is designed on the principle that bodies **same** "period" of vibration will be in resonance; that is, they will **ether.** It consists of a series of steel reeds, L-shaped at their ends. **of each reed** is adjusted so that its vibration is of a definite period. **atus** is to be set upon the frame of the machine of which the speed

.'s magneto type of electric generator which indicates speeds by **' graduated** voltmeter, is probably the best apparatus available for **ɛ high** speeds. It should preferably be attached directly to the **which** the speed is to be measured. By any application of belting **.** be some error due to slipping.

of Tachometers. Hand counters: Starrett's, $2 to $3; Veeder's, "V-P," $2; ıs counters, $5 to $15. Tachometers: Centrifugal (according to size of dial), 0 (Schaeffer & Budenburg, Brooklyn, N. Y., and Schuchardt & Schütte, West dg., N. Y.); eddy current, $35 to $50 (Warner Instr. Co., Beloit, Wis.); liquid 5 (Veeder Co., Hartford, Conn.); resonance, $25 to $60 (James G. Biddle, phia).

SURVEYING

BY

WILLIAM G. RAYMOND

REFERENCES: Johnson-Smith, "Theory and Practice of Surveying," Wiley. Breed and Hosmer, "Principles and Practice of Surveying," Wiley. Tracy, "Plane Surveying," Wiley. Raymond, "Plane Surveying," American Book Company. Pence and Ketchum, "Surveying Manual," McGraw-Hill. Gillespie-Staley, "A Treatise on Surveying," Appleton.

LINEAR MEASUREMENTS

Tapes. The linear measuring instrument most used is the **steel ribbon tape.** For **surveying,** the **tape** is 100 or more ft. long, graduated to ft., with 1 ft. at the end graduated to tenths and sometimes hundredths. The **builder's tape** is graduated to ft., in., and 8ths. On the reverse side the engineer's tape is usually graduated to links of Gunter's chain, which is 66 ft. long, divided into 100 **links** of 7.92 in. This is used only in land surveying, and was devised so that 10 square chains are 1 acre. **Linen tapes,** even when wire strands are woven in them, are useless for work of precision, but answer for laying out road and railroad earthwork and the like. They are not sufficiently precise for laying out foundations or placing machinery.

Variations in Tape Measurements Due to Temperature, Tension and Sag. Steel tapes are usually of **standard length** at 62 deg. fahr. They change 0.0000065 of their length per fahr. deg. change in temperature. A 100-ft. tape standard at 62 deg. fahr. will be short 0.04 ft. at 0 deg. and long 0.025 ft. at 100 deg.

A steel tape is usually standard for the pull necessary to straighten it when supported throughout its length. Additional pull stretches it at about the rate $1/28{,}000{,}000S$ of its length per lb. of pull, S being its cross-sectional area in sq. in. For the common **sectional area** of 0.002 sq. in. a pull of 10 lb. will produce an elongation of 0.002 ft. in 100 ft. The sectional area of a tape may be determined by dividing the weight of the tape in lb. by its length in in. and the quotient by 0.284.

When a tape is unsupported throughout its length, the measured distance is less than that indicated by about $C_s = l\,(wl/P)^2/24$, in which l is the nominal length of unsupported tape, w the weight of the tape in lb. per unit of length, and P the pull in lb. A 100-ft. tape weighing 0.624 lb. pulled with 10 lb. and unsupported throughout its length would in effect be shortened by 0.016 ft. Calling the correction for temperature C_t, for pull C_p and for **sag** C_s, the distance between two points would be given by the measured length $\pm C_t + C_p - C_s$. The **temperature correction is positive or negative** according as the temperature is *higher* or *lower* than standard. If a line of given length is to be measured from a given point, all of the signs of the corrections are reversed. (See also theory and tables for catenary curves, pp. 147 to 151.)

To Measure a Horizontal Line on Sloping Ground. Most engineering linear measurements are horizontal or vertical. All land measurements mentioned in descriptions are horizontal. Vertical measurements may be made with tape or leveling instrument. When horizontal measurements are to be made on sloping ground, one of the two following methods is used: (1) The low end of the tape is raised to make the tape horizontal, the proper point on the tape or ground being transferred to the ground or tape by a plumb line held by the tapeman. When the slope is so steep that a full tape cannot be used, part of it is used—called "breaking the tape"—and it is better to pull

FIG. 1.

ape clear out, raising the several necessary sections consecutively, rather than to ne particular part of the tape several times. (2) The measurement is made along **slope,** the angle of which or its rise in a tape length is determined, and the slope urement reduced to the horizontal. In Fig. 1, the horizontal distance $B = S - S$, approximately, with an error of about 0.0013 of 1 per cent. for a 10 per cent. :, and less for flatter slopes.

Measure or Lay Out an Angle With a Tape. In Fig. 2, from the apex of the A measure equal distances d along its sides and the distance a be- n the ends of these measurements. Then $\sin \frac{1}{2}A = a/2d$. For ll angles A (in degrees) $= 57.3\ a/d$, approximately, or, if d is 100 s, A (in degrees) $= 0.573a$ (approx.) $= 4a/7$ (approx.). Two lines rating at the rate of n deg. separate in distance at the approximate of $7n/4$ units per hundred.

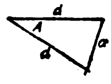

FIG. 2.

o lay out an angle, reverse the process. From the apex measure 100 units along one ; from the point obtained describe an arc with a radius of 200 $\sin \frac{1}{2}A$ or (approxi- ely) $7A/4$ units long; and from the apex with a radius of 100 units, ribe an arc intersecting the first.

'o Lay Out a Right Angle. In Fig. 3, from the point A where the le is to be, measure along one side a distance of $4n$ units; from the nt thus obtained swing an arc with radius of $5n$ units; and from A ng an arc with a radius of $3n$ units to intersect the first arc at B; line joining A and B is perpendicular to the $4n$ line.

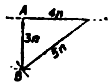

FIG. 3.

LEVELING

The Level, shown in Fig. 4, consists of a telescope EO resting in supports ' attached to a bar B and carrying a level bubble L. The bar B is attached a spindle D which rests in a socket carrying the ball, J, of a ball-and-socket int. The bearing of the spindle carries the upper leveling plate P and the cket of the ball joint is part of the lower leveling plate P' which screws on the tripod head T. By the veling screws S working through ate P and resting on plate P', e upper part of the instrument ay be tipped with respect to P'. the telescope, whose objective at O and eyepiece at E, there is ring R carrying two fine wires t right angles. This may be ad- usted so that the intersection of he wires is in the optical axis of he telescope, and one wire may e made vertical when the other vill be horizontal. Fig. 4 shows **Y-level,** the supports YY being n the form of Y's (wyes) in which the telescope rests and from which it may e easily removed by opening clips on the Y's. In the Y-level the tele- scope is usually an erecting one, *i.e.*, it shows objects as they are. In another form of level, the supports are part of the telescope tube or are fastened rigidly to it and are held to the bar by screws. This is called a **dumpy level** and its (short) telescope (of large aperture) is usually inverting, *i.e.*, it shows objects upside down and right side left. When the axis of the bubble tube and the line of sight of the telescope are parallel, the line of sight will be horizontal when the bubble is brought to the center of its tube. The level is **used with** some form of **graduated rod** read by a movable tar- get or slide and vernier.

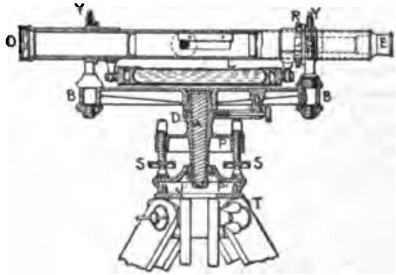

FIG. 4.—Y-level.

To Set Up the Level, the legs are planted firmly, with the lower leveling plate as nearly horizontal as practicable. The telescope and frame are swung over one diagonally opposite pair of leveling screws by which the bubble is brought to the middle of the tube. The frame is then brought over the other pair of screws and leveled; back to the first pair; to the second pair, etc., until the bubble remains in the middle of its tube for any position of the telescope. The screw which clamps the spindle motion should not be used in ordinary leveling operations. The eyepiece should be focused so that the wires are sharp against a blank ground as the sky or side of a light-colored building. It will not need changing so long as the same eye uses it. The objective is focused for each object looked at if the distance varies.

To Determine the Difference in Level Between Two Points, set the level nearly midway between the points, hold a rod on one, look through the level and see where the line of sight as defined by the eye and horizontal cross-wire cuts the rod, called **rod reading.** Move the rod to the second point and read. The difference of the readings is the difference in level of the two points. If it is impossible to see both points from a single setting of the level, one or more intermediate points, called **turning points,** are used. The readings taken on points of known or assumed elevation are called **plus sights,** those taken on points whose elevations are to be determined are called **minus sights.** The elevation of a point plus the rod reading on it gives the elevation of the line of sight; the elevation of the line of sight minus the rod reading on a point of unknown elevation, gives that elevation. In Fig. 5, I_1 and I_2 are intermediate points between A and B. The set-ups are numbered. Assuming A to be of known elevation, the reading on A is a + sight; the reading on I_1 from 1 is a − sight; the reading on I_1 from 2 is a + sight and on I_2 is a − sight. The algebraic sum of the plus and minus sights is the difference of level between A and B. Target rods may usually be read by vernier to thousandths of a foot. In grading work the nearest tenth of a foot is good; in lining shafting the finest possible reading is none too good. It is desirable that the sum of the distances to the plus sights shall approximately equal the sum of the distances to the minus sights to insure compensation of errors of adjustment. On a side hill this may be accomplished by "zigzagging." If, when the direction of pointing is changed, the bubble leaves the middle of its tube, the instrument should be releveled with the telescope in the direction of sight. If adjustments have been properly made little releveling will be necessary, but it must be remembered that **the bubble must be in the middle of its tube whenever a rod reading is taken.**

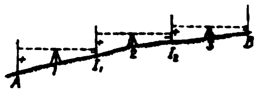

FIG. 5.

To Make a Profile of a Line. A **"bench mark"** is a point of reasonably permanent character whose elevation above some surface—as sea level—is known or assumed and used as a reference point for levels. The level is set up either on or a little off the line some distance—not more than about 300 ft.—from the beginning end or a convenient bench mark (B.M.), as at K in Fig. 6. A reading is taken on the B.M. and added to the known or assumed elevation to get the height of the instrument, called H.I. Readings are then taken at regular intervals (or **stations**) along the line and at such irregular points as may be necessary to show change of slope, as at B and

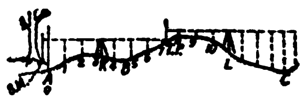

FIG. 6.

between the regular points. The regular points are marked by stakes previ-ısly set "on line" at distances of 100 ft., 50 ft. or other distance suitable to ıe character of the ground and purpose of the work. When the work has ·oceeded as far as possible—not more than about 300 ft. from the instru-ent for good work—a **turning point** (T.P.) is taken at a regular point · other convenient place, the instrument moved ahead and the operation ›ntinued. The first reading on the B.M. and the first reading on a T.P. ter a new set-up are plus sights (+S); readings to points along the line ıd the first reading on a T.P. to be established are minus sights (− S).
The **notes** are taken in the following form. The elevation of a given point, ›th sights taken on it and the H.I. determined from it all appear on a line ith its station (Sta.) designation. In plotting the **profile**, the vertical scale usually exaggerated from 10 to 20 times.

Right-hand page

This page is for remarks describing B.M.s and T.P.s or other important particulars.

Adjustment of the Y-level. (1) Plumbing the Wire. Set up the level and bring he vertical wire to cover a suspended plumb line or the vertical corner of a building by wisting the wire ring if necessary after loosening its screws.

(2) Line of Sight. Loosen the Y clips and by means of the leveling screws and the lamp and slow motion of the spindle bring the intersection of the wires to cover a ninute distant point; carefully turn the telescope upside down in the Y's, keeping the ye at the glass; if the intersection remains on the point, the line of sight is in adjustment; f not, bring the intersection half way back to the point by the screws carrying the wire ing, and repeat till the distant point is covered by the intersection of the wires in either ›osition of the telescope.

(3) The Bubble Tube. Level the bubble over two sets of screws and carefully ›ver one set; lift the telescope from the Y's, turn it end for end and replace in the Y's; f the bubble returns to the center of the tube, its axis is parallel to the lower side of the elescope barrel and to its axis if the bearing rings are of equal diameter. For practically ıll work they are nearly enough so. If the bubble moves from the center of its tube, ›ring it halfway back by the adjusting nuts at the ends of the bubble tube, relevel and repeat until the bubble remains in the center of its tube for both positions of the telescope.

(4) The Y's. With the instrument leveled and more carefully over one set of screws, turn end for end on the vertical spindle and note whether the bubble remains in the middle of its tube; if not, adjust by the capstan nuts on the Y's at one end of the bar, bringing the bubble halfway back to the middle; relevel and repeat till the bubble remains in the middle through a complete revolution on the spindle. This last adjustment of the Y's is not essential to correct leveling, but is convenient in that when once set up the level requires no releveling for a change in the direction of pointing.

Adjustment of the Dumpy Level. The dumpy level is adjusted by adjusting the bubble and afterward the line of sight to it.

(1) THE BUBBLE TUBE. Set up and, having the instrument level over one set of screws, swing through 180 degrees on the vertical axis; if the bubble moves from the center, bring it halfway back by the adjusting screws, relevel and repeat the test and adjustment until complete.

(2) LINE OF SIGHT. Set the instrument midway between two stakes from 200 to 400 ft. apart, as in Fig. 7. With the bubble in the center of the tube, read a rod on each stake. The difference in readings is the difference in level, d, of the two stakes. Remove the level and set it up near one of the stakes and in line with both. If set between the two stakes and close to the near stake so that the eye end will just clear a rod held on the stake, look through the object end at the rod and with a pencil point get the reading in the middle of the small spot of light that will be seen; remove the rod to the distant stake, set a target to read the reading on the near rod + allowance for earth's curvature $\pm d$ according as the far stake is the lower or higher; turn the telescope line of sight toward the distant rod and adjust the horizontal wire till it reads on the target when the bubble is centered. Earth's curvature is approximately 0.001 ft. for 200 ft. distance and varies with the square of the distance. If the set-up is a distance b outside the stakes which are a ft. apart, read on the near stake, add earth's curvature e and add or subtract d for the trial reading r on the distant rod; if the reading is not r but r', move the target from r' by a distance $(r - r')(a + b)/a$, up if the result is plus, down if minus; by the wire adjusting screws bring the wire to read on the target, the bubble being kept in the middle of its tube. It is convenient to make $b = a/10$, so that $(a + b)/a = 11/10$.

FIG. 7.

TRANSIT WORK

The Transit. The essential parts of a surveyor's transit are shown in Fig. 8. The telescope T swings on axis A in standards S resting on plate P carrying verniers seen through openings in its upper side which permit readings on a graduated circle on plate P' which may be turned on a spindle in a socket in the leveling head and clamped in position by the clamp H. The clamp D clamps the plates P and P' together, but it is still possible to move one on the other by the slow-motion or tangent screw F. A similar slow-motion screw attached to the clamp H serves to move the whole upper part of the instrument a little in a horizontal plane when the two plates are clamped together. The leveling head is like that of the level, but to the bottom of the spindle a hook is attached, from which a plumb line may be suspended for centering the transit over a point. For doing leveling and measuring vertical angles, there is a level under the telescope and a vertical circle C attached to the horizontal axis of the telescope and read by a vernier V. There is a clamp and slow-motion screw for the telescope axis of revolution. The telescope, though of shorter focal length, is like that of the level.

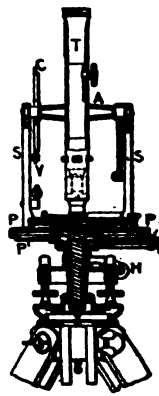

FIG. 8.—Surveyor's Transit.

To Set Up the Transit Over a Point, plant the legs firmly in the ground with the plumb swinging as nearly as possible over the point. At the same time, the lower plate on the leveling head should be nearly level, as judged by eye. Loosen the leveling screws of the leveling head and shift the upper part on the lower plate till the bob swings over the required point. Bring the screws again to bearing—never tight—swing the upper part of the instrument so that the plate bubbles are respectively parallel to the two diagonally opposite sets of leveling screws, and by the screws bring the bubbles to the center by first leveling one and then the other in turn until both are level. Focus the eyepiece of the telescope so that the cross wires are distinct against the sky or a light ground. Set the zeros of the verniers and graduated circle together by the clamp and slow-motion screws of the plates.

To Produce a Straight Line. Set up the transit over one end of the line; with the lower motion clamp and tangent screw bring the telescopic line of sight to the other end of the line marked by a flag, a pencil, a pin or other object; transit the telescope, *i.e.*, plunge it by revolving on its horizontal axis, and set a point (drive a stake and "center" it with a tack or otherwise) a desired distance ahead in line with the telescopic line of sight; loosen the lower motion clamp and turn the instrument in azimuth until the line of sight may be again pointed to the other end of the line, which do; again transit and set a point beside the first point set. If the instrument is in adjustment the two points will coincide; if not, the point marking the projection of the line lies midway between the two established points.

To Measure a Horizontal Angle. Set up the transit over the apex of the angle; with the lower motion bring the line of sight to a distant point in one side of the angle; unclamp the upper motion and bring the line of sight to a distant point in the second side of the angle, clamp and set exactly with the tangent screw; read the circle by the vernier for the angle turned.

To Measure a Vertical Angle. Set up the transit over a point marking the apex of the angle A (see Fig. 9); by the lower motion and the motion of the telescope on its horizontal axis bring the intersection of the vertical and horizontal wires of the telescope in line with a point as much above the point defining the lower side of the angle as the telescope is above the apex; read the vertical circle; turn the telescope to a point which is the height of the instrument above the point marking the upper side of the angle and read the vertical circle. How to combine the readings to find the angle will be obvious.

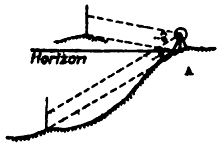

FIG. 9.

To Run a Traverse. A traverse is a broken line marking the line of a road, bank of a stream, fence, ridge or valley, or it may be the boundary of a piece of land. The bearing or azimuth and length of each portion of the line are determined, and this constitutes "running the traverse."

The **bearing** of a line is the angle it makes east or west of a north and south line either true, magnetic or assumed for the purpose of the survey. The bearing is read north or south so many degrees east or west, and never east or west so many degrees north or south. Thus, a line running only 1° north of east would have a bearing N 89° E, and one running 1° south of east would have a bearing S 89° E, etc.

To determine the bearing, set up over one end of the line, loosen the needle clamp, turn the telescope with its object end over the *fleur de lis* or north side of the compass box toward the farther end of the line and read the needle, using the two letters between which its north end lies. It should be noticed that the compass box letters E and W are reversed to make the reading agree with the telescope pointing.

The **azimuth** of a line is the angle the line makes with a north and south line, true, magnetic, or assumed, and differs from bearing in being measured always in one direction through 360°, while bearing is measured in each of four directions through 90°. Azimuth is measured to the right or clockwise. Astronomers use the south for zero azimuth. Surveyors, with some exceptions, use the north. Lines whose bearings are N 88° E, S 38° E, S 70° W, and N 60° W, have azimuths of 88°, 142°, 250°, and 300°, respectively.

To determine the azimuth of a line, set up over one end, set the horizontal circle to read the azimuth of a known line through the point of set-up (as the meridian or the preceding line of a traverse), and by the lower motion turn the line of sight in the direction of the known line; loosen the upper motion and set the line of sight in the direction of the required azimuth and read the circle. Always read the same vernier and the same row of figures—those inclined to the left—since the vernier reads with these when the telescope is turned clockwise. When the preceding line of the traverse is used for orienting the transit, the "back azimuth" should be set on the circle. The **back azimuth** is the azimuth read in a direction opposite to that in which the survey proceeds, and is the forward azimuth plus 180 deg. If this gives more than 360 deg., subtract 360 deg. The distance may be measured with the tape or with the stadia, as explained on p. 1705.

In work with the transit, bearings are not usually read by the needle except for checking. Instead, the deflection angles from one course produced to the next are measured; one course—as the initial course—is taken as a meridian, and the bearings of the other courses with respect to the assumed meridian are calculated. The true or magnetic bearing of the first course may be determined, from which the bearings of all courses will be calculated from the true or magnetic meridian. To determine the **magnetic bearing** of the first course and to establish a meridian of reference, set up the transit over the initial point, let the needle swing free; with the zeros together turn the instrument on its vertical axis by the lower motion till the needle reads north, and set a point some distance away in the line of sight. The line ranged will be the magnetic meridian. By the upper motion set the telescope in the line of the initial course; the vernier will read the angle with the meridian, from which the bearing is calculated.

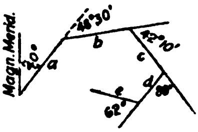

FIG. 10.

In Fig. 10, the bearing of a is N 40° E, of b is N 88° 30′ E, of c is S 49° 20′ E $= 180° - (40° + 48°\ 30' + 42°\ 10')$, of d is S 36° 40′ W $= 86° - 49°\ 20'$, or $40° + 48°\ 30' + 42°\ 10' + 86° - 180°$, of e is N 81° 20′ E $= 180° - (36°\ 40' + 62°)$. A meridian is established because the needle cannot be depended on to give exactly the same line twice. The needle pointing varies as much as 10 min. or more during the day.

To Adjust a Transit. The adjustment of the transit consists in: (1) Making the plate bubbles parallel to the plates, *i.e.*, perpendicular to the vertical axis; (2) making the line of sight perpendicular to the horizontal axis of revolution; (3) adjusting horizontal axis horizontal so that the line of sight may revolve in a vertical plane; (4) making the telescope bubble parallel to the line of sight; and (5) making the vernier of the vertical circle read zero when the line of sight is horizontal or determining the index error.

(1) THE PLATE BUBBLES. Set up the transit; when both plate bubbles are in the centers of their tubes turn the instrument on its vertical axis 180 deg., thus reversing the bubbles. If the bubbles remain in the centers of their tubes they are in adjustment; if not, raise or lower one end of one bubble tube with a small adjusting pin till the bubble seems to move halfway back to the center; do the same with the other tube; relevel with leveling screws, turn 180 deg. to test correctness of work and repeat till perfect.

(2) LINE OF SIGHT. Set up and fix the vertical wire on a suspended plumb line or corner of a vertical building. If the wire does not coincide with the vertical line, loosen all capstan screws carrying the wire ring, twist the ring in the barrel by the screws

until the wire is vertical, and then tighten the screws. By the lower motion and the vertical swing of the telescope fix the line of sight, as defined by the vertical wire, on a distant point about on a level with the instrument or the ground under it (do not clamp the horizontal axis); transit the telescope, *i.e.*, plunge it on its horizontal axis, and, finding a minute point in the line of sight, note it carefully; turn in azimuth, *i.e.*, on the vertical axis, until the line of sight covers the first point sighted; transit and note whether line of sight covers the second point; if not, adjust the wires, moving the ring right or left as the case may be by the capstan-headed screws that carry it till the vertical wire seems to pass over ¼ the distance between the two distant points; again set on the first point, transit and note a point in line—it will be neither of the points previously noted, but if the work has been completed at the first trial, the new point will lie midway between the two previously noted points—reverse in azimuth to the first point, transit, adjust if necessary, and repeat till the adjustment is complete. Stakes centered with pins or pencils 200 or more ft. either side of the transit may be used for points.

(3) The Horizontal Axis. With the transit set up near a tall building, turn the line of sight on a plumb corner near the top; plunge the telescope and note if the line of sight follows down the edge of the building; if not, raise or lower one end of the horizontal axis—one end is adjustable—until the line of sight will revolve in a vertical plane. If no vertical line is available, set the line of sight on some high point, plunge and set a point on the ground; reverse in azimuth, transit and set again on the high point and plunge; if the line of sight cuts the point set on the ground the horizontal axis is in adjustment; if not, adjust the axis until the line of sight cuts the same point below when plunged from the high point both direct and reversed.

(4) Level under Telescope. This is adjusted by the "peg" method described for the dumpy level (see p. 1701), except that—the plate bubbles being centered—the wires are brought to the correct target reading by tipping the telescope, and the bubble is adjusted to bring it to the center, the wires being undisturbed.

(5) Vertical Circle. If the bubble tube is parallel to the line of sight and the latter is horizontal, the bubble will be in the center of its tube and the vertical circle should read zero. If it does not, the vernier may be moved slightly after loosening the screws that hold it. If not convenient, the reading may be noted and used as an index error. If the reading indicates a small angle of elevation, all angles of elevation will be read too large, *i.e.*, the index error is to be subtracted; while depression angles will be read too small—the index error is to be added.

(6) Line of Sight for Leveling. For good leveling, the horizontal wire should be in the center of the telescope tube. If the eyepiece is non-adjustable, it will generally be sufficient to adjust the wire so that it appears to be in the field of view. This is not true of all instruments, and the only way to make the adjustment with certainty is to remove the telescope with its horizontal axis, place it in a pair of Y's made, for instance, by cutting notches in the ends of a starch box or other box of suitable size, and adjust the wires as in the Y-level. (See p. 1701.)

To Measure Distances with the Stadia. In the transit telescope are two extra horizontal wires so spaced (when fixed by the maker) that they are 1/100 of the focal length of the objective apart. When looking through the telescope at a rod held in a vertical position, 100 times the rod length S intercepted between the two extra horizontal wires plus an instrumental constant (C) is the distance (D) from the center of the instrument to the rod if the line of sight is horizontal, or $D = 100\,S + C$, see Fig. 11. If the line of sight is inclined by a vertical angle A, as in Fig. 12, then if S is the space intercepted on the rod and C is the instrumental constant, the distance is given by the formula $D = 100\,S\cos^2 A + C\cos A$. For angles between 5 deg. and 6 deg. the distance is given with sufficient exactness by $D = 100\,S$. Although theory would indicate that distances may be thus determined to within 0.2 ft., yet in practice it is not well to rely on a precision greater than the nearest foot for distances of 500 ft. or less.

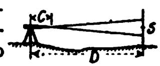

Fig. 11.

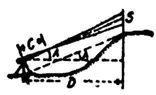

Fig. 12.

The instrumental constant is usually stated on a paster in the transit box. When not so given, it may be determined by measuring several distances on level ground, reading the distances with the stadia, as $D_1 = 100\ S_1$, $D_2 = 100\ S_2$, etc., subtracting the readings from the measurements and averaging the remainders. For most transits, the so-called instrumental constant is not constant, but has an extreme variation of perhaps 0.1 ft. With different instruments its average value varies from about 0.75 ft. to 1.25 ft. It is made up of the focal length of the objective and the distance from the objective to the horizontal axis.

For good work, the wire interval, *i.e.*, the coefficient of the rod space, should be determined daily, as it may change slightly with atmospheric changes and may not always be 100. This may be done, if C is known, by measuring $(100 + C)$ ft., $(200 + C)$ ft., etc., from the instrument, noting the rod intercepts. When C is not known, measure two distances on level ground and read the intercepts S and S_1; then, if K be the coefficient of S, C the instrumental constant, and D and D_1 the two distances, $K = (D - D_1)/(S - S_1)$, and $C = D - KS$ or $D_1 - KS_1$. Several sets of readings should be taken and average results used.

The stadia wires are sometimes adjustable as to the space between them. When so, they are not in the same plane with the line and level cross wires, and hence are not seen with the same focusing of the eyepiece. Adjustable stadia wires should be tested daily and so set that 100 shall be the coefficient of the rod intercept. This may be done by laying off $(100 + C)$ ft. from the center of the instrument and adjusting the wire to cover 1 ft. on a rod held at the further end of the line.

To Measure Differences of Level with Transit and Stadia. Measure the angle of elevation from the point of set-up to the distant point required, according to the method already described, and read the rod intercept on a rod held *vertical* at the distant point. The rod intercept being S, its coefficient K, the instrumental constant C, angle of elevation or depression A, and difference of level H,

$$H = KS \cos A \sin A + C \sin A.$$

If the rod be held normal to the line of sight,

$$H = (KS + C) \sin A.$$

Tables of horizontal distances and differences of level for various vertical angles and a 100-unit rod, are found in all surveying text-books and in most railway surveyors' field-books.

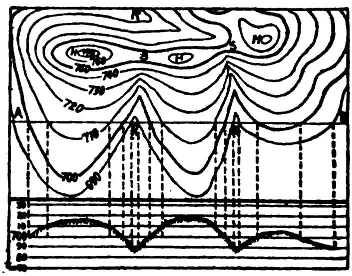

FIG. 13.—Contour Map.

Contour Maps. A contour map is one on which the configuration of the surface is shown by lines of equal elevation called **contour lines.** In Fig. 13, contour lines varying by 10 ft. in elevation are shown. *H*, *H* are hill peaks, *R*, *R* ravines, *S*, *S* saddles or low places in the ridge *HSHSH*. The horizontal distance between adjacent contours shows the distance for a fall or rise of the contour interval—10 ft. in the figure. A profile of any line as *AB* can be made from the contour map as shown in the lower part of the figure. Conversely, a contour map may be made from a series of profiles properly chosen. Thus, a profile line run along the ridge *HSSH* and radiating profile lines from the peaks down the hills and from the saddles down the ravines would give data for projecting points of equal elevation which could be connected for contour lines. This is the best method for making contour maps of very limited areas, such as city squares or very small parks. If the ground is not too much broken, the small tract is divided into squares and levels are taken at each square corner, and between two corners on some lines if necessary to get correct profiles.

Contours with the Transit and Stadia. When a large area of several hundred or more acres is to be contoured, or a long belt within which a railroad line is to lie, the best method is the transit and stadia method. Referring to Fig. 13, a traverse line would be run along the ridge by transit and stadia, establishing points in the saddles and on the peaks; from these, radial lines would be run, establishing points on the slopes of the hills; from each of these points a number of readings would be taken to slope-governing points, the azimuth, distance and vertical angle being read, from which each point could be located in place and elevation.

THE PLANE TABLE

Topography with the Plane Table. The plane table is the standard instrument of the United States Geological Survey and the United States Coast and Geodetic Survey for filling in topography. It consists essentially of a drawing board with a suitable leveling device mounted on a tripod (see Fig. 14). Accompanying the plane table is a telescope or open line of sight attached to a ruler which may be moved over the drawing board. The combined line of sight and ruler is called the **alidade.** The purpose of the plane table is to make a map directly from the measurements made in the field, without notes. The general method of use in locating points is as follows:

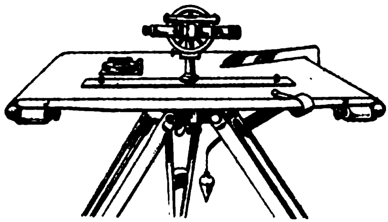

Fig. 14.—Plane Table.

A line is drawn on the paper to scale to represent a known line on the ground. The table is set over one end of the line on the ground, the ruler brought to the line on the paper representing the line on the ground, and the table is swung in azimuth until the line of sight is in the direction of the distant end of the line. The table is then clamped and is said to be **oriented.** The ruler is now moved about the plotted point on the paper representing the occupied point on the ground as a center, and various points in the surface to be mapped are located by directing the line of sight to them, measuring the distance and vertical angle as in the stadia method and plotting the points observed to scale along the edge of the ruler. When the various points that can be conveniently located from the first setting have been mapped, the table is moved either to the other end of the line with which the work began or to one of the plotted points which has been marked by a stake, and the table is set up and oriented on the point previously occupied in the same manner as described for the first set-up, and further points are located and mapped as before.

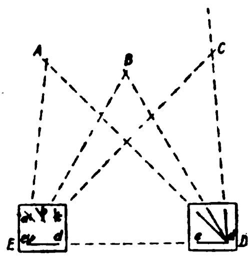

Fig. 15.

Location by Intersections. A method much used with the plane table is known as the method of intersections. In Fig. 15, let it be required to locate the points *A*, *B*, *C* from the points *D* and *E*. Measure *DE*, and lay off to scale on the paper a line equivalent to DE in proper position so that the points desired will fall on the paper. Set the table over D and orient on E. Swinging the alidade about d, draw lines toward C, B, and A. Set the table over E and orient on D. Swinging the alidade about e, draw lines toward C, B, and A, and note the intersections of these lines with those drawn from d to corresponding points. These intersections locate the points.

Adjustments. The bubbles for leveling the table are adjusted to be parallel to the base of the alidade. The line of collimation (*i.e.*, the axial line of the telescope) and the axis of the telescope bubble are made parallel by the "peg" adjustments as applied to the transit. The horizontal axis is adjusted like that of the transit.

SPECIAL PROBLEMS IN SURVEYING AND MENSURATION

Volume of Earth in Foundation and Area Grading. The volume of earth removed from a foundation pit or in grading an area may be computed in several ways, of which two follow.

(1) The area (Fig. 16) is divided into squares or rectangles, levels are taken at each corner before and after grading, and the volumes are computed as a series of prisms. If A be the area (in sq. ft.) of one of the squares or rectangles—all being equal—and h_1, h_2, h_3, h_4 be corner heights (in ft.) equal to the differences of level before and after grading, the subscripts referring to the number of prisms of which h is a corner, then the volume in cubic yards is

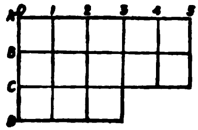

FIG. 16.

$$Q = A(\Sigma h_1 + 2\Sigma h_2 + 3\Sigma h_3 + 4\Sigma h_4)/(4 \times 27)$$

In Fig. 16 the h's at A_0, D_0, D_3, C_5, and A_5 would be h_1's; those at B_0, C_0, D_1, D_2, C_4, B_5, A_4, A_3, A_2 and A_1 would be h_2's; that at C_3 an h_3; and the rest h_4's. The rectangles or squares should be of such size that their tops and bottoms are practically planes.

(2) A large-scale profile of each line one way across the area is carefully made, as the A, B, C, and D lines of Fig. 16, the final grade line is drawn on it and the areas in excavation and embankment are separately measured with a planimeter or by estimation from the drawing. The excavation area of profile A is averaged with that of profile B, and the result multiplied by the distance AB and divided by 27 to reduce to cu. yd. Similarly, the material between B and C is found.

To Pass an Obstacle. Four cases are shown in Fig. 17. If the obstacle be large, as a building, (1) turn right angles at B, C, D, and E, making $BC = DE$ when $CD = BE$. All distances should be long enough to insure sufficiently accurate sighting. (2) At B turn the angle K and measure BC to a convenient point. At C turn $\angle = 2K - 180$ deg; measure $CD = BC$. At D turn K for line DE. $BD = 2BC \cos(180 \text{ deg.} - K)$. (3) At B lay off a right angle and measure BC. At C measure any angle to clear object and measure $CD = BC/\cos C$. At D lay off $K = 90$ deg. $+ C$ for the line DE. $BD = BC \times \tan C$. If the obstacle is small, as a tree, (4) at A, some distance back, turn the small angle a necessary to pass the obstacle and measure AB. At B turn the angle $2a$ and measure $BC = AB$. At C turn the small angle a for the line AC, and transit, or turn the large angle $K = 180$ deg. $- a$. If a is but a few minutes,

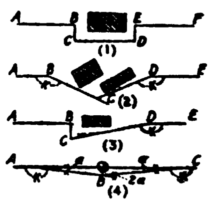

FIG. 17.

$AC = AB + BC$ with sufficient exactness. If only a tape is available, the right-angle method (1) above given may be used; or, an equilateral triangle ABC (Fig. 18) may be laid out, AC produced a convenient distance to F, the similar triangle DEF laid out, FE produced to H making $FH = AF$, and the similar triangle GHI then laid out for the line GH. $AH = AF$.

To Measure the Distance Across a Stream. To measure AB (Fig. 19), B being any established point, tree, stake, or building corner: 1. Set a transit over A; turn a right angle from AB and measure any distance AC; set over C and measure the angle ACB. $AB = AC \tan ACB$. 2. Set over A, turn any convenient angle BAC' and measure AC'; set over C' and measure $AC'B$. Angle $ABC' = 180$ deg. $- AC'B - BAC'$. $BA = AC' \times \sin AC'B/\sin ABC'$. 3. Set up on A and produce BA any measured distance to D; establish a convenient point C about opposite A and measure BAC and CAD; set over D and measure ADC; set over C, and measure DCA and ACB; solve ACD for AC, and ABC for AB. For best results the acute angles of either method should lie between 30 deg. and 60 deg.

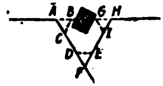

FIG. 18.

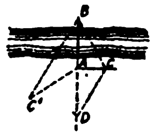

FIG. 19.

To Measure a Visible but Inaccessible Distance, as AB in Fig. 20. Measure CD. Set a transit at C and measure angles ACB and BCD; set at D and measure angles CDA and ADB. $CAD = 180$ deg. $- (ACB + BCD + CDA)$. $AD = CD \times \sin ACD/\sin ACD$. $CBD = 180$ deg. $- (BCD + CDA + ADB)$. $BD = CD \times \sin BCD/\sin CBD$. In the triangle ABD, $\frac{1}{2}(B + A) = 90° - \frac{1}{2}D$; where A, B and D are the angles of the triangle; $\tan \frac{1}{2}(B - A) = \cos \frac{1}{2}D(AD - BD)/(AD + BD)$; $AB = (AD + BD) \sin \frac{1}{2}D/\cos \frac{1}{2}(B - A)$, $= (AD - BD) \cos \frac{1}{2}D/\sin \frac{1}{2}(B - A)$.

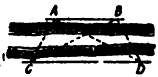

FIG. 20.

Setting Stakes for Trenching. A common way to give line and grade for trenching (see Fig. 21) is to set stakes K ft. from the center line, driving them so that the near face is the measuring point and the top is some whole inch or tenth of a foot above the bottom grade or grade of the center or top of the pipe to be laid. The top of the pipe barrel is perhaps the better line of reference. If preferred, two stakes may be driven on opposite sides and a board nailed across, on which the center line is marked and the depth to pipe line given. When only one stake is used, a graduated pole sliding on one end of a level board at right angles is convenient for workmen and inspectors. On long grades the grade stakes are set by "shooting in." Two grade stakes are set, one at each end of the grade, a transit is set over one, its height above grade determined, and a rod reading calculated for the distant stake such as to make the line of sight parallel to the grade line; the transit line of sight is then set at this rod reading; when the rod is taken to any intermediate stake, the height of instrument above grade less the rod reading will be the height of the top of the stake above grade. If the ground is uniform, the stakes may all be set at the same height above grade by driving them so as to give the same rod readings throughout.

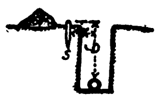

FIG. 21.

To Reference a Point. The point P (Fig. 22) which must be disturbed during construction operations and will be again required as a line point in a railway, pipe line, or other survey, is referenced as follows: 1. By setting the transit over it and setting four points, A, B, and C, D, on two intersecting lines. When P is again required, the transit is set over B and with foresight on A two temporary points close together near P but on opposite sides of the line DC are set; the transit is then set on D and, with foresight on C, a point is set in the lines DC and BA by setting it in DC under a string stretched between the two temporary points on BA. 2. Points A and E and C and F may be established instead of A, B, C, D. 3. If the ground is fairly level and is not to be much disturbed, only points A and C need be located, and these by simple tape measurement from P. They should be less than a tape length from P. When P is wanted, arcs struck from A and C with the measured distance for radii will give P at their intersection.

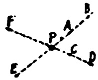

FIG. 22.

Foundations. The corners and lines of a foundation are preserved by setting stakes outside the area to be disturbed, as in Fig. 23. Cords stretched around nails in the stakes marking the reference points, will give the referenced corners at their intersections and the main lines of the building. These corners can be plumbed down to the level desired if the height of the stakes above grade is given. It is well to nail boards across the stakes at AB, putting nails in the top edge of the board to mark the points A and B, and if the ground permits, to put all the boards at the same level.

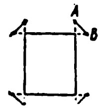

FIG. 23.

To Test the Alignment and Level of a Shaft. Having placed the shaft hangers as closely in line as possible by the use of a chalk line, the shaft is finally adjusted for line by hanging plumb lines over one side of the shaft at each hanger and bringing these lines into a line found by stretching a cord or wire or by setting a transit instrument at one end and adjusting at each hanger till its plumb line is in the line of sight. The position of the line will be known either on the floor or on the ceiling rafters or beams to which the hangers are attached. If the latter, the transit may be centered over a point found by plumbing down, and sighted to a plumb line at the farther end.

To level the shaft, an ordinary carpenter's level may be used near each hanger, or, better, a pole with an improvised sliding target may be hung over the shaft at each hanger by a hook in one end. The target is brought to the line of sight of a leveling instrument set preferably about under the middle of the shaft, by adjusting the hanger.

When the hangers are attached to inclined roof rafters, the two extreme hangers may be put in a line at right angles to the vertical planes of the rafters by the use of a square and cord. The other hangers will then be put as nearly as possible without instrumental test in the same line. The shaft being hung, the two extreme hangers, which have been attached to the rafters about midway between their limits of adjustment, are brought to line and level by trial, using a transit instrument with a well-adjusted telescope bubble, a plumb line and inverted level rod or target pole. Each intermediate hanger is then tested and may be adjusted by trial.

To Determine the Verticality of a Stack. If the stack is not in use and its top is accessible, a board may be fitted across the top, the center of the opening found and a plumb line suspended to the bottom, where its deviation from the center will show any leaning. If the stack is in use or its top not accessible and its sides are battered, the following procedure may be followed: Referring to Fig. 24, set up a transit at any point T and measure the horizontal angles between vertical planes tangent respectively to both sides of the top and the base and also the angle a to a second point T_1. On a line through T approximately at right angles to the chimney diam., set the ıd perform the same operations as at T, measuring also K and n the drawing board, lay off K to as large a scale as convenient, ›lotted T and T_1 lay off the shown in the figure. By cumferences tangent to the rals formed by the intersect- ›f the base and top, respec- ine joining the centers of rences will be the deviation ;al in direction and amount. square, T and T_1 should be

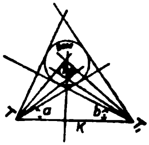

FIG. 24.

REFRIGERATING MACHINES AND PROCESSES

Means of Producing Refrigeration

Refrigeration may be produced (1) by transferring heat from a warmer body to a colder one (*e.g.*, refrigeration by cooled brine, etc.); (2) by the absorption of heat by a compressed gas when expanding, as in the air machine; (3) by melting or dissolving solid bodies, as in the melting of ice, the solution of salts in water, and in chemical machines; (4) by evaporating liquids which have a low boiling point, as liquid ammonia, water, carbonic acid, sulphurous acid, ether, etc.

Air Machines (For theory, see p. 346). Compressed-air machines are but little used except on shipboard, on account of their low efficiency. Table 1 gives results of tests of several of these machines. See also Table 4, p. 1718.

Table 1. Test Results on Cold-air Machines

(Linde, *Trans. A. S. M. E.*, vol. 14, p. 1416)

	System		
	Bell-Coleman	Lightfoot	Haslam
Air pressure in receiver, lb. per sq. in. abs	61.0	65.0	64.0
Temperature of air entering compression cylinders, deg. fahr	65.5	62.0	....
Temperature of air after expansion, deg. fahr	−52.6	−82.0	−85.0
I.h.p. in compression cylinder	124.5	43.1	346.4
I.h.p. in expansion cylinder	58.5	28.0	176.2
I.h.p. in steam cylinder	84.4	24.6	332.7
B.t.u. abstracted per hour per i.h.p. of steam cylinder, at 20 deg. fahr	668.0	1554.0	954.0

Chemical Machines. In most of these the temperatures of water and brine are successively lowered by dissolving a salt (usually nitrate of ammonia) in water, the salt being recovered later by evaporating the water. They have no commercial importance. For **freezing mixtures,** see p. 297.

Vaporization Machines. The machines now used for the production of refrigeration on a large scale, make use of the evaporation of liquids. Ammonia, sulphurous acid, carbonic acid, or a mixture of the latter two (Pictet's fluid) have been employed. These machines may be classified as vacuum machines, absorption machines, and compression machines.

Vacuum Machines. In these, water is generally employed as the refrigerating medium, its volatilization at a sufficiently low temperature being effected by means of vacuum pumps, with or without the assistance of strong sulphuric acid. The sulphuric acid may be reconcentrated and used over and over again.

35. The comparative efficiency of the ammonia compression machine increases with the suction pressure, and decreases slightly with increased condenser pressure. The efficiency of the carbon-dioxide machine decreases only slightly with the lowering of the suction pressure, within the ordinary temperature limits, but quite rapidly with the increase of the condenser temperature, especially after the temperature of the condensing water exceeds 80 deg. fahr. The compressed-air machine is affected adversely in its efficiency by the moisture content of the air, decreasing very rapidly with the increase of moisture, but it is affected only moderately by changes of temperature on either side of the machine.

Basis of Rating of Refrigerating Machines. The commercial **unit of capacity** of a refrigerating machine is taken as the abstraction of an amount of heat equal to the heat of fusion of 1 ton (2000 lb.) of ice per day (24 hr.). The determinations of the heat of fusion of ice by the Bureau of Standards show slight deviations between plate ice, can ice, and natural ice. The mean of twenty-one determinations is 79.63 cal. per gram, or 143.33 B.t.u. per lb. avoirdupois. This is equivalent to 286,600 B.t.u. per ton, or the taking up of heat in a machine of unit capacity at the rate of 199.028 B.t.u. per min. This is so close to the convenient round figures of 200 B.t.u. per min., 12,000 B.t.u. per hour, or 288,000 B.t.u. per ton, that these latter figures are always used except where extremely close calculations are necessary.

The rating of the tonnage of a refrigerating machine taken in connnection with the plane of temperatures at which heat is to be taken up and that at which it is to be discharged (*i.e.*, temperature of the refrigerant in the evaporating or refrigerator coils and the highest temperature in the condenser), has not been finally agreed upon internationally. European engineers suggest +14 deg. fahr. at the refrigerating coil and +77 deg. fahr. at the condenser, but in America, where the cooling water is as a rule much warmer than in Europe and the demand for lower temperatures in the refrigerator is greater, it is the custom to rate the tonnage of the machine at 0 deg. fahr. for the temperature of the refrigerant leaving the refrigerator coil, and 95.5 deg. fahr. in the condenser. This is equivalent in ammonia machines to practically 200 lb. abs. for condenser pressure, and 30 lb. abs. leaving the refrigerator piping. For the influence of change in the plane of temperatures on the capacity and horse power of ammonia compressors, see Table 8, p. 1720.

The refrigerating capacity of a machine is different from the actual **ice-making capacity** of a plant; the latter is considerably less, being 50 per cent. and upward of the refrigerating capacity, according to temperature of water, etc.

The Refrigeration Research Committee of the (British) Institution of Mechanical Engineers has adopted (1914) the **calory per sec.** (= 342,860 B.t.u. per 24 hr.) as the unit of refrigeration, and has adopted as "standard conditions" a temperature range of the cooling water from 15 deg. cent. (59 deg. fahr.) at inlet to 20 deg. cent. (68 deg. fahr.) at outlet, and a temperature range of the brine from 0 deg. cent. (32 deg. fahr.) to −5 deg. cent. (23 deg. fahr.). For direct-expansion systems the standard vapor temperature in the refrigerator is to be taken as −10 deg. cent. (14 deg. fahr.). The **rated capacity** of a machine is the number of units of refrigeration developed under the above standard conditions.

Compression Machines

The **compression system** should be selected for mild-temperature refrigerating systems. It is particularly economical where the exhaust steam from the compressor can be used for heating, dyeing and other industrial purposes. It is the only system which can be favorably considered where electric current, and especially direct current, is low in price. Direct-current

efficiency of 80 to 85 per cent. in machines of 50 tons and over; under good average working conditions, with a reasonable amount of care to maintain tight valves and tight piston rings, it should run from 75 to 80 per cent.

Table 3. Theoretical Horse Power to Produce 1 Ton of Refrigeration

(Add 50 per cent. for probable actual horse power; see also Table 41, p. 849)

Suction pressure (gage) and corresponding temperature		Condenser pressures (lb. per sq. in. gage), and corresponding temperatures (deg. fahr.)

Wet Compression vs. Dry Compression. The considerable superheat of the ammonia vapor at the end of compression may be reduced or prevented either by injecting refrigerated oil or by carrying liquid ammonia into the compressor. If the latter method is used and sufficient liquid is admitted to keep the vapor always in a saturated condition, the operation is known as **wet compression.** If the ammonia gas is dry or superheated when admitted to the compressor and there is no liquid injected during the compression stroke, the operation is known as **dry compression.** The form of a compressor should be especially adapted either to wet or dry compression. The **advantages of wet compression** over dry compression are as follows: (1) A higher back pressure can be maintained; (2) the surface of the refrigerator can be materially reduced; (3) the volumetric efficiency is higher; (4) the oil taken in through the stuffing box remains in the liquid state; (5) no water jacketing is necessary. The regulation for wet compression is simple, because the temperature of the delivering pipe, as indicated by touch, shows whether a sufficient amount of ammonia is passed through the system.

There are two means of producing wet compression. In the **wet-suction-gas method** liquid ammonia is fed to the cooler in such quantity that a part of it remains unvaporized and passes to the compressor in the form of finely divided liquid suspended in the gas. With this method of wet compression it is impossible in practice to maintain a definite condition of the gas at the compressor; at times there will be comparatively dry gas and at other times an excess of liquid, which is left in the clearance and produces a heavy re-expansion loss which more than nullifies the gain made on the compression stroke. With this wet-gas method the capacity of a machine has been found to be much less than with dry compression, and the horse power per ton of refrigeration correspondingly greater.

Tests made by the York Mfg. Co. on a horizontal double-acting compressor gave a tonnage with dry compression of nearly 3 times that made with wet compression when the suction pressure was 5 lb. gage, and of 1.5 times that made by wet compression when the suction pressure was 25 lb. The increased re-expansion at low suction pressure causes the considerable falling off in volumetric efficiency and capacity.

Efficiency of Compression and Absorption Machines at the Quincy Market Cold Storage and Warehouse Co. A number of tests, each of 24 hr. duration, with a 1000-ton compressor doing 750 tons of refrigeration showed an average result of a ton of refrigeration at 0.9 h.p., with a steam consumption of 228 lb. per ton in 24 hr. In these tests the gas came to the compressor at + 10 deg. fahr., and was discharged into shell condensers with 70 deg. fahr. condensing water, corresponding to a head pressure of approximately 115 lb. The engine driving this compressor was a cross-compound Corliss, using steam at 150 lb. pressure, superheated 100 deg., and exhausting into a vacuum of approximately 28 in.

Similar tests of a 400-ton machine under the same conditions gave the following results at rated load: With the gas coming to the compressor at −10 deg. fahr., and a head pressure of 115 lb., a ton of refrigeration was produced for 1.25 h.p. and a con-pipe line to the condenser may be based on a velocity of 8000 to 10,000 ft. per min., depending upon the length of line, fittings, etc.

Water Jackets. The water jackets on the compressor of a dry-compression machine change the compression curves only slightly. In single-acting machines the compression line will usually fall slightly under the adiabatic, making a card about 4 per cent. smaller than the adiabatic. The control of the **superheat** is not attempted, the jacket water used being merely enough to keep down the temperature of the cylinder, valves and gaskets.

Liquid Receiver. If the shell type of condenser is not used, a liquid receiver should be provided. This receiver acts as an oil separator. It should be vented to the condenser at the top, the liquid entering at the bottom. Where the piping to the condenser is long, the flow of liquid from the condenser to the receiver may be interrupted by gas formed in this liquid line; in such cases a cooling coil with water circulation may be inserted. The receiver is sometimes made large enough to store the entire ammonia charge of the plant. For average conditions a reasonable **receiver capacity** will be obtained by allowing ½ cu. ft. per ton up to 20 tons, ⅓ cu. ft. for 25 to 50 tons, ¼ cu. ft. for 60 to 100 tons, ⅙ cu. ft. for 150 to 200 tons, and 1/10 cu. ft. above 200 tons.

Weight of Ammonia in System. The amount of anhydrous ammonia needed in a compression plant may be estimated by assuming the whole space of the condenser to be filled with ammonia vapor at 165 lb. pressure, the ammonia expansion pipes to be filled with ammonia vapor at 20 lb. pressure, and allowing besides 25 lb. of liquid ammonia for every cubic foot of liquid receiver capacity. The following table, derived from the averages of a number of commercial installations, gives the weight of anhydrous ammonia required for the **compression side** of refrigerating plants:

Tons of refrigeration	5	10	20	40	100	200	300	500
Ammonia, lb.	110	150	230	300	440	620	840	1215

The anhydrous ammonia required per 100 running feet of pipe on the **expansion side** is approximately as follows:

Size of pipe, in.	1	1¼	1½	2
For refrigerating plants, direct expansion and brine cooling coils, lb.	14	18	20	25
For ice plants, expansion coils for can and plate use, lb.	8	11	12	15

The total ammonia required in the system in **ice-making plants** is as follows:

Tons ice per 24 hr.	5	10	15	25	50	100
Ammonia, lb.	100	250	500	1000	2000	4000

Operation of Ammonia Compression Plant

Preliminary Leakage Tests. To prove a new plant before it is charged with ammonia, it should be filled with compressed air (at about 100 lb. pressure) by working the compressor while the suction valves provided for this purpose are opened. Thick soap lather spread over the pipes, etc., indicates leaks by the formation of bubbles. The coils in brine tanks, filled with water, show leaks by the bubbles of air escaping through the water. After the pressure is equalized throughout the whole system, the pressure shown by the gage will remain stationary if the plant is absolutely air-tight. A similar test should be made under vacuum.

Charging the Plant. After obtaining the best possible vacuum, a drum of ammonia is connected to the charging valve and the expansion valve is closed. The liquid ammonia is then admitted into the system, while the compressor is kept running at a very slow speed with suction and discharge valves opened and water running in the condenser. If the air is not completely exhausted from the plant, **charging by degrees** is advisable. First, about one-half of the total amount of ammonia is charged, and after this has thoroughly circulated in the system, most of the remaining air will have collected in the top of the condenser, whence it can be blown off. The balance of the ammonia is then charged in a similar way, in one or two operations.

Operation of Plant. The working of a compression machine is regulated chiefly by the expansion valve. The pipe conveying the compressed ammonia to the condenser should not get hotter than 300 deg. fahr., and the temperature of the brine should be also recommended for closing leaks. When so used the cement must be fortified by the application of sheet rubber and sheet-iron sleeves, kept in position by iron clasps.

Absorption Machines

For the theory of the absorption system of refrigeration, see p. 348. In this system there is no positive action of the machine, and the capacity and efficiency depend not only upon details of design, but also to a much larger extent upon the skill and watchfulness of the operator. An absorption machine, under best conditions of design and operation, using low gas pressure, with a temperature in the refrigerator of not more than 0 deg. fahr., and of a capacity of 50 to 100 tons, gives refrigerating results practically equal to those of a compression machine also under favorable conditions. For capacities exceeding 100 tons the compression machine is not only more positive but becomes more efficient because of the greater efficiency of the larger steam engine, which is commonly compound-condensing and may use superheated steam. The absorption machine gives best comparative results as the suction pressures are reduced; the compression machine as they are raised. Absorption machines have been confined to comparatively small units (up to about 225 tons), while compression machines are now in successful operation with capacities as high as 1000 tons.

Where local conditions are favorable, a **combination of the two machines** will result in an increased efficiency, the absorption machine being run with the exhaust steam from the compression machine—which in this case may be simple, non-condensing, and which would handle the refrigerating load of a high-temperature system—while the absorption machine handles the load of the low-temperature system. This is seldom done in practice, for the reason that the two systems are never constant with relation to each other, making necessary some manipulation of the steam supply to either machine, which, together with the lack of interchangeability of coolers and condensers, tends to make this method of combining the two systems undesirable. The coolers and condensers after having been used on a compression system cannot be used on an absorption system because the lubricating oil of the compressor which deposits in these devices upsets the operation of an absorption system. Cleaning is possible but not practicable.

Advantages and Disadvantages of Absorption System. The absorption system would be favorably indicated where refrigeration is to be accomplished in a plant in which there are steam engines operated for power purposes, as in small electric-light plants and in some manufacturing plants, the machine being run with the exhaust steam from these other units.

The **repair costs** of the absorption machine may be heavy when overdriven and when using a corrosive water in the absorber and rectifier. Slight quantities of oil have a very bad effect upon the efficiency of the absorption machine. Faulty **rectification,** due either to faulty design or operation, is one of the greatest sources of loss in the use of the absorption system. This defect has been known to be so serious as to nullify 85 to 90 per cent. of the total capacity of the machine. The best systems of rectification should consist of an efficient analyzer, a mechanical separator, a cooling coil and preferably a second separator with liquid drip after the cooling coil for the purpose of testing the results of rectification. At the full capacity of the machine from 1 to 5 per cent. of the water vapor is usually carried through the rectifier to the condenser and cooler. The analyzer, first separator and cooling coils should discharge their drips as returns to the generator; the drip from the final separator gives an indication of the condition of the rectified gas, which should be used as a basis for the regulation of the machine.

the same conditions when driven by a simple non-condensing engine (S.C.) using 28 lb. of steam per engine i.h.p. per hour, and when driven by a compound condensing engine (C.C.) using 15 lb. per i.h.p-hour. The variation in the calculated capacity of an absorption plant with change of condenser and suction pressures is much less than with a compression machine, as is shown by the last two lines of Table 9.

Comparison of Compression and Absorption Plants. Denton and Jacobus (*Trans. A. S. M. E.*, vol. 13) have made a theoretical comparison of compression and absorption plants under various assumed conditions of operation, showing that the refrigeration per lb. of coal does not vary greatly with variation in the temperature range of the ammonia in an absorption system, whereas it decreases rapidly in a compression machine as the temperature range widens. The range of temperatures at which the two systems are theoretically of equal efficiency depends upon the steam consumption of the engine driving the compressor. In Table 10, 15 per cent. is added to the theoretical work of compression for compressor and engine friction. Each pound of coal is assumed to give 10,000 B.t.u. to the boiler. It is assumed that no water goes over to the condenser of the absorption machine; if 5 per cent. is entrained it will lower the efficiency of the machine 15 to 20 per cent.

Table 10. Comparison of Absorption and Compression Plants Under Various Conditions of Operation

Temperatures, deg. fahr.			Pounds of ice-melting effect per lb. of coal				B.t.u. per lb. of ammonia circulated through the system				
			Compression machine		Absorption machine						
Condenser	Refrigerating coils	Absorber	Using 3 lb. of coal per steam i.h.p.-hour.	Using 1.6 lb. of coal per steam i.h.p.-hour.	Strong liquor pump exhausts to the generator	Strong liquor pump exhausts to feed heater; feed water at 212 deg. fahr.	Heat furnished to generator of absorption machine.	Refrigerating effect (same for both systems)	Heat abstracted from condenser (same for both systems)	Equivalent of work of compression (same for both systems)	Heat abstracted from absorber of absorption machine

* Average concentration; per cent. of ammonia by weight.

Charging an Absorption Plant. Pump a vacuum in the system and close all the valves when a vacuum of 25 in. is obtained. Then admit aqua ammonia through the charge pipe in the generator until the vacuum in the machine is gone, and pump in the balance with the ammonia pump until nearly the requisite charge is in; then heat the ammonia slowly by turning steam through the heater coils. When the pressure gage indicates about 100 lb., purge the condenser, turn on the water into the condenser and absorber, and apply the steam until liquefied gas shows in the glass gage of the condenser. Open the expansion valve and turn the poor liquor into the absorber; the ammonia pump may be started as soon as liquor has filled the glass gage. An absorption machine, if charged when cold to its working level, will be **overcharged** under working conditions, so that the liquor may rise out of sight in the gage glass of the generator.

To recharge an absorption plant when the gas has leaked out or the liquor has become impoverished, add anhydrous ammonia to the required amount. When the liquor is lacking it is best to recharge the machine with strong aqua ammonia at 26 to 28 deg. Baumé until the original level is reached. The weight of anhydrous ammonia, x (lb.), which must be added to m lb. of ammonia liquor of the percentage strength a to raise it to the percentage strength b, is given by the equation: $x = m\ (b - a)/(100 - b)$. The drum of anhydrous ammonia may be mounted on scales and connected by a long ½-in. pipe to the low-pressure side of the expansion valve until the desired weight has entered the system.

Ammonia Piping and Fittings

Three general types of fittings are now furnished by a number of manufacturers (see also p. 832): (1) The **gland end,** in which the fitting is tapped with the regular pipe thread, outside of which is a recess for a rubber washer, which is pressed into the recess and against the pipe at the joint by a gland which slips over the pipe and bolts to the end of the fitting; (2) the **flanged end,** which usually makes a tongue-and-groove joint with its companion flange; (3) the **threaded end** fitting, which may or may not have a recess at the outer end for soldering. The defects of the soldering method are: (*a*) When used on lines larger than 3 in., the vibration, expansion and contraction ultimately break the soldered joint, allowing the fitting to leak; (*b*) when used on the discharge gas line of a compressor operating at a pressure of from 175 to 200 lb., the temperature of the gas, which often reaches 300 deg. fahr. or more, brings the solder to a plastic state where it is of little or no value for maintaining a tight joint.

It is customary on high-grade work to use extra-heavy pipe. Vibration, expansion and bending stresses may produce excessive stresses at the root of the thread, just outside of the fitting. The heavier the piping the more trouble from this cause. In the practice of the Quincy Market Cold Storage and Warehouse Co. no threaded pipe over 3 in. in diam. is used. Up to 3 in. a plain screwed fitting is used and the joint is coated with a cement made of litharge and glycerine before screwing together. For **piping over 3 in.** the Fairbanks method is employed, and, as no threads are used, only standard-speed of the water should be from 250 to 300 ft. per min. for the best results and the heat exchange about 170 B.t.u. per hr. per deg. fahr. mean difference between the ammonia and the water. This type is badly affected by corrosive and muddy water, making it necessary to clean often (either by scraper or compressed air) through the end of each section. Leakages can be detected only by regular tests of the outlet water. Table 12 shows the rate of heat exchange with varying velocities of fluid for double-pipe (2-in. and 3-in.) condensers and brine coolers. Table 13 gives results of tests by the York Mfg. Co. on a 1¼-in. × 2-in. double-pipe condenser, showing the effects of varying the amount (and velocity) of the condensing water (at 70 deg. fahr.); gage suction pressure, 15.66 lb. per sq. in.

Table 12. Heat Transmission through 2-in. × 3-in. Double-pipe Condensers and Brine Coolers

Velocity of fluid in pipe, ft. per min.		100	200	300	400	500	600	700

300	1.88	1.240	148	1.40	2.33
400	2.40	1.300	140	1.33	3.11

Flooded or Circulating Condensers are made both atmospheric and double-pipe. In these condensers advantage is taken of the fact that the rate of heat transfer between a liquid and a liquid is much greater than between a liquid and a gas. As usually constructed, the gas is first passed through sufficient pipe to remove the superheat. It is then fed by an injector action into the lower part of the condenser proper, and the piping is so arranged that the condenser is kept full of liquid ammonia moving rapidly and subjected to the cooling effect of the condensing water so that the liquid ammonia when arriving at the injector is cold enough to condense the incoming gas. The liquid ammonia is drawn off from the rapidly circulating liquid at a point just before the injector and conveyed to the receiver. For 70 deg. fahr. condensing water and a head pressure of 200 lb. absolute, a coil of 12 pipes high, atmospheric type, 2-in. pipe 20 ft. long, *i.e.*, with 150 sq. ft. of pipe surface, will have a capacity of 39.3 tons, using 60 gal. of cooling water per min. or 1.53 gal. per min. per ton per day. The surface is 150/39.3 = 3.81 sq. ft. per ton, or only about 60 per cent. of that required for the regular double-pipe type or about 15 per cent. of the pipe required in a regular atmospheric condenser. The flooded condenser is adversely affected by oil, air and foul gases, and for this reason 25 to 30 per cent. additional surface should be added.

Shell-and-tube Condensers are practically the same as steam surface condensers. The water passes back and forth through tubes and the am-the tubes. The surface required is from 12 to 20 sq. ft. per on. These condensers must be shut down for cleaning. With igh vertical shells and plenty of water, this type is very e pass, the water flowing upward through the tubes. The t open so that tubes can be cleaned by blowing with com- scraping and brushing, without interfering with the opera- e makes a good oil, air and foul-gas separator and acts as a eceiver; leaks are easily detected and repaired and tubes can aced.

oil Condensers usually have a circular shell into which the e cooling coils are helical concentric coils through which the ows at a speed usually about 100 to 150 ft. per min. The coils o a header at each end. About 16 sq. ft. of surface per ton is y have the advantage of being compact and clearing the sur- ammonia as fast as formed. With clean water and where is obtainable for blowing out the coils, this type is satisfactory. **d condensers** the ammonia coils are submerged in a tank the cooling water flows. Except in very small machines they on account of the large water area and consequent slow speed ver the coils calling for large coil surface. When used, from 30 surface should be provided for each ton of refrigeration.

ndenser is similar to the steam jet condenser and consists of a el into which the ammonia gas is discharged from the compres- of cool liquid anhydrous ammonia is sprayed upon the gas as it th pass through a combining cone and the resulting liquid flows rough a liquid cooler. This type gives a minimum condenser is suitable only for large plants.

Surface and Cooling-water Requirements of Different Types of Refrigerating Condensers*

	Surface, sq. ft. per ton of refrigeration	Transmission, B.t.u. per sq. ft. per min. per ton	Pipe per ton of refrigeration		Water, gal. per min. per ton
			Size most used, in.	Lineal ft.	
le-pipe...	5	40.0	1¼	14	1½–2
spheric...	6	33.3	2	11	1½–2
....	8	25.0	1¼	22	1½–2
....	16	12.5	2 1½ 1¼	30 38 44	2–2½
e........	18	11.0	1½	55	2–3
....	24	8.3	2	45	1½–3
....	35	5.7	2	65	3–7

water at 70 deg. fahr., condenser pressure 200 lb. abs. Where the condens- oul and local conditions do not admit of frequent cleaning, both surface and should be increased from 10 to 25 per cent.

Methods of Applying Refrigerants

ation is carried out either by direct expansion or by the use of th **direct expansion** the liquid at approximately the condenser fed through an expansion valve directly into the piping which is for cooling. The liquid spray from the expansion valve passes e coils at high velocity, maintaining a wetted inner surface, and is vaporized by the absorption of heat through the pipe walls; the vapor is removed and liquefied by the refrigerating machine and delivered to the expansion valve again.

In the **brine system** the direct-expansion system is used for cooling brine and the cooled brine is pumped through pipe lines to the point where the cooling is to be done, the heat being absorbed by the brine and the brine returned to be again cooled. The brine-cooling vessel is usually either a double or triple pipe coil or of the shell type.

In refrigeration by **compressed air** the exhaust from the motor cylinder is passed through the room to be cooled and allowed to escape (open system) or is passed through piping and returned to the compressor (closed system); the latter system is the more efficient and used for lower temperatures, the open system being used principally where mild temperatures are required and where ventilation is a factor.

Piping of Rooms. The **size of pipe** usually employed for piping rooms varies from 1 to 2 in. If a room is to be held at a temperature of 34 deg. fahr. and the temperature of the expanding ammonia is 10 deg., it will take only half as much pipe to convey a certain amount of refrigeration as with an ammonia temperature of 22 deg. It is generally advisable to use the larger amount of pipe in order to enable the compressor to work with a higher back pressure.

Allowing a difference of 8 to 15 deg. fahr. between the temperatures inside and outside of the pipes, it is usually assumed that 1 sq. ft. of pipe surface will absorb 2500 to 4000 B.t.u. in 24 hr. in direct expansion. Assuming a **rate of heat transmission** of 10 B.t.u. per hour per sq. ft. of surface per deg. fahr. difference between the temperatures inside and outside of pipe, in case of **direct expansion,** if R is the amount of refrigeration (tons) required for a room in 24 hr., and t and t_1 the temperatures of the room and within the ammonia coils (deg. fahr.), respectively, then the **pipe surface required** (sq. ft.) $= S = 288{,}000R/240(t - t_1)$. In **brine circulation** the brine, with the same back pressure, has a higher temperature than the ammonia, and consequently from one to one and one-half times as much pipe is used in brine circulation as in direct expansion for a given back pressure.

Practical Rules for Piping. The following rules, which are commonly used, give surfaces in excess of those determined by the foregoing equation. They are likely to yield satisfactory results under very adverse conditions.

One running foot of 2-in. pipe (direct-expansion) will take care of 10 cu. ft. of space in rooms which are to be kept between 32 deg. and 10 deg. fahr.; of 40 cu. ft. of space in rooms to be kept at or above the 32 deg. fahr., and of 60 cu. ft. of space in rooms to be kept at 50 deg. fahr. and above. These rules are intended to cover rooms of 50,000 cu. ft. capacity and less, poorly insulated, and operated with small differences in temperature. Still more liberal is the common assumption that 1 ton of refrigerating capacity will take care of 4500 cu. ft. of cold-storage capacity to be held at 32 to 35 deg. fahr., and that from 260 to 300 ft. of 1¼-in. pipe should be used to distribute 1 ton of refrigeration. The extra cost of liberal piping allowance will often be offset by the consequent improvement in the efficiency of operation of the compressor. An expansion valve should be provided for every 400-ft. length of 1-in. pipe, every 500 ft. of 1¼-in. pipe, and every 1000 ft. of 2-in. pipe. The **pipes in storage rooms** should be placed where they are least in the way, and should be arranged in independent sections connected by manifolds in such a way that each section can be shut out to throw off the frost which gathers on the surface.

Brine Circulation is preferred by many to direct expansion, in consequence of the fear of danger from escaping ammonia in case the pipes should leak. This danger has probably been exaggerated, as but few accidents of this kind have been known, the pressure in the ammonia pipe being generally ing point than common salt. It is, however, higher in price. It is supplied in 600-lb. drums, either solid or granulated, and in tank cars containing 6000, 8000 or 10,000 gal. of liquid at 1.350 sp. gr. The properties of sodium chloride solutions are given in Tables 6 and 11, pp. 296–9, and of calcium chloride in Table 11, p. 299, and Fig. 4. The specific gravities in Fig. 4 are measured at 60 deg. fahr. The Solvay Co. calcium chloride crystals are of approximately the following percentage composition: Calcium chloride, 73.6; sodium chloride, 1.45; water, 24.9; constituents insoluble in water, 1.07. Table 15 gives the densities of Solvay calcium chloride solutions.

The density of brine is sometimes measured by a **salinometer**. This is a simple hydrometer the indications on which are 4 times greater than on the corresponding Baumé scale (see p. 85).

It is undesirable to use a **strength of solution** of salt greater than is necessitated by its freezing temperature, as the specific heat (Table 6, p. 296 and Table 11, p. 299) decreases as the concentration of the brine increases and consequently the stronger the brine the less heat a given amount of it will be able to convey between certain definite temperatures. Moreover, brine which is too strong may cause clogging of pipes, etc., by depositing salt. On the other hand, if the solution is too weak it may not be able to withstand the temperature existing in the expansion coil, so that a layer of thin ice will form around the latter and interfere with the absorption of heat from the brine. The surface of the expansion coils in the brine tank should be inspected from time to time to see if any ice has formed on them. In larger plants it is customary to use a solution with a freezing point not less than 10 deg. below the lowest temperature which will be obtained in the operation of the plant. In smaller isolated plants and where careful supervision is not insured, it is customary to make the solution as strong as possible without being unstable, usually 1.240 to 1.250 sp. gr. A solution of 1.250 sp. gr. at 60 deg. fahr. becomes unstable at approximately −37 deg. fahr.

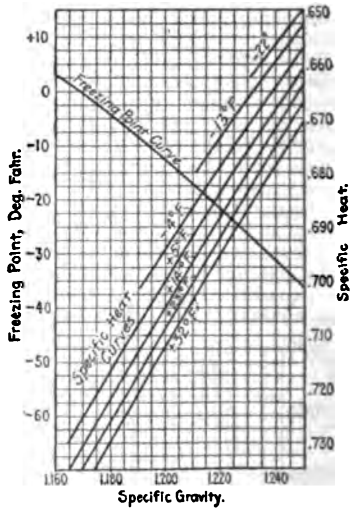

FIG. 4.—Properties of Calcium Chloride Solutions.

Table 15. Density of Calcium Chloride Solutions (at 64 deg. fahr.)

Specific gravity	$CaCl_2$, per cent.	Specific gravity	$CaCl_2$, per cent.	Specific gravity	$CaCl_2$, per cent.	Specific gravity	$CaCl_2$, per cent.
1.007	0.943	1.065	8.487	1.131	16.031	1.205	23.575
1.014	1.886	1.073	9.430	1.140	16.974	1.215	24.518
1.021	2.829	1.081	10.373	1.149	17.917	1.225	25.461
1.028	3.772	1.089	11.316	1.158	18.860	1.236	26.404
1.035	4.715	1.097	12.259	1.167	19.803	1.246	27.347
1.043	5.658	1.105	13.202	1.176	20.746	1.257	28.290
1.050	6.601	1.114	14.145	1.186	21.689	1.268	29.233
1.058	7.544	1.112	15.088	1.196	22.632	1.279	30.176

intervals, with expansion joints at definite distances from each other, confining the expansion and contraction to those distances and to calculable limits; and (2) welding the pipes in a continuous length from manhole to manhole and putting expansion joints at the manhole or "U" bends on the run.

Brine Circulation System. In large installations the ammonia should be confined to the power house, where it can be controlled readily, and the transmission of refrigeration accomplished by means of brine circulation. The **brine coolers** used are either of the tank-and-submerged-coil type or shell coolers of either the coil or straight-tube type. For other than small capacities coolers of the shell type with straight tubes are more efficient, offer less frictional resistance to flow, and are cleaned and repaired more readily. The **brine pumps** are preferably of the reciprocating type. The centrifugal pump is not well adapted for the larger work, not only on account of its low mechanical efficiency, but also because the work lost in fluid friction in the pump heats up the brine, sometimes as much as 20 per cent. of the total cooling work being done on the brine. This is especially true when the flow from the centrifugal pump is restricted by line friction or by the valves used to regulate the brine supply.

In general practice, the **amount of brine required** per min. per ton of refrigeration is from 5 to 6 gal. Assuming 5 gal. per ton at 1.2 sp. gr., or 50 lb. per min. per ton, and a specific heat of 0.700, the difference in temperature of the incoming and outgoing brine will be 200 B.t.u./(50 $\times$ 0.700) = 5.7 deg. fahr. With 6 gal. per min. per ton the temperature difference would be 4.8 deg.; an average of 5 deg. is good practice. A fair-sized street system supplying brine to boxes in the third and fourth stories of a building will require (including line friction) a pressure of about 75 lb. (= 172.8 ft. head) on the discharge side of the pump. The useful work done on the brine will be: Head (ft.) $\times$ lb. brine per min./33,000 = 172.8 $\times$ 50/33,000 = 0.26 h.p. per ton of refrigeration for 24 hr. With a pump of 50 per cent. mechanical efficiency, the **horse power required** would therefore be 0.26/0.50 = 0.52; with 85 per cent. efficiency, which is obtainable with pumping engines of the type used in the largest installations, the pump will use 0.3 h.p. per ton. The **discharge pressure** of the Quincy Market Cold Storage & Warehouse Co.'s street system averages 100 lb., with a suction pressure varying from 15 to 35 lb., pumping 6,000,000 gal. of brine in 24 hr. This will supply brine to the tenth story of a building with ample reserve pressure.

The **street mains** for brine circulation may be either of cast iron of the bell-and-spigot type, the ordinary flanged and screwed type, or of the gland-end type. The Fairbanks joint (p. 1728) gives the necessary tightness and flexibility, but costs about 10 per cent. more than the other types; it lacks, however, the quality which the bell-and-spigot type has, namely, that of varying the alignment at each joint to get around obstructions.

Mains, as far as possible, should be **laid below the frost line,** and expansion joints, either of the packed-sleeve type or the accordion type, should be provided at least every 500 ft.; where large branch mains are taken off expansion joints should be not more than 250 ft. apart. All **expansion joints** should be placed in manholes for easy inspection and repair. As a further protection against expansion a 1-in. by-pass should be connected between the supply and return main at the end of each section of not more than 500 ft. when laid, and brine circulation set up so that the lines may be brought down to the average service temperature before being anchored, insulated and covered in. The destructive effects of expansion and contraction are best safeguarded against by the provision of power-plant equipment pipe in the middle of each expansion section so that the cork and pitch will weld to the pipe as well as to the box itself.

Cold Storage

Insulation. For general theory and tables of conductivities, see p. 304. Insulation used in refrigeration is usually compound. The insulating value of filling material is nearly inversely as its specific gravity. This goes down to a point where the material is so loose as to permit air circulation. With most material a specific gravity of 0.160 seem to be the limit. When any fibrous material so far in use is arranged so that it weighs much under this, the effect of an open air space is obtained. This does not apply to **material arranged in layers** of different densities transversely to the direction of the heat. **Dryness of insulation** is of great importance; moist shavings pass 70 per cent. more heat than dry shavings. Paper insulation is often valuable in keeping out moisture.

Refrigerating-coil Pressures, according to Matthews, should be as follows for the room temperatures given:

Temperature of room, deg. fahr.	10	15	20	28	32	36	40	50	60
Coil pressure, lb. per sq. in., gage	10	12	15	22	25	27	30	35	40

Cold-storage Temperatures. Modern cold-storage warehouses of the larger concerns are cooled by brine which is furnished at two different temperatures only. The higher temperature for the mild-temperature warehouses is from 10 to 12 deg. above zero (fahr.), and the low-temperature brine for the freezers is from 10 to 12 deg. below zero. All temperatures above that of the brine are obtained by regulating the amount of brine circulated in any particular set of coils. In the low-temperature warehouses the piping is arranged for two classes of service: (1) **Sharp freezers,** where the goods which are to be frozen are kept while their temperature is brought down quickly to the holding temperature (say in from 24 to 48 hr.), after which they are stored in (2) **holding rooms** where the desired temperature is maintained.

Sharp freezers are now piped with 2 sq. ft. of pipe surface per cu. ft. of room space for fish, meats, game, etc., where the material is open to a more ready absorption of the heat, and with 1 sq. ft. per cu. ft. for packaged goods such as poultry, pork, butter or other goods in boxes or barrels. Holding rooms are usually piped with 1 sq. ft. of pipe surface per 7 cu. ft. of room space; this will allow for an ordinary amount of removal and replacement of goods without materially raising the temperature of the room. Where the warehouse has a high grade of insulation and the goods are not disturbed for a considerable period of time, a piping ratio of 1 sq. ft. of pipe surface to 10 cu. ft. of room space may be used.

The system of cooling which is now being installed in the highest type of warehouses consists of a coil room containing the necessary brine coils, through which the air from the different rooms is circulated by a pressure blower. The inlet and outlet of each room are so arranged that the cooled circulating air will cover the entire room in its transit; this is usually accomplished by having the cold-air inlet in the center of the room and two return outlets—one at each end of the room. The piping ratio for the coil room in this system, assuming a high-grade insulation with 2 to 4 B.t.u. transmission per sq. ft. per 24 hr. per degree difference in temperature, should be sq. ft. of external pipe surface to 15 cu. ft. of space to be cooled (with brine at 10 to 12 deg. below zero) for warehouses carrying temperatures of zero and below, and 1 sq. ft. of pipe surface to 24 cu. ft. of space to be cooled for freezing different thicknesses of ice is proportional to the square of the thickness.

Size of Cans. Commercial sizes of galvanized-iron cans as made by the Triumph Ice Machine Co. are as follows:

Size of can, in..	6×12×24	8×18×32	8×16×40	11×22×32	11×22×44	11×22×57
Weight of cake, lb.	50	100	150	200	300	400
Time to freeze, hr.	20	36	36	55	60	60

Cans are made to hold about 5 per cent. more than their rated capacity, to allow for thawing. The freezing times given are based on a bath temperature of 14–18 deg. fahr.

Brine Tanks are made of sheet iron or steel, of wood, or of cement. Sheet steel is commonly considered the best material and will last from 10 to 12 years. Wooden tanks are built of 2× 4 or 2 × 6-in. planks, according to size of tank, lined with ¼-in. matched flooring. All the 2 × 4-in. plank or the matched flooring is laid and bedded in pure hot asphaltum before being nailed together. Cedar or cypress and hard yellow pine are the woods recommended. Cement tanks must be made of the best cement, thoroughly hardened and dried, and coated with hot asphaltum before being used. A 2-in. space is left between molds and a 3-in. space where the pipes pass between them. Three feet additional length of tank should be allowed for the agitator.

Insulation of Brine Tank. The insulation of the brine tank should be 12 to 18 in. thick at the sides and at least 12 in. under the bottom if granulated cork, sawdust or shavings are used. An excellent insulation consists of not less than 6 in. of waterproof-lith or cork board or a combination of the two in two layers with broken joints thoroughly sealed, and a water- and air-proof material between the two. The intermediate material may be any high grade of waterproof felt paper, but is preferably a heavy coating of cement composed principally of asphalt which is laid with a brush as heavily and smoothly as possible on the outer surface of the first layer of insulation; the second layer is applied to the first as soon as possible so that the asphalt cement will unite the layers of insulation. The cork board is preferably used for the outer layer and should be plastered with a coat of waterproof Portland cement plaster thick enough to stand ordinary wear and tear and to prevent moisture reaching the insulation from the outside.

Top-and-bottom-feed Brine Coil. The expansion coils in brine tanks are fed from the bottom in dry compression systems, and from the top in wet compression systems. The disadvantages of both methods of feeding can be avoided by using "top feed and bottom expansion." In this system alternate coils in the tank are connected to a liquid manifold at the top of the tank, and the ammonia is evaporated downward through one-half of the coils in the tank. All of the coils in the tank are connected to a large bottom manifold from which the gas is returned up through the remaining half of the coils to a gas suction manifold at the top of the tank, located behind and a little above the liquid manifold.

Brine Circulation is effected by the use of propeller wheels, paddles, or pumps (preferably centrifugal pumps). For a 10-ton plant and smaller, a 12-in. propeller wheel run at 200 r.p.m. is recommended, while for a larger plant an 18-in. wheel should be employed.

Economical Method of Operation. According to Voorhees, considerable saving is possible in can-system plants by operating at two different back pressures; the low pressure for freezing the ice and a higher pressure for cooling the water before it goes to the cans and for cooling the liquid ammonia on its way to the expansion valve. By using a multiple-effect system (see p. 1717) and receiver the following (unverified) results are claimed:

Temperature of condensing water, deg fahr...	100	90	80.0	70	60.0	50
Increase in ice-making capacity, per cent......	80	70	58.0	48	38.0	29
Decrease in horse power per ton, per cent....	35	25	22.5	20	17.5	15

Water and Coal Required. For every ton of ice about 2400 lb. of water are required, allowing for loss and leakage, and with good coal (evaporating about 8½ lb. of water per lb. of coal) it takes an average of about 1 lb. of coal to produce 7 lb. of distilled-water ice by the can system (9 lb. with the

PATENTS FOR INVENTIONS

BY

ODIN ROBERTS

REFERENCES: Albert H. Walker, "Patents," Baker Voorhis & Co. William C. Robinson, "Patents," Little, Brown & Co., Boston.

UNITED STATES OF AMERICA

What Subject-matter is Patentable. Any original and useful art (*i.e.*, process or method), machine, article of manufacture, or composition of matter, or any improvement on either, which has not been

(1) Known to or used by others in the United States prior to the invention or origination;

(2) Described anywhere in any patent or printed publication prior to the invention or origination, or more than 2 years before application is made for patent in the United States;

(3) In public use or on sale in the United States more than 2 years before application is made for patent in the United States;

(4) Patented to the inventor in some other country, which by treaty or convention has established reciprocal relations with the United States in patent matters, upon an application filed more than 1 year prior to the patent application in the United States. (This applies to practically all civilized countries.)

Who May Apply for Patent. The original inventor, or inventors jointly, if more than one. The existence of joint invention can be determined only by the facts of each case. The only general rule is that if two or more have worked and consulted together in the development of an invention they are properly joined as applicants for patent. The *owner* of an invention, by assignment and sale from the inventor, may not *apply* for patent, but may receive the patent as assignee, provided the deed of assignment has been recorded in the Patent Office with request by the inventor-applicant that the patent be granted to the assignee.

Term of Patent. Seventeen years from the date of issue. No extensions are granted under the general law.

The Patent Grant gives to the patentee for the term of the patent, the sole and exclusive right to manufacture, sell and use the alleged invention patented.

The Patent Application should be prepared by a competent solicitor. For information concerning the forms and rules, obtain from the Commissioner of Patents, Washington, D. C., a copy of the Rules of Practice of the United States Patent Office.

Cost of Obtaining a Patent. The Patent Office fees are: Filing fee, $15; final fee to obtain patent after allowance, $20. The cost of preparing drawings and specifications will, of course, vary with the subject-matter.

›r **Assignment of Patent,** to be binding, must be by an instrument g. Acceptable forms are found in the Rules of Practice of the ffice. To provide for constructive notice to all, an assignment must led in the Patent Office within 3 months of its date.

of Fractional Interests in Patents. Undivided fractions or l divisions of patent rights are advisable only in special cases, with the best intentions the interests of joint or territorial owners are interfere.

ses are permissions by the patentee to make, use or sell the thing , and, broadly speaking, a license may carry any imaginable provi- parties agree on. The "Act to Supplement Existing Laws Against l Restraints and Monopolies, etc.," approved October 15, 1914, ; unlawful for any person engaged in interstate or interterritorial :e, to lease or sell, or make contract for sale of, *patented* or unpatented or fix prices, discounts, or rebates, on the condition that the lessee ıaser thereof shall not use or deal in commodities of a competitor ›titors of the lessor or seller, where the effect may be to "substantially ›mpetition or tend to create a monopoly in any line of commerce." :ontracts should be reduced to writing. License by oral arrangement ıplication from circumstances, is as binding on the parties as if re- › writing, the difference lying in difficulty of proof.

ions of Employer and Employee, when the latter makes an n. Unless by express contract, or by implication from circumstances, loyee agrees that his patentable inventions shall be the property of loyer, the employer has no title or claim to the invention or to the or it. Even if the employee has developed his invention in the time h materials belonging to the employer, the claim of the employer is the value of time and materials and does not extend to the invention. the employer, with the employee's consent, express or implied, put ›ntion into use, license under the patent to continue use to the extent l is implied, but no such implication extends to any enlargement se.

ngements of Patent. As the grant purports to give the exclusive › make, sell or use, so an unlicensed manufacture, sale or use of the atented is an infringement, and the maker, seller, or user may be a District Court of the United States. **Suit** must be **brought** in rict wherein the defendant resides, or where the defendant, though not ;, has a regularly established place of business, and has committed the nfringement. In all but very exceptional cases, the courts will not ›**reliminary injunctions** in a suit on a patent which has not previ- een held valid in another contested litigation. In the first suit, the r of the patent is only *prima facie*, and is open to contest.

sues of Patent. If, through inadvertence, accident or mistake the l patent was defective, or claimed too much or too little, the error may aired by surrender of the patent and reissue, provided the reissue tion be filed without unreasonable delay and will not, if granted, be cial to rights of others which have been established in the interval n issue and application for reissue. The term of a reissued patent on the day when the original patent would have expired.

king Patented Articles. Unless the patentee has given particular of his patent, or general notice by marking the patented articles ıted," or "Pat.," with the date of his patent, he may not recover damages for infringement. If the patented articles themselves cannot be marked, the mark may be affixed to the packages in which they are contained.

False Marking. Any person who, with intent to deceive the public, falsely marks an article or parcel with a patentee's mark, without leave or authority, or so marks an unpatented article or parcel with patent marks, is liable to a fine of $100 for each offense, one-half to the use of the United States, and one-half to the person bringing the information to a District Court by proper action.

Proceedings in the U. S. Patent Office. Each application for patent found to be correct in form, is examined in its turn. Rejections of claim or requirements of amendment must be answered by the applicant (or his attorney) within 1 year after the date of the official communication, or the application will be held to be abandoned. It can be renewed only by filing a fresh application.

After allowance of an application the applicant has 6 months in which to pay the final fee. Lapse of 6 months without payment of the fee makes forfeiture of the application, which may, however, be renewed within 2 years from the date of allowance in the original case.

Interferences. When an application for patent is found to interfere with, *i.e.*, to present or claim substantially the same inventions as (1) another pending application, (2) a patent issued on a date less than 2 years prior to the date of the application in question, (3) a reissued patent, of which the original was granted on a date less than 2 years prior to the date of the application in question, the two interfering cases are impleaded in an action called an interference, the purpose of which is to determine, in the Patent Office, which of two or more rival claimants is the first inventor. The practice before the Patent Office in Interference is of such a character that an interference should be conducted only by legal counsel equipped with special experience in that practice.

FOREIGN COUNTRIES

International Convention for the Protection of Industrial Property. The important provision of the Convention is that any person who has duly applied for a patent in one of the contracting states shall have a right of priority for 12 months in making application in the other states. Such subsequent application is unaffected by any acts accomplished in the interval, as for example, by publication of the invention, or by the working of it.

The Convention (subject to war conditions) is in force in Australia, Austria, Belgium, Brazil, Ceylon, Cuba, Denmark, with the Faröe Islands, Dominican Republic, France, with Algeria and other colonies, Hungary, Germany, Great Britain, Italy, Japan, Mexico, Netherlands, with their East and West India Colonies, Dutch Guiana (Surinam), New Zealand, Norway, Portugal, with the Azores and Madeira, Servia, Spain, Sweden, Switzerland, Tunis, Tobago, Trinidad and the United States of America.

PRINCIPAL PROVISIONS OF THE PATENT LAWS OF FOREIGN COUNTRIES

Who May Obtain Protection. GREAT BRITAIN. (1) The inventor. (2) The inventor jointly with one or more persons, firms or corporations. (3) A person, firm or corporation residing in Great Britain, on a communication from a person, firm or corporation residing abroad, in which case the communicator need not be the inventor. GERMANY, FRANCE, BELGIUM, AUSTRIA, ITALY, SWITZERLAND, HUNGARY. Any person, firm or corporation, whether inventor or not. The patent office does not require the applicant to establish his right to apply. DENMARK, SWEDEN, JAPAN. The inventor duly authorised assignee. CANADA. The inventor. MEXICO. The inventor or orney.

n of Patent. GREAT BRITAIN. 14 years. GERMANY, FRANCE, SWEDEN, SWITD, HUNGARY, JAPAN, DENMARK, ITALY, AUSTRIA, 15 years. BELGIUM. 20 years. i. 18 years. MEXICO. One year or 20 years. A patent for 1 year is extensible ears during the first year.

uirements as to Novelty. Barring the Provisions of the International Conven- › invention is held to be new: GREAT BRITAIN, SWITZERLAND;—if prior to the date ication, it has become known within the country by printed publication or other- CANADA;—if it was known or used by others before the applicant's invention , or has been in public use with his consent for more than 1 year previous to his tion for patent thereof in Canada. But an application may be filed in Canada 1 year from the date of the first foreign patent therefor. FRANCE, SWEDEN, ITALY, ›, JAPAN;—if prior to the date of application it has been described in print or made in any other way in any country. This rule is subject to the following excep- In Italy, officially printed copies of foreign patents are not a bar; in Sweden re in an International Exposition is not a bar if the application is filed in Sweden 6 months after the opening of the Exposition; in Mexico, exposure in an Inter- l Exposition is not a bar if a description is first filed in Mexico and an application ed within 3 months after the close of the Exposition; or if a foreign patentee in Mexico within 3 months after the first publication of the invention by a foreign office. GERMANY;—if the invention has been described in print in any country the last 100 years prior to the application, or if it has been publicly used in ny before the German application. BELGIUM;—if the invention has been used rcially in Belgium prior to the application, or has become known by a printed tion in any country, unless such prior publication was officially prescribed. A, DENMARK;—if the invention has been described in a printed publication in untry prior to the application, or has been in public use within the country prior application. HUNGARY;—if the invention has been described in print in any y within the last 100 years prior to the application, or if it has been publicly l or exhibited in any country prior to the application in such a manner as to en- ose skilled in the art to use it.

king. (In Great Britain and Canada working must be on an industrial scale. other countries named the requirement as to working is usually met by adver- nts with a view of finding a purchaser or a licensee.) GREAT BRITAIN;—within s from date of grant. CANADA, FRANCE;—within 2 years from date of grant. M;—within 1 year of working elsewhere. AUSTRIA, DENMARK, SWEDEN, HUNGARY, —within 3 years from date of grant. GERMANY;—within 3 years from publica- the grant in the Official journal. Patentees who are citizens of the United States t required to work their patents. SWITZERLAND;—within 3 years from date of tion. This provision has no application to citizens of the United States, pro- the invention covered by the Swiss patent is being worked in the United States. O;—no requirement as to working.

es. GREAT BRITAIN. Progressive annual taxes, beginning before the end of urth year. GERMANY, FRANCE, AUSTRIA, SWEDEN, DENMARK, ITALY, HUNGARY, RLAND, BELGIUM, JAPAN. Annual taxes. CANADA, MEXICO. No taxes.

ortation. Importation of the patented invention is permitted in all the coun- amed in this summary; but importation into Canada after the expiration of 1 om the date of the Canadian patent, invalidates the importer's interest in the .

npulsory Licenses. A patentee may be required to grant licenses in GREAT N, if the reasonable requirements of the public with respect to the invention have en satisfied. In Sweden, if the patentee fails substantially to work the invention. NGARY, if the patentee fails to work the invention to an extent sufficient to supply me demand. In AUSTRIA, (1) when public interest demands; (2) when the holder ter patent cannot employ his invention without using that of an earlier patent, h cases each patentee may be ordered to license the other,

INSTRUCTIONS TO LAYMEN FOR FIRST-AID TREATMENT OF COMMON INJURIES AND DISORDERS

The following instructions have been prepared by a board of 20 physicians in industrial practice organized for co-operative effort in introducing into industrial establishments the most effective measures for the treatment of injuries or ailments of employees. They have been approved by the Conference Board on Safety and Sanitation of the National Founders' Association, the National Association of Manufacturers, the National Metal Trades Association and the National Electric Light Association, and are reproduced here by permission.

Wounds That Bleed. (Abrasions, Cuts, Punctures.) Drop 3 per cent. alcoholic iodine into wound freely, then apply dry sterile gauze to wound and bandage it. Do not otherwise cleanse wound.

Severe Bleeding. Place patient at rest and elevate injured part. Apply sterile gauze pad large enough to allow pressure *upon*, *above* and *below* wound. Bandage *tightly*. If severe bleeding continues, apply tourniquet *between* wound and heart and secure doctor's services at once. Use tourniquet with caution and only after other means have failed to stop bleeding.

Nose Bleeding. Maintain patient in upright position with arms elevated. Have him breathe gently through mouth and not blow nose. If bleeding continues freely, press finger firmly on patient's upper lip close to nose or have him snuff diluted white-wine vinegar into nose.

Injuries Which Do Not Bleed. (Bruises and Sprains.) Cover injury with several layers of sterile gauze or cotton, then bandage tightly. Application of heat or cold may help; other means are unnecessary. If injury is severe, place patient at rest and elevate injured part until doctor's services are secured.

Eye Injuries. (Except Eye Burns.) For ordinary eye irritations flood eye with 4 per cent. boric acid solution. Remove only loose particles which can be brushed off gently with absorbent cotton wrapped around end of toothpick or match. Do not remove foreign bodies stuck in the eye. In that case and for other eye injuries drop castor oil freely into eye, apply sterile gauze, bandage loosely and send patient to doctor.

Splinters or Slivers Embedded in Skin. (Except in Eyes.) If easily reached, withdraw with tweezers, then treat same as "Wounds that Bleed;" otherwise let doctor attend to it.

Fire Burns, Electrical Burns and Sunburn (also **Scalds.**—Ed.). Do not open blisters. Use burn ointment (3 per cent. bicarbonate of soda in petrolatum) freely on sterile gauze applied directly to burn. Cover with several thicknesses of flannel or other soft material, then bandage, *but not tightly*.

Acid Burns. Thoroughly flush wound with water, then dry wound, apply burn ointment and bandage as above.

Alkaline Burns. Thoroughly flush wound with water, then flood with white-wine vinegar to neutralize (dilute vinegar for alkaline *eye* burns), dry wound, apply burn ointment and bandage as above.

Eye Burns. Treat in the same manner as other burns.

Dislocations. In case of dislocation of finger (except second joint of thumb), grasp finger firmly and pull it gently to replace joint; then place finger in splint and bandage it. In all other cases place dislocated part at rest and promptly secure doctor's services.

The jars may be obtained from the Executive Secretary of the Conference Board on Safety and Sanitation, 928 Western Avenue, West Lynn, Mass., or from the Secretary of any of the four Associations named at the head of this article. They cost $6.50 each. In Massachusetts, the Board of Labor and Industries requires three extra articles which cost 40 cents.

MISCELLANEOUS

Lenses

Lenses are transparent bodies which, from the curvature of their surfaces, cause light waves traversing them to converge or diverge. Optical lenses have one or both surfaces of spherical curvature. Biconvex (), plano-convex (| and concavo-convex ((lenses are thicker at the center than at the edges and have a convergent effect. Biconcave)(, plano-concave)| and convexo-concave ((lenses are thinner at the center than at the edges and have a divergent effect. The distance from the center of a lens to the point at which incident plane light waves are brought to a focus, is called the **focal length** (f). If u is the distance from the source of light to the lens, and v the distance from the lens at which the image is formed, then, for a biconvex lens, $1/f = 1/u + 1/v = (n - 1)[(1/r_1) + (1/r_2)]$, where $r_1(r_2)$ is the radius of curvature of the lens surface nearer to (farther from) the source of light, and n is the index of refraction of the material of the lens (= 1.5 to 2.0 for glass). For a biconcave lens, minus signs should precede the reciprocals of f, v, r_1 and r_2 in the formula. For a plano-convex or plano-concave lens, $r_2 = \infty$ and $1/r_2 = 0$. When $u = \infty$ (*i.e.*, the incident waves are plane), $f = v$; when $u = f$, $v = \infty$ (*i.e.*, the transmitted rays are parallel). The **magnifying power** of a lens is measured by $1/f$, the practical unit being that of a lens for which $f = 1$ meter. The magnifying power of a number of lenses in contact is the algebraic sum of their individual powers, the powers of diverging lenses being considered negative. Thus, for two *convex* lenses of focal lengths f_1 and f_2, $1/f = 1/f_1 + 1/f_2$; if the second lens be concave (*i.e.*, divergent), $1/f = 1/f_1 - 1/f_2$.

Approximate Altitudes Corresponding to Different Heights of the Barometer

Reading of barometer		Altitude		Reading of barometer		Altitude	
Millimeters	Inches	Meters	Feet	Millimeters	Inches	Meters	Feet
762	30.0	0	0	660	25.98	1147	3763

Velocity of Sound and Light

The **velocity v of sound in air** is independent of the pressure and, in consequence, of the altitude above the surface of the earth. It is, however, affected by the direction of the wind and by the moisture in the air.

A. S. M. E. TESTING CODES

RULES FOR CONDUCTING EVAPORATIVE TESTS OF BOILERS

Object of Test. Ascertain specific object of test, as determination of capacity and efficiency, comparison of different conditions or methods of operating and of different kinds of fuel, effect of changes in design or capacity or efficiency, etc., and keep same in view in the work of preparation as well as throughout test.

Preparations. Obtain dimensions of principal parts of apparatus to be tested and note general features. Heating surfaces are those in contact with the fire or hot gases. The submerged surfaces in boilers at mean water level are to be considered as water-heating surfaces, and other surfaces which are exposed to the gases as superheating surfaces.

Examine boilers and settings thoroughly for steam and air leakages, and heating surfaces for deposits of soot, mud or scale, remedying such defects as are found in case the test is to determine the highest efficiency or capacity obtainable. The steam main should be so arranged that condensed and entrained water cannot flow back into the boiler.

In steam tests make sure that there is no leakage through blow-offs, drips, etc., or through any steam or water connections of plant or apparatus under test, which would in any way affect the results. Such connections should preferably be blanked off.

Fuel. For tests of maximum efficiency or capacity the coal selected should be the best of its class, especially free from slagging and unusual clinker-forming impurities, and of some kind locally regarded as a commercial standard. In the Eastern States such standards are: Pocahontas (Va. and W. Va.) and New River (W. Va.) semi-bituminous coals; fresh-mined No. 1 buckwheat size anthracite coals containing not over 13 per cent. of ash by analysis; Youghiogheny and Pittsburg bituminous coals. Also, in some sections east of the Allegheny Mountains, Clearfield (Pa.) and Cumberland (Md.) semi-bituminous coals. In the Western States the best coal obtainable in any particular locality is used as a standard.

For guarantee and other tests with a specified coal containing not more than a certain amount of ash and moisture, the coal selected should not be higher in this amount, because any increase is liable to reduce the efficiency and capacity more than the equivalent proportion of such increase.

Apparatus and Instruments Required: (*a*) Platform scales for weighing coal and ashes; (*b*) graduated scales attached to the water glasses; (*c*) tanks and platform scales for weighing water (or water meters calibrated in place), single tanks having a capacity such as to require emptying not oftener than every 5 min. (If two or more are used, interval should be not less than 3 min.); (*d*) pressure gages, thermometers and draft gages; (*e*) calorimeters for determining the calorific value of fuel and the quality of steam; (*f*) furnace pyrometers; (*g*) gas-analysing apparatus. All properly calibrated. (For description of apparatus see "Engineering Measurements," pp. 1670–1697.)

Operating Conditions. Determine proper operating conditions and method of firing, and maintain them throughout test as nearly as possible. Where uniformity in the rate of evaporation from a single boiler is required, this can be accomplished by discharging steam through a waste pipe and regulating the amount by means of a valve. In a battery of boilers, in which only one is tested, the draft may be regulated on the remaining boilers to meet the varying demand for steam, leaving test boiler to work under a steady rate of evaporation.

Duration of Tests. Efficiency tests: Hand-fired boilers and stoker-fired boilers which permit quality and condition of fuel bed to be accurately estimated at beginning and end of test, 10 hr. of continuous running, or sufficient time to burn 250 lb. of coal per sq. ft. of grate. Stoker-fired boilers, 24 hr. Commercial tests, where the service

ous operation night and day, should continue at least 24 hr., for both **toker-fired** boilers. Tests to determine maximum evaporative capacity **be less than** 3 hr. in duration.

l Stopping. The temperature of furnace and boiler, the quantity and **.ve coal and** ash on the grates, the water level, and the steam pressure, **›arly as possible** the same at the end as at the beginning of test. To **ility of conditions** with hand-fired boilers, heat furnace well by a prelimi- **fire low, and** thoroughly clean it, leaving a 2- to 4-in. layer of evenly spread **.te (1 to 2 in.** for small anthracite coals) as a foundation for the new fire. **;hickness** of fuel bed, water level, steam pressure, and time, recording **arting time.** Fire fresh coal from that weighed for test, thoroughly clean **:oceed with test.**

›f test, burn fire low and clean so as to leave same amount of live coal on **rt.** Observe quickly the water level, steam pressure and (stopping) time. **is not the same** as at beginning, make correction therefor by computa- **·t blow down** water-glass column for at least 1 hr. before initial and final **·aken.)** Remove ashes and refuse from ash pit.

containing several boilers where it is not practicable to clean them simul- **›** fires should be cleaned one after the other as rapidly as may be, and each **ıning charged** with enough coal to maintain a thin fire in good working **\fter the last** fire is cleaned and in working condition, burn all the fires **› 6 in.),** note quickly the thickness of each, also the water levels, steam pres- **ıe.** At the time for closing the test the fires should be quickly cleaned one then burned low the same as at the start, and the various observations made **'hese** directions also apply in the case of a large boiler having several **rs** requiring the fire to be cleaned in sections one after the other.

ıechanical stoker other than a chain grate is used, regulate coal feed so as to the low condition required for cleaning. Shut off coal-feeding mechanism pers level full. Clean ash or dump plate, note quickly the depth and condi- on grate, water level, steam pressure, and (starting) time. Then start coal- :hanism, clean ash pit, and proceed with test.

e time arrives for closing test, shut off coal-feeding mechanism, fill hoppers re to same low point as at beginning. Then note water level, steam pressure ing) time. Finally clean ash plate and haul ashes.

ase of chain-grate stokers, the desired operating conditions should be main- 30 min. before starting a test and for a like period before its close, height of te and speed of grate being the same during both of these periods.

s of data should so be made that the test may be divided into periods of 1 hr. ı order that the degree of uniformity obtained may be seen. Half-hourly f instruments are usually sufficient. If there are sudden and wide fluctuations, ings every 15 min. or even oftener. The coal should be weighed and delivered n in amounts sufficient for 1 hr. run, thereby ascertaining the degree of y of firing. The records should be such as to show the consumption of feed :h hour, thereby determining the degree of uniformity of evaporation.

:y of Steam. If the boiler does not produce superheated steam, the percentage ıre should be determined with a throttling or separating calorimeter. If the s superheating surface, the steam temperature should be determined by use of ometer inserted in a thermometer well.

ıturated steam insert a sampling pipe (see p. 1677) in the steam main at a point he entrained moisture is probably most thoroughly mixed. This pipe should ›laced near a point where water may pocket, or where such water may affect the of moisture contained in the sample. If it is necessary to attach sampling ıear the end of a long horizontal run, provide a drip pipe near the front of nozzle ıbly at a pocket) to draw off the water running along bottom of main; add the of this water to that determined by the calorimeter, or, better, install a steam ›or at the point noted.

›sting a stationary boiler, locate sampling nozzle as near boiler as possible, ermometer well in same vicinity when the steam is superheated. For complete ation, provide also sampling nozzle and thermometer well close to throttle of engine or turbine.

Sampling and Drying Coal. Select a representative shovelful from each barrow load as fired, and store samples in a covered metal receptacle in a cool place. When all sampled, break up the lumps, mix intimately and reduce to a sample (of pea size) weighing about 5 lb. by repeated quartering and crushing. Then fill two 1-qt. air-tight fruit jars or other vessels for subsequent use in determinations of moisture, calorific value and chemical composition.

When the sampled coal has been reduced by quartering to, say, 100 lb., withdraw, say, 15 lb., place it in a shallow iron pan and dry on the hot iron boiler flue for 12 hr. or more, weighing before and after drying on scales reading to ¼ oz. The moisture thus determined is approximately reliable for anthracite and semi-bituminous coals, but not for coals containing much inherent moisture. For these, one of the jar samples should be thoroughly air-dried in a thin layer in a warm room, being weighed before and after to determine the surface moisture. Then crush into somewhat coarse grains (less than 1/16 in.), thoroughly mix, and withdraw, say, ½ to 2 oz., weigh in a delicate balance and dry for 1 hr. in an air or sand bath at 240–280 deg. fahr. Then weigh sample and record the loss, and heat and weigh again until the minimum weight is reached. The difference between original and minimum weight is the moisture in the air-dried coal. This added to the surface moisture gives the total moisture.

Ashes and Refuse withdrawn from furnace and ash pit during test and at its close should be weighed as far as possible in a dry state. If wet, the amount of moisture should be ascertained and allowed for, a sample being taken for this purpose, as well as for use in analysis and in determining the unburned carbon and for fusing tests.

Calorific Tests and Analyses of Coal. The quality of the fuel should be determined by calorific tests and an analysis of the sample above referred to. (See p. 603 for methods employed.)

Analyses of Flue Gases. For approximate determinations, use the Orsat or similar apparatus. If momentary samples are obtained, the analyses should be made very frequently, say every 15 to 30 min. If the sample drawn is a continuous one, the intervals may be longer. (For methods of analysis, see p. 1695.)

Smoke Observations. In tests of bituminous coals requiring a determination of the amount of smoke produced, observations should be made regularly throughout the trial at intervals of 5 min. (or if necessary every minute), noting at the same time the furnace and firing conditions. (See p. 885.)

Calculation of Results

Corrections for Moisture in Steam. When the percentage is less than 2 per cent. deduct same from the weight of water fed. If greater than 2 per cent., or if extreme accuracy is required, the factor of correction equals $1-[P(H-h_1)/(H-h)]$, in which P is the proportion of moisture, h_1 the total heat of water at the temperature of the steam, h the total heat of the feed water, and H the total heat of saturated steam of the given temperature. For superheated steam, correction factor $= (H_s-h)/(H-h)$, where $H_s =$ total heat of the steam at the observed temperature and pressure.

Correction for Live Steam Used for Aiding Combustion. If live steam is admitted into the furnace or ash pit for producing blast, injecting fuel, or aiding combustion, it is to be deducted from the total evaporation, and the net evaporation used in the various calculations.

Equivalent Evaporation. (See p. 893.)

Efficiency. For "efficiency of boiler, furnace and grate," and "efficiency of boiler and furnace," see p. 896.

The "combustible burned" is determined by subtracting from the weight of coal supplied to the boiler the moisture in the coal, the weight of ash and unburned coal withdrawn from the furnace and ash pit, and the weight of dust, soot, and refuse, if any, withdrawn from the tubes, flues, and combustion chambers, including ash carried away in the gases, if any, determined from the analyses of coal and ash. The "combustible" used for determining the calorific value is the weight of coal less the moisture and ash found by analysis.

The "heat absorbed" per lb. of coal, or combustible, is calculated by multiplying the equivalent evaporation from and at 212 deg. per lb. of coal or combustible by 970.4.

ıt **Balance.** (See p. 898.)

al **Heat of Combustion of Coal, by Analysis.** (See p. 596.)

for **Combustion.** (See p. 369.)

ı **and Results** should be reported in accordance with the Form given below, *lines* for data not provided for, or omitting those not required, as may conform to ect in view. For a short report, the items designated by letters of the alphabet omitted.

t. For the determination and exposition of the complete boiler performance, the ıg of readings and data should be plotted on a chart and represented graphically.

with Oil and Gas Fuels. Tests of boilers using oil or gas fuel should accord ı rules here given, excepting as they are varied to conform to the particular ristics of the fuel. The duration in such cases may be reduced, and the "flying" of starting and stopping employed. The table of data and results should conıs stating character of furnace and burner, quality and composition of oil or ›erature of oil, and data regarding performance of apparatus supplying the fuel.

---

* The term "as fired" means actual condition including moisture, corrected for estimated difference in weight of coal on the grate at beginning and end.
† If either of the two Items 22 (*B*) and 22 (*C*) is omitted, the fact should be so stated.
‡ Corrected for inequality of water level and of steam pressure at beginning and end.
§ The symbol "U. E.," meaning Units of Evaporation, may be substituted for the expression, "Equivalent evaporation from and at 212 deg."
‖ If the calorific value is desired per lb. of coal "as fired," multiply Item 42 by (100 − Item 20) ÷ 100.

If it is desired that the heat balance be based on coal "as fired" or on "combustible burned," the items in first column are multiplied by the proportion (100 − Item 20)/100 for coal "as fired," or by the proportion (100 − Item 20)/[100 − (Item 20 + Item 24)] for "combustible burned."

The Principal Data and Results of a Boiler Test are given by Items (4), (7), (8), (9), (10), (11), (13), (17), (20), (29), (30), (32), (33), (35), (36), (40), (41), (42), (43), (44) and (45).

RULES FOR CONDUCTING TESTS OF RECIPROCATING STEAM ENGINES

The code for steam engine tests applies to tests for determining the performance of the engine alone (including reheaters and jackets, if any) apart from that of steam-driven auxiliaries which are necessary to its operation. For tests of engine and auxiliaries combined, and tests of multiple-expansion engines from which steam is withdrawn for heating feed water or otherwise, refer to the Code for Complete Steam-power Plants, p. 1763.

Object and Preparations. Determine the object of the test, take the dimensions, and note the physical condition not only of the engine but of all parts of the plant that are concerned in the determinations, and examine for leakages.

Apparatus and Instruments. The determination of the heat and steam consumption of an engine by feed-water test requires the measurement of the various supplies of water fed to the boiler; of the water wasted by separators and drips on the main steam line; of steam used for other purposes than the main-engine cylinders; and of water and steam which escape by leakage of the boiler and piping; all of these last being deducted from the total feed water measured.

Where a surface condenser is provided and the steam consumption is determined from the water discharged by the air pump, no such measurement of drips and leakage is required, but assurance must be had that all the steam passing into the cylinders finds its way into the condenser. If the condenser leaks, the defects causing such leakage should be remedied, or suitable correction should be made. The water of condensation from jackets and reheaters, if not included in the air-pump discharge, should be added thereto.

When no other method is available the steam consumption may be determined by the use of a steam meter, which should be calibrated under the exact conditions of use.

The steam consumed by steam-driven auxiliaries which are required for the operation of the engine should not be included in the total steam from which the heat consumption is calculated, but the quantity of steam thus used should be determined and reported.

Duration. A test for steam or heat consumption, with substantially constant load, should be continued for such time as may be necessary to obtain a number of successive hourly records, during which the results are reasonably uniform. For a test involving the measurement of feed water for this purpose, 5 hr. is sufficient. Where a surface condenser is used, and the measurement is that of the water discharged by the air pump, the duration may be somewhat shorter. In this case, successive half-hourly records may be compared and the time correspondingly reduced. When the load varies widely at different times of the day, the duration should be such as to cover the entire period of variation.

Starting and Stopping. The engine and appurtenances having been set to work and thoroughly heated under the prescribed conditions of test (except in cases where the object is to obtain the performance under working conditions), note water levels in boilers and feed reservoir, take the time, and consider this the starting time. Then begin the measurements and observations and carry them forward until end of period determined on, when the water levels and steam pressure should be brought as near as practicable to the same points as at the start. If there are differences in the water levels, proper corrections are to be applied.

Where a surface condenser is used, the collection of water discharged by the air pump begins at the starting time, and the water is thereafter measured or weighed until the end of the test.

Care should be taken in cases where the activity of combustion in the boiler furnaces affects the height of water in the gage glasses that the same conditions of fire and drafts n at the beginning and end of the test. For this reason it is best to start and stop ; without interfering with the regularity of the operation of the feed pump, pro- the latter can be regulated to run so as to supply the feed water at a uniform rate. ne cases where the supply of feed water is irregular, as, for example, where an in- of excessive capacity is used, the supply of feed water should be temporarily ff. Suitable care should be observed in noting the average height of the water glasses, taking sufficient time to satisfactorily judge of the full extent of the ation of the water line, and thereby its mean position.

ords. Half-hourly readings of the instruments are sufficient, excepting where re wide fluctuations. A set of indicator diagrams should be obtained at intervals : 20 min., and oftener if the nature of the test makes it necessary. Mark on each e cylinder and the end on which it was taken, also the time of day. Record on d of each set the readings of the steam and vacuum gages. These records should iently be entered on the general log, together with the areas, pressures, lengths, asured from the diagrams, when these are worked up.

Calculation of Results

Steam. The quantity of dry steam consumed is determined by deducting the , if any, found by calorimeter test from the total amount of feed water (the latter rected for leakages and other losses) or from the amount of air-pump discharge, ise may be. If the steam is superheated, no correction is to be made for the t.

Consumption. The number of heat units consumed by the engine is found by ng the weight of feed water consumed, corrected for moisture in the steam, if for plant leakages and other exterior losses, by the total heat of 1 lb. of steam l or superheated) at the pressure in the steam pipe near the throttle, less the b. of water at the temperature corresponding to the pressure in the exhaust pipe engine.

ıcy. The thermal efficiency, that is, the proportion of the total heat consump- is converted into work, is found by dividing 2546.5 (B.t.u. equivalent of one y the number of heat units actually consumed per h.p.-hr.

ciency of the corresponding Rankine cycle is to be calculated between the ıd temperature in the steam pipe near the throttle and the pressure and tem- the exhaust pipe near the engine. See p. 344.

kine cycle ratio (or the efficiency ratio referred to the Rankine cycle) is found ; the efficiency of the actual engine (referred to the i.h.p. or b.h.p., as the e) by the efficiency of the Rankine cycle.

Accounted for by Indicator Diagrams at Points Near Cut-off and The steam accounted for, expressed in lb. per i.h.p. per hour, may readily be ing the formula

$$(13{,}750/\text{m.e.p.})[(C+E)Wc-(H+E)Wh]$$

e.p. = mean effective pressure; C = proportion of direct stroke completed expansion line near cut-off or release; E = proportion of clearance; H = f return stroke uncompleted at point on compression line just after exhaust = weight of 1 cu. ft. steam at pressure shown at cut-off or release point; eight of 1 cu. ft. steam at pressure shown at compression point.

-expansion engines the mean effective pressure to be used in the above form- gregate m.e.p. referred to the cylinder under consideration. In a com- the aggregate m.e.p. for the h.-p. cylinder is the sum of the actual m.e.p. of inder and that of the l.-p. cylinder multiplied by the cylinder ratio. aggregate m.e.p. for the l.-p. cylinder is the sum of the actual m.e.p. of the and the m.e.p. of the h.-p. cylinder divided by the cylinder ratio.

d Ratio of Expansion. To find the percentage of cut-off, or what may ! the "commercial cut-off," the following rule should be observed: point of maximum pressure during admission draw a line parallel to the ıe. Through a point on the expansion line where the cut-off is complete, olic curve. The intersection of these two lines is the point of commercial proportion of cut-off is found by dividing the length measured on the this point by the total length.

To find the ratio of expansion divide the volume corresponding to the piston displacement, including clearance, by the volume of the steam at the commercial cut-off, including clearance.

In a multiple-expansion engine the ratio of expansion is found by dividing the volume of the l.-p. cylinder, including clearance, by the volume of the h.-p. cylinder at the commercial cut-off, including clearance.

Data and Results should be reported in accordance with the Form given herewith, adding lines for data not provided for, or omitting those not required, as may conform to the object in view. If a shorter form is desired the items designated by letters of the alphabet may be omitted; or if the principal data and results pertaining to steam consumption only are desired, those indicated in paragraph following the Form may be used. Unless otherwise indicated, the items should be the averages of the data.

(See note following Item 55 for reference to engines driving electric generators and other machinery.)

(54) Ft.-lb. of net work per B.t.u. consumed by engine (1,980,000 ÷ Item 48)...ft.-lb.

Sample Diagrams

(55) Sample diagrams from each cylinder.......................................
(*a*) Steam-pipe diagrams.

Note. For an engine driving an electric generator the Form should be enlarged to include the electrical data, embracing the average voltage, number of amperes each phase, number of watts, number of watt-hours, average power factor, etc.; and the economy results based on the electric output embracing the heat units and steam consumed per electric h.p.-hr. and per kw.-hr., together with the efficiency of the generator. (See Steam Turbine Code, p. 1761).

Likewise, in a marine engine having a shaft dynamometer, the Form should include the data obtained from this instrument, in which case the b.h.p. becomes the shaft h.p.

The Principal Data and Results of a Reciprocating Engine Test are given by Items (6), (7), (11), (12), (13), (15), (16), (18), (22), (29), (34), (38), (40), (43), (45) and (47).

RULES FOR CONDUCTING TESTS OF STEAM TURBINES AND TURBO-GENERATORS

The code for steam-turbine tests applies to tests for determining the performance of the turbine alone, apart from that of steam-driven auxiliaries which are necessary to its operation. For tests of turbine and auxiliaries combined, and tests of turbines from which steam is withdrawn for heating feed water or other purposes, refer to the Code for Complete Steam Power Plants, p. 1763. For methods of conducting tests of generators, etc., and for general information bearing on the subject, reference may be made tandardisation Rules of the A. I. E. E.

t and Preparations. See Steam Engine Code, p. 1756.

'atus and Instruments. For the determination of the heat and steam con- of a turbine or turbo-generator, employ the methods described in the Steam Code, p. 1756. If the steam consumption is determined from the water dis- by the wet vacuum or hot-well pump, correction should be made for water through the packing glands of the turbine shaft, for condenser leakage, and for foreign supply of water.

on, Starting and Stopping, Records, Calculation of Results. See re- headings in the Steam Engine Code, pp. 1756, 1757 (with the exception of lating to indicator diagrams and results computed therefrom).

nd Results should be reported in accordance with the form given herewith, es for data not provided for, or omitting those not required, as may conform ct in view. For a shorter form of report, omit the items designated by letters abet; or if only the principal data and results are desired, those indicated in following the Form may be used. Unless otherwise indicated, the items the averages of the data.

Efficiency Results

(41) Thermal efficiency of turbine (2546.5 ÷ Item 39) × 100..............per cent.
(42) Efficiency of Rankine cycle between temperatures of Items 13 and 14.....per cent.
(43) Rankine cycle ratio (Item 41 ÷ Item 42)..

Work Done per Heat Unit

(44) Ft.-lb. of net work per B.t.u. consumed by turbine (1,980,000 ÷ Item 39)...ft.-lb.

The Principal Data and Results of Turbine Test are given by Items (2a) to (2f), (7), (8), (9), 12), (15), (22), (31), (32), (35), (37), (38), (39) and (40).

FOR CONDUCTING TESTS OF COMPLETE STEAM-POWER PLANTS

team-power plants to which this code applies are assumed to be plants embrac- or more boilers using coal for fuel, one or more engines or turbines, and the es concerned, the power being utilized for any industrial purpose, such as mill generation of electricity, pumping water or compressing air. The object of such a plant is the determination of the performance of the plant as a whole of its component parts, and the efficiency of the plant based on coal and steam tion.

plant contains a number of power-generating units (especially if of different classes), the test when practicable should determine the performance of each ddition to that of the plant as a whole. If the boilers also supply steam for r other industrial purposes, the various quantities of steam thus used should red and the complete distribution of the steam output ascertained.

thods to be followed in testing the component parts of a complete plant, such engines, turbines, pumping machinery, and air machinery, reference may be he respective codes which apply thereto.

See Steam Boiler Code, p. 1750.

n. The duration of a plant test should be not less than 1 day of 24 hours, ably in some cases, such as ice-making plants, a full week of 7 days, including

determine the steam consumption of the individual parts of a plant should be gth as to secure a number of consecutive hourly or half-hourly records show- nity within the desired limits of accuracy. In cases where the engine or r-developing machine is in operation only a part of the day, the duration on ourly results are computed should be considered the length of time that the ther power-developing machine is in operation at its working speed.

and Stopping. In a plant operating continuously day and night, the times rting and stopping should follow the regular periods of cleaning the fires. ure, **see 3rd and 2nd** paragraphs under "Starting and Stopping," p. 1751. unning only a part of the day, and with fires banked during the balance of time selected for the beginning and end of the test should be that following the day's run, when the fires have been burned low preparatory to cleaning . The amount of live coal left on the grates under these circumstances is the beginning of the test, and the fires brought to the same condition, as be, at the close of the test the next day. If the two quantities differ, a ection is made in the weight of coal fired, as found by calculation.

See Steam Engine Code, p. 1757.

and Drying Coal, Ashes and Refuse, Calorific Tests and Analyses e Steam Boiler Code, p. 1752.

Calculation of Results

umption. The number of heat units consumed by the engine and its hour is found by multiplying the total weight of the feed water consumed e total heat of 1 lb. of steam supplied to the engine (corrected for moisture less the heat in 1 lb. of water at the temperature of the water entering conomizer, if any). If the water is supplied from a number of sources and peratures, the weight of each supply is to be taken and the heat in the temperature of supply, the various individual quantities thus obtained gether to obtain the total heat consumption.

esults should be reported in accordance with the following Form; the ne topics on p. 1761 also apply. The **report** should clearly set forth the t findings and conclusions bearing on the work, taking care that these d by minor considerations and details. It is desirable to plot the princi- **hart,** especially the indicated horse power, kilowatt or other load, and consumption.

Data and Results of Steam Power Plant Test

 (c) Efficiency of engine or turbine referred to b.h.p. [(2546.5 ÷ 39b) × 100].....

duration should be that of the regular commercial operating cycle, or the time elapsing between two successive renewals of the fuel bed.

Starting and Stopping. The conditions regarding the temperature of the producer and its contents, and the quantity and quality of the latter, should be as nearly as possible the same at the end as at the beginning of the trial. To secure this equality, the starting and stopping should occur at times of regular cleanings, and they should be preceded for a period of not less than 10 hours by the same regular working conditions as are intended to characterize the test as a whole. The operations of starting and stopping should then be carried on as follows:

Continuous Producers with Grate and No Ash Bed. Remove ash and clinkers from grate and lower part of furnace space, taking care that the crust or closely united layer which supports the coal above is not unduly disturbed. Then break open crust and allow mass to drop into space left vacant. Introduce a poker rod through poke holes in upper head and stir up coal within, thereby causing it to settle and fill remaining spaces. As a final step, quickly replenish producer with coal to the working depth, fill hopper level-full, take time, and consider this the starting time. Then clean ash pit, and thereafter proceed with the regular work of test, using weighed coal. When the time arrives for bringing trial to a close, the cleaning operations described above are repeated, ending with filling hopper, taking time, and considering this the stopping time; finally hauling the ashes and refuse from ash pit.

Continuous Producers with Supporting Ash Beds. Remove ashes until top of ash-bed is lowered to normal working point. Introduce poker-rod and break down any bridge or crust that may have formed, at the same time closing up channels that run through fuel bed, thereby making bed homogeneous. Then replenish producer with coal to working depth, fill hopper level-full, take time, and consider this the starting time. Thereafter proceed with regular work of test, using weighed coal. When the time approaches for closing test, the operations above described are repeated, ending with replenishing producer and filling hopper with weighed coal, taking time, and considering this the stopping time. The ashes and refuse finally removed are to be dried before weighing, unless already dried, or a sample should be taken and the moisture, as determined therefrom, allowed for.

Intermittent Producers. Thoroughly clean producer of its entire contents. Introduce a weighed supply of coke or coal, start fire, and build up fuel bed to its working condition, using weighed coal. When this point is reached, take time, and consider this the starting time. Thereafter proceed with regular work of test. When the time approaches for closing test, burn fuel bed as low as practicable to prepare for cleaning, note time, and consider this the stopping time. Then completely empty producer, quench fire remaining in the live coals, separate and weigh coke and ash, and deduct weight of former from that of coke as charged. Finally dry the ash and refuse, or take a sample and allow for the moisture determined therefrom.

Note. To gain some idea of the depth of the ash bed, insert a long poker-rod through fuel bed, and determine how many minutes it takes to become red-hot. Cool it, and insert it again through two or more poke holes successively for the determined time, cooling it after each trial. Measure the distance from top of the producer to the lower end of red portion in each case, and subtract average of distances thus found from total depth of producer. The result gives the approximate depth of ash bed. The length of red portion furnishes also some idea of the depth of zone of burning fuel. The distance from top of producer to surface of fuel bed may be found by direct measurement with the poker-rod, noting by sense of touch when end of rod reaches fuel.

Records, Sampling and Drying Coal, Ashes and Refuse, Calorific Tests and Analyses of Coal. See same topics in Steam Boiler Code, pp. 1751, 1752.

Calorific Tests and Analyses of Gas Output. The quality of the gas should be determined by calorific tests and analyses, continuous samples for this purpose being taken from the delivery pipe at a point near the producer and at other points as may be needed. A satisfactory sample can be obtained by tapping into the main or delivery pipe a ¼-in. pipe, extending it to the center, and leaving its end open. The thermometer for obtaining temperature of gas should be located near the sampling pipe.

The calorific test should be made with a Junker calorimeter or its equivalent. Unless otherwise required the "higher value" should be employed in calculating the results of the test. If the lower value is used, the fact should be so stated. For an approximate determination of the composition of the gas, the Orsat apparatus (p. 1695) may be used, The "combustible" is determined by subtracting from the weight of coal charged the moisture in the coal and the weight of ash refuse and unburned coal withdrawn from the producer or ash pit during the progress of the trial. The "combustible" used for determining the calorific value is the weight of the coal less the moisture and ash found by analysis.

The efficiency of "conversion and cleaning" or "gross efficiency" in the above calculation is found by using the total volume of gas delivered. The "efficiency of the plant" or "net efficiency" is found by using the net volume of gas delivered.

Heat Balance. The various quantities showing the distribution of heat in the heat balance, given in the Form below, are computed in the following manner:

Calorific value of dry gas = cu. ft. of gas at 60 deg. and 30 in. per lb. of dry coal × calorific value of 1 cu. ft. of gas at 60 deg. and 30 in. (higher value).

Sensible heat in the dry gas = weight of gas per lb. of coal × mean specific heat of gas × gas temperature measured above 60 deg.

Heat carried away by scrubber = weight of water fed to scrubber × number of degrees rise of temperature + total weight of dry coal consumed.

Heat contained in moisture leaving producer = total weight of dry gas per lb. of dry coal × proportion of moisture in the gas × total heat of 1 lb. of superheated steam at temperature of gas leaving producer, reckoned from 60 deg.

Loss due to combustible matter in ash = proportion that this combustible bears to the whole amount of dry coal × 14,600 B.t.u.

Data and Results should be reported in accordance with the following Form, to which the remarks on same topics on p. 1761 also apply. If a preliminary trial of the fuel is made in a test-producer, add to the table the general results obtained. In trials having for an object the determination and exposition of the complete performance from beginning to end, the entire log of readings and data should be plotted on a **chart** and represented graphically.

Data and Results of Gas Producer Test
CODE OF 1915

(For a short report the items designated by letters of the alphabet may be omitted)

(1) Test of.................producer located at.....................................
To determine...............Test conducted by.............................

DIMENSIONS, ETC.

(2) Outside diameter and height of producer.....................................ft.
(3) Inside diameter of producer.....................................ft.
(4) Area of grate. (diameter = ...) ....sq. ft.
(*a*) Percentage of air space in grate.............................per cent.
(*b*) Area of blast inlet..........sq. ft. (*c*) Area of exit flue.............sq. ft.
(5) Area of fuel bed (at maximum diameter)...............................sq. ft.
(*a*) Area of water heating surface in vaporizer..........................sq. ft.
(6) Rated capacity of producer in lb. of coal* per hour.........................lb.

DATE, DURATION, ETC.

(7) Date........................... (8) Duration..........................
(9) Kind and size of coal*...

AVERAGE PRESSURES, TEMPERATURES, ETC.

(10) Steam pressure in vaporizer by gage.....................................lb.
(11) Gas pressure in main at point where gas is measured..................in. water
(*a*) Pressure at top of producer..................................in. water
(*b*) Pressure beyond scrubber...
(*c*) Pressure beyond purifier..
(12) Force of blast or draft in ash pit, or bottom of producer ....in. water
(*a*) Barometric pressure....in merc. (*b*) Relative humidity of air...per cent.
(*c*) Depth of fuel bed.........(*d*) Intervals between cleaning..............
(*e*) Intervals between poking...
(13) Temperature of feed water entering vaporizer..............................deg.
(*a*) Temperature of gas in exit flue at producer..........................deg.

* If other fuel than coal is used, change line to read accordingly.

Economy Results

(57) Equivalent cu. ft. of dry gas at 60 deg. and 30 in. per lb. of dry coal.......cu. ft.
(a) Equivalent cu. ft. of dry gas at 60 deg. and 30 in. per lb. of combustible...cu. ft.
(58) Net cu. ft. of dry gas at 60 deg. and 30 in. per lb. of dry coal.............cu. ft.
(a) Net cu. ft. of dry gas at 60 deg. and 30 in. per lb. of combustible....cu. ft.

Efficiency

(59) Gross efficiency of producer, based on dry coal.........................per cent.
(a) Net efficiency of producer, based on dry coal.....................per cent.
(60) Gross efficiency of producer, based on combustible.....................per cent.
(a) Net efficiency of producer, based on combustible.................per cent.

Cost of Coal

(61) Cost of coal per ton of ——— lb. delivered...........................dollars
(62) Cost of coal required for producing 1000 net cu. ft. of gas at 60 deg. and 30 in. ....dollars
(a) Cost of coal for producing 1,000,000 B.t.u...........................dollars

Heat Balance Based on 1 Lb. of Dry Coal

	B.t.u.	Per cent.
(63) Total calorific value of 1 lb. of dry coal, same as Item 54	....	....
(a) Calorific value of dry gas....................	....	....
(b) Sensible heat in hot dry gas above 60 deg. fahr.	....	....
(c) Total heat of moisture in gas above 60 deg......	....	....
(d) Heat lost in scrubber..........................	....	....
(e) Heat lost by combustible in ash................	....	....
(f) Heat lost by radiation, and unaccounted for (difference between the sum of items *a*, *b*, *c*, *d*, *e* and item 63)...........................	....	....

Note. If steam is supplied to the producer from an outside source the data and results should be modified accordingly.

RULES FOR CONDUCTING TESTS OF GAS AND OIL ENGINES

Duration. The test of a gas or oil engine with substantially constant load should be continued for such time as may be necessary to obtain a number of successive records covering periods of half an hour or less during which the results are found to be uniform. In such cases a duration of 3 to 5 hours is sufficient for all practical purposes.

Starting and Stopping. The engine having been set to work under the prescribed conditions, the test is begun by commencing to weigh the oil, or measure the gas, as the case may be, and take other data concerned; after which the regular measurements and observations are carried forward until the end.

Records. See same topic under Steam Engine Code, p. 1757.

Calorific Tests and Analyses. The quality of the oil or gas should be determined by calorific tests and analyses made on representative samples.

Calculation of Results

Volume of Gas at 60 deg. and 30 in. See method for obtaining equivalent volume, p. 1769.

Heat Consumption. The number of heat units consumed by the engine = heat units per lb. of oil or per cu. ft. of gas (higher value) as determined by calorimeter test × total weight of oil in lb. or volume of dry gas in cu. ft. consumed.

Efficiency. See methods used in Steam Engine Code, p. 1757.

Heat Balance. The various quantities showing the distribution of heat in the heat balance given in the following Form are computed as below:

Heat rejected in the cooling water = weight of water supplied × number of degrees rise of temperature ÷ indicated horse power.

Total Quantities

(12) Gas (or oil) consumed..cu. ft.(lb.)
(13) Moisture in gas, in per cent. by weight, referred to dry gas..............per cent.
(14) Equivalent dry gas at 60 deg. and 30 in......................................cu. ft.
(a) Air supplied in cu. ft...cu. ft.
(15) Cooling water supplied to jackets..lb.
(a) Water or steam fed to cylinder...lb.
(16) Calorific value of oil per lb., or of dry gas per cu. ft. at 60 deg. and 30 in. by calorimeter test (higher value)..B.t.u.

Hourly Quantities

(17) Gas (or oil) consumed per hour.......................................cu. ft.(lb.)
(18) Equivalent dry gas per hour at 60 deg. and 30 in..............................cu. ft.
(19) Cooling water supplied per hour...lb.
(20) Heat units consumed per hour (Item 16 × Item 18)..........................B.t.u.

Analysis of Oil

(21) Carbon (C)...........per cent. (22) Hydrogen (H)..................per cent.
(23) Oxygen (O)...........per cent. (24) Sulphur (S)...................per cent.
(a) Moisture.........per cent. (b) Result of fractional distillations..per cent.

Analysis of Fuel Gas by Volume

(25) Carbon dioxide (CO_2).....per cent. (26) Carbon monoxide (CO).....per cent.
(27) Oxygen (O)................per cent. (28) Hydrogen (H).............per cent.
(29) Marsh gas (CH_4)..per cent.
(30) Heavy hydrocarbon C_nH_m..per cent.
(a) Sulphur dioxide (SO_2)...per cent.
(b) Hydrogen sulphide (H_2S)...per cent.
(c) Nitrogen (N) by difference..per cent.

Analysis of Exhaust Gases by Volume

(31) Carbon dioxide (CO_2)...per cent. (32) Carbon monoxide (CO)........per cent.
(33) Oxygen (O)...........per cent. (34) Nitrogen (N).................per cent.

Indicator Diagrams

(35) Pressure in lb. per sq. in. above atmosphere.......................................lb.
(a) Maximum pressure........... (b) Pressure at beginning of stroke......
(c) Pressure at end of expansion... (d) Exhaust pressure at lowest point.....
(36) Mean effective pressure in lb. per sq. in...lb.

Speed

(37) Revolutions per minute..rev.
(38) Average number of explosions or firing strokes per min..........................
(a) Variation of speed between no load and full load..............................rev.
(b) Momentary fluctuation of speed on suddenly changing from full load to half load...

Power

(39) Indicated horse power...i.h.p.
(40) Brake horse power..b.h.p.
(41) Friction horse power by difference (Item 39 − Item 40)*.................fr.-h.p.
(a) Friction horse power by friction diagrams......................................fr.-h.p.
(42) Percentage of indicated horse power lost in friction Item 41 ....per cent.

Economy Results

(43) Heat units consumed by engine per i.h.p. hour†..................................B.t.u.
(44) Heats units consumed by engine per b.h.p..B.t.u.
(45) Pounds of oil or cubic feet of dry gas at 60 deg. and 30 in. consumed per i.h.p.-hr...lb., cu. ft.
(46) Pounds of oil or cubic feet of dry gas per b.h.p.-hr.........................lb., cu. ft.

* In two-cycle engines this includes the power required for compression.
† If these results, in the case of a gas engine, are based on the low value of the heat of combustion, that fact should be so stated.

case of float measurement, repeated observations should be made one after the other throughout the whole period of the trial.

Data and Results should be reported in accordance with the following Form, adding lines for data not provided for or omitting those not required, as may conform with the object in view.

Data and Results of Water-wheel Test with Brake Measurement of Power

CODE OF 1915

(1) Test of........................water wheel located at........................
To determine..
Test conducted by...
(2) Type of wheel and class of service...
(3) Type of generator, if any, kind of current, etc...........................
(4) Rated power of wheel...h.p.
(5) Cross-section of stream where velocity of water is measured..................sq. ft.

GENERAL DATA

(6) Date...
(7) Duration of period covered by test.......................................hr.
(8) Average net weight on brake arm..lb.
(9) Average revolutions per minute...r.p.m.
(10) Total average head of water on wheel....................................ft.
(11) Average velocity of water per second in measuring canal..................ft.
(12) Cu. ft. of water flowing per second.....................................cu. ft.
(13) Weight of water flowing per second (Item 12 × 62.35)......................lb.
(14) Leakage per second..lb.
(15) Net water discharged by wheel per second (Item 13 − Item 14)..............lb.

POWER

(16) Total power of water available..h.p.
(17) Brake horse power developed by wheel....................................b.h.p.

EFFICIENCY

(18) Efficiency of wheel (Item 17 ÷ Item 16) × 100...........................per cent.

RULES FOR CONDUCTING TESTS OF STEAM-DRIVEN COMPRESSORS, BLOWERS AND FANS*

Duration, Starting and Stopping, Records. See same items under Steam Engine Code, p. 1756.

The quantity of air discharged may be measured by a gasometer, or by delivery into tanks of known capacity. Where these means are not available the Pitot tube may be used, or some other means which is subject to calibration. If the air end is of the reciprocating type, indicator diagrams should be regularly taken from this end as well as from the steam end.

Calculation of Results

For rules pertaining to dry steam, heat consumption, and indicated horse power of the steam end, see Steam Engine Code, p. 1757.

Air Horse Power. The gross work done at the air end of a reciprocating machine is obtained from the indicator card.

The net work at the air end of either reciprocating or rotary machines (ft.-lb. per min.) = corrected volume of compressed air (cu. ft.) delivered into main delivery pipe per min. × the impact or total pressure (lb. per sq. ft.) × hyp. log. of ratio of total pressure to the atmospheric pressure (all pressures absolute). Net air horse power (a.h.p.) = above product ÷ 33,000. Corrected volume of compressed air = sectional area of delivery main (sq. ft.) × mean velocity (ft. per min., determined by Pitot tube or other measurement) × $(460 + T_1) / (460 + T_2)$, in which T_1 = temperature of air supplied to machine and T_2 = temperature of air in delivery main.

* When some other prime mover than a steam engine or turbine is employed, the code may be modified to meet the particular requirements.

(16) Pressure in delivery main by gage (impact pressure)*........................lb.
(a) Pressure in each stage, if more than one................................lb.

QUALITY OF STEAM

(17) Percentage of moisture in steam near throttle, or number of degrees of superheating.. per cent. or deg.

TOTAL QUANTITIES

(18) Total water fed to boilers..lb.
(19) Total condensed steam from surface condenser (corrected for condenser leakage)...lb.
(20) Total dry steam consumed (Item 18 or 19 less moisture in steam)............lb.
(21) Total volume of compressed air delivered, as measured..................cu. ft.
(a) Total volume of compressed air delivered, reduced to atmospheric temperature and pressure ....cu. ft.
(b) Total weight of air delivered ....lb.

HOURLY QUANTITIES

(22) Total water fed to boilers, or drawn from surface condenser, per hour..........lb.
(23) Total dry steam consumed for all purposes (Item 20 + Item 8)..............lb.
(24) Steam consumed per hour for all purposes foreign to main engine.............lb.
(25) Dry steam consumed by engine or turbine per hour (Item 23 − Item 24)......lb.
(a) Circulating water supplied to condenser per hour....................lb.
(26) Volume of compressed air delivered per hour, as measured.................cu. ft.
(a) Volume of compressed air delivered per hour, reduced to atmospheric temperature..cu. ft.
(b) Volume of compressed air delivered per hour, reduced to atmospheric temperature and pressure.............................cu. ft.
(c) Weight of air delivered per hour......................................lb.

HOURLY HEAT DATA

(27) Heat units consumed by engine or turbine per hour (Item 25 multiplied by total heat of 1 lb. of steam at pressure of Item 9, less heat in 1 lb. of water at temperature of Item 14..B.t.u.

INDICATOR DIAGRAMS

		1st cyl.	2d cyl.
(28) Mean effective pressure, each steam cylinder............	lb.	....	....
(a) Mean effective pressure, each air cylinder..........	lb.	....	....

SPEED

(29) Revolutions per minute ....r.p.m.
(a) Number of single strokes per minute...........................strokes

POWER

(30) Indicated horse power of steam end.....................................i.h.p.
(31) Gross air horse power as indicated in air cylinders..........................h.p.
(a) Brake horse power consumed by blower or fan ....b.h.p.
(32) Net air horse power (see p. 1776)...h.p.
(33) Friction horse power (Item 30 − Item 31)....................................h.p.
(34) Percentage of i.h.p. lost in friction of machine...........................per cent.

CAPACITY

(35) Compressed air delivered per min. as measured..........................cu. ft.
(a) Compressed air delivered per min., reduced to atmospheric temperature ....cu. ft.
(b) Compressed air delivered per min. at 100 lb. pressure, reduced to 62 deg... cu. ft.
(36) Compressed air delivered per min., reduced to atmospheric temperature and pressure (free air)..................................... cu. ft.

* In the case of compressors or blowers having more than one stage, additional data should be given covering pressures and temperatures in the different stages, the quantity of water used for cooling, and temperatures of the air and water entering and leaving the intercooler.

ECONOMY RESULTS

ɛat units consumed per i.h.p.-hr.................................B.t.u.
ɛat units consumed per net h.p.-hr. of Item 32........................B.t.u.
·y steam consumed per i.h.p.-hr.......................................lb.
:y steam consumed per net air h.p.-hr. of Item 32.........................lb.

EFFICIENCY RESULTS

ıermal efficiency referred to i.h.p. [(2546.5 + Item 37) × 100]........per cent.
ıermal efficiency referred to net air h.p. [(2546.5 + Item 38) × 100]...per cent.
ficiency of compression [(Item 32 + Item 31) × 100]................per cent.
(*a*) Mechanical efficiency of machine [(Item 31 + Item 30) × 100]....per cent.
(*b*) Volumetric efficiency [(Item 36 + displacement in cu. ft. per min. of first compressor) × 100]..................................per cent.

WORK DONE PER HEAT UNIT
