THE MAPLE PRESS YORK PA

LIST OF CONTRIBUTORS

L. P. Alford, Editor-in-Chief of The American Machinist. *Machine Tools and Machine-shop Practice.*

C. Kemble Baldwin, M. E., Vice-President, Robins Conveying Belt Co. *Hoisting and Conveying.*

Murray C. Beebe, Professor of Electrical Engineering, University of Wisconsin. *Electrical Engineering.*

Louis Bell, A. B., Ph. D., Consulting Engineer, Past President, Illuminating Engineering Society. *Illumination.*

David S. Beyer, Ph. B., Manager Accident Prevention Dept., Massachusetts Employees' Insurance Association, Director National Safety Council. *Prevention of Accidents.*

H. M. Boylston, B. S., A. M., Consulting Metallurgical Engineer. *Iron and Steel.*

W. H. Carrier, M. E., President, The Carrier Engineering Corporation. *Air Conditioning.*

Guilliam Henry Clamer, B. S., First Vice-President and Secretary, The Ajax Metal Company, Pres. Am. Inst. of Metals. *Non-ferrous Metals and Alloys.*

Charles Day, B. S., E. E., Consulting Engineer (Day & Zimmermann). *Industrial Buildings; Electric Drives.*

Hugo Diemer, B. A., M. E., Professor of Industrial Engineering, Pennsylvania State College. *Cost and Other Factory Accounts.*

William F. Durand, Ph. D., Professor of Mechanical Engineering, Leland Stanford, Jr. University. *Marine Engineering.*

William D. Ennis, M. E., Professor of Mechanical Engineering, Polytechnic Institute of Brooklyn. *The Steam Engine.*

Frank L. Fairbanks, Chief Engineer, Quincy Market Cold Storage & Warehouse Co. *Mechanical Refrigeration.*

Louis A. Fischer, B. S., Chief of the Division of Weights and Measures, U. S. Bureau of Standards. *Weights and Measures; General Properties of Materials.*

Henry A. Gardner, Asst. Director, the Institute of Industrial Research. Washington, D. C. *Paints and Protective Coatings.*

Augustus H. Gill, A. M., Ph. D., Professor of Technical Analysis, Massachusetts Institute of Technology. *Lubricants.*

G. A. Goodenough, M. E., Professor of Thermodynamics, University of Illinois. *Heat.*

C. W. Ham, M. E., Asst. Professor of Machine Design, Cornell University. *Pipe and Pipe Fittings.*

William Kendrick Hatt, C. E., Ph. D., Professor of Civil Engineering and Director of Laboratory of Testing Materials, Purdue University, Mem. Advisory Board, Forest Products Laboratory, U. S. Forest Service. *Strength of Materials; Strength of Wood.*

Harrison W. Hayward, S. B., Assoc. Professor of Applied Mechanics, Massachusetts Institute of Technology. *Mechanics of Rigid Bodies; Stresses in Framed Structures.*

P. M. Heldt, Technical Editor of The Horseless Age. *Automobiles.*

Howard D. Hess, M. E., Professor of Machine Design, Cornell University. *Friction.*

Ozni P. Hood, M. S., M. E., Chief Mechanical Engineer, U. S. Bureau of Mines. *Fuels.*

J. C. Hunsaker, M. S., Instructor in Aeronautical Engineering, Massachusetts Institute of Technology, Asst. Naval Constructor, U. S. Navy. *Aeronautics.*

Edward V. Huntington, Ph. D., Associate Professor of Mathematics, Harvard University. *Mathematical Tables; Mathematics.*

F. A. Kartak, E. E., Instructor in Electrical Engineering, University of Wisconsin. *Electrical Engineering.*

H. O. Lacount, S. B., Engineer, Associated Factory Mutual Fire Insurance Co. *Fire Protection.*

L. C. Loewenstein, E. E., Ph. D., Engineer with General Electric Company. *Elements of High-speed Machines; Steam Turbines; Gas Turbines; Centrifugal Pumps; Centrifugal Compressors.*

Lionel S. Marks, B. Sc., M. M. E., Professor of Mechanical Engineering, Harvard University and Massachusetts Institute of Technology. *Internal-combustion Engines; Cost of Power; Building Construction.*

Konrad Meier, Consulting Mechanical Engineer for Heating and Ventilating. *Heating and Ventilation.*

Richard Moldenke, E. M., Ph. D., Consulting Metallurgist, Sec'y. Am. Foundrymen's Assn. *Iron and Steel Castings.*

James Ambrose Moyer, S. B., A. M., Director of the Department of University Extension, Mass. Board of Education; formerly Professor of Mechanical Engineering and Director of the Engineering Experiment Station, Pennsylvania State College. *Measuring Instruments.*

F. F. Nickel, Engineer with Henry R. Worthington. *Pumps.*

George A. Orrok, Mechanical Engineer, The New York Edison Co. *Condensation.*

Arthur D. Pratt, A. B., Assistant to the Advisory Engineer, Babcock & Wilcox Co. *Steam Boilers.*

Walter Rautenstrauch, M. S., Professor of Mechanical Engineering, Columbia University. *Machine Elements.*

William G. Raymond, C. E., LL. D., Professor of Civil Engineering, and Dean of College of Applied Science, State University of Iowa. *Surveying.*

Odin Roberts, A. M., LL. B., Counsellor at Law. *Patents for Inventions.*

Charles M. Sames, B. Sc., formerly Assoc. Editor of Industrial Engineering and the Engineering Digest. *Water Wheels; Industrial Management.*

Edward C. Schmidt, M. E., Professor of Railway Engineering, University of Illinois. *Railway Engineering.*

Ernest W. Schoder, B. S., Ph. D., Professor in charge Hydraulic Laboratory, Cornell University. *Hydraulics.*

Morgan B. Smith, A. B., Chief Chemist, Detroit United Lines. *Corrosion.*

Sanford E. Thompson, S. B., Consulting Engineer. *Cement, Mortar and Concrete; Reinforced-concrete Construction.*

H. J. Thorkelson, M. E., Professor of Mechanical Engineering, University of Wisconsin. *Air Compressors.*

Brackett K. Thorogood, Demonstrator of Engineering Drawing, Harvard University. *Mechanism.*

Hermann von Schrenk, A. M., Ph. D., Consulting Timber Engineer. *Wood.*

W. M. White, B. Eng., Manager and Chief Engineer, Hydraulic Dept., Allis-Chalmers Mfg. Co. *Hydraulic Turbines.*

H. V. Wille, M. E., Asst. General Superintendent, Baldwin Locomotive Works, Consulting Metallurgist, Remington Arms Co. and Eddystone Ammunition Co. *Iron and Steel.*

E. B. Williams, Manager of Dept. of Air and Fan Engineering, B. F. Sturtevant Co. *Centrifugal Fans.*

Carl F. Woods, B. S., Secretary, Arthur D. Little, Inc. *Miscellaneous Non-metallic Materials.*

PREFACE

This Handbook is intended to supply both the practicing engineer and the student with a reference work which is authoritative in character and which covers the field of mechanical engineering in a comprehensive manner. It is no longer possible for a single individual or a small group of individuals to have so intimate an acquaintance with any major division of engineering as is necessary if critical judgment is to be exercised in the statement of current practice and the selection of engineering data. Only by the co-operation of a considerable number of specialists is it possible to obtain the desirable degree of reliability. This Handbook represents the work of fifty specialists.

Each contributor is to be regarded as responsible for the accuracy of his section. The number of contributors required to ensure sufficiently specialized knowledge for all the topics treated is necessarily large. It was found desirable to enlist the services of thirteen specialists for an adequate handling of the "Properties of Engineering Materials." Such topics as "Automobiles," "Aeronautics," "Illumination," "Patent Law," "Cost Accounting," "Industrial Buildings," "Corrosion," "Air Conditioning," "Fire Protection," "Prevention of Accidents," etc., though occupying relatively small spaces in the book, demanded each a separate writer.

A number of the contributions which deal with engineering practice, after examination by the Editor-in-Chief, were submitted by him to one or more specialists for criticism and suggestions. Their co-operation has proved of great value in securing greater accuracy and in ensuring that the subject matter does not embody solely the practice of one individual but is truly representative. The Editor-in-Chief begs to acknowledge his indebtedness for services of this character to the following gentlemen:

S. R. Bartlett (Lockwood, Greene & Co.), *Building Construction.* W. H. Bassett, Technical Superintendent and Metallurgist, American Brass Co., *Non-ferrous Metals.* F. N. Bushnell, Vice-president, Stone & Webster Engineering Corporation, *Cost of Power.* R. I. Clegg, Editor of Woodcraft, *Woodworking machines.* J. M. Darke (General Electric Company), *Miscellaneous Non-metallic Materials.* H. B. Emerson, Superintendent of Mechanical Department, Arlington Mills, Lawrence, *Electric Drives.* E. H. Fish, Associate Editor, American Machinist, *Machine Shop Practice.* H. J. Freyn, Consulting Engineer, *Internal Combustion Engines.* A. M. Houser, Mechanical Expert, Crane Company, *Pipe and Pipe Fittings.* G. B. Haven, Professor of Machine Design, Mass. Institute of Technology, *Machine Elements.* D. S. Jacobus, President, A. S. M. E., Advisory Engineer Babcock & Wilcox Co., *Steam Boilers.* D. D. Kimball (Richard D. Kimball Company), *Heating and Ventilation.* Albert Kingsbury, Consulting Engineer, *Friction.* H. S. McDewell, Instructor, University of Illinois, *Internal Combustion Engines.* Charles T. Main, Consulting Engineer, *Building Construction.* E. D. Meier (Deceased) Past President, A. S. M. E., President Heine Boiler Co., *Steam Boilers.* F. Nagler, Hydraulic Engineer, Allis-Chalmers Co., *Hydraulic Turbines.* W. S. Schwanhausser, Chief and Consulting Engineer, International Steam Pump Co., *Reciprocating Pumps.* F. N. Speller, Metallurgical Engineer, National Tube Co., *Pipe and Pipe Fittings.* F. R. Still, Chief Engineer, American Blower Co., *Centrifugal Fans.* G. W. Swett, Assistant Professor of Machine Design, Mass. Institute of Technology, *Machine Elements.* F. W. Taylor (Deceased), Past President, A. S. M. E., Consulting Engineer, *Industrial Management.* E. Touceda, Metallurgical Engineer, *Iron and Steel Castings.* J. F. Vaughan, Consultant with Stone & Webster Engineering Corporation, *Hydraulic Turbines.* W. H. Walker, Professor of Chemical Engineering, Mass. Institute of Technology, *Corrosion.* W. R. Webster, General Superintendent Bridgeport Brass Co., *Non-ferrous Metals.* Gardner S. Williams, Consulting Engineer, *Hydraulic Turbines.*

An accuracy of four significant figures has been assumed as the desirable limit; figures in excess of this number have been deleted, except in special cases. In the mathematical tables only four significant figures have been kept.

The Editor-in-Chief desires to express here his appreciation of the spirit of co-operation shown by the Contributors and of their patience in submitting to modifications of their sections. He wishes also to thank the Publishers for giving him complete freedom and hearty assistance in all matters relating to the book from the choice of contributors to the details of typography. And finally, he desires to express his indebtedness to his Editorial Assistant, Mr. Charles M. Sames, for numerous valuable suggestions, for the preparation of certain of the staff contributions, and for aiding him throughout in editing and styling manuscripts, correcting proofs, and compiling the index.

SYMBOLS AND ABBREVIATIONS

For symbols of chemical elements, see p. 452; for electric and magnetic symbols, see p. 1568; for abbreviations applying to metric weights and measures, see p. 72.

Pairs of parentheses, brackets, etc., are frequently used in this work to indicate corresponding values. For example, the statement that "the cost per kw. of a 30,000-kw. plant is $53; of a 15,000-kw. plant, $62; and of a 8000-kw. plant, $72," is condensed as follows: The cost per kw. of a 30,000 [15,000] (8000)-kw. plant is $53 [62] (72).

$\pi^2 = 9.86960$ $(\pi/2)^2 = 2.46740$ $1/\pi^2 = 0.101321$

Explanation of Table of Squares (pp. 2–7).

This table gives the value of N^2 for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure).

To find the square of a number N outside the range from 1 to 10, note that moving the decimal point **one** place in column N is equivalent to moving it **two** places in the body of the table. For example:

$(3.217)^2 = 10.35$; $(0.03217)^2 = 0.001035$; $(3217)^2 = 10350000$

This table can also be used inversely, to give square roots.

Explanation of Table of Cubes (pp. 8–11).

This table gives the value of N^3 for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the cube of a number N outside the range from 1 to 10, note that moving the decimal point **one** place in column N is equivalent to moving it **three** places in the body of the table. For example:

$(4.852)^3 = 114.2$; $(0.4852)^3 = 0.1142$; $(485.2)^3 = 114200000$

This table may also be used inversely, to give cube roots.

10.0	1000.0										

$\pi^3 = 31.0063$ $\qquad 1/\pi^3 = 0.0322515+$

Moving the decimal point ONE place in *N* requires moving it THREE places in body of table (see p. 10).

$\sqrt{\pi} = 1.77245+$ $1/\sqrt{\pi} = 0.56419$ $\sqrt{\pi/2} = 1.25331$ $\sqrt{e} = 1.64872$

Explanation of Table of Square Roots (pp. 12–15).

This table gives the values of $\sqrt{N}$ for values of N from 1 to 100, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the square root of a number N outside the range from 1 to 100, divide the digits of the number into blocks of two (beginning with the decimal point), and note that moving the decimal point **two** places in N is equivalent to moving it **one** place in the square root of N. For example:

$$\sqrt{2.718} = 1.648; \quad \sqrt{271.8} = 16.48; \quad \sqrt{0.0002718} = 0.01648;$$

$$\sqrt{27.18} = 5.213; \quad \sqrt{2718} = 52.13; \quad \sqrt{0.002718} = 0.05213.$$

$\sqrt[3]{\pi} = 1.46459 \qquad 1/\sqrt[3]{\pi} = 0.682784$

Explanation of Table of Cube Roots (pp. 16–21).

This table gives the values of $\sqrt[3]{N}$ for all values of N from 1 to 1000, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the cube root of a number N outside the range from 1 to 1000, divide the digits of the number into blocks of three (beginning with the decimal point), and note that moving the decimal point three places in column N is equivalent to moving it one place in the cube root of N. For example:

$$\sqrt[3]{2.718} = 1,396; \quad \sqrt[3]{2718} = 13.96; \quad \sqrt[3]{0.000002718} = 0.01396.$$
$$\sqrt[3]{27.18} = 3.007; \quad \sqrt[3]{27180} = 30.07; \quad \sqrt[3]{0.00002718} = 0.03007.$$
$$\sqrt[3]{271.8} = 6.477; \quad \sqrt[3]{271800} = 64.77; \quad \sqrt[3]{0.0002718} = 0.06477.$$

This table gives $N^{3/2}$ from $N = 1$ to $N = 100$. Moving the decimal point TWO places in N requires moving it THREE places in body of table. Thus:

$(7.23)^{3/2} = 19.44$; $(723.)^{3/2} = 19440$; $(0.0723)^{3/2} = 0.01944$

$(72.3)^{3/2} = 614.8$; $(7230.)^{3/2} = 614800$; $(0.723)^{3/2} = 0.6148$

Used inversely, table gives $M^{2/3}$ from $M = 1$ to $M = 1000$. Thus: $(0.6148)^{2/3} = 0.7230$.

THREE-HALVES POWERS (*continued*) (See also p. 20)

$1/\pi = 0.318310 \qquad 1/e = 0.367879$

Explanation of Table of Reciprocals (pp. 24–27).

This table gives the values of $1/N$ for values of N from 1 to 10, correct to four figures. (Interpolated values may be in error by 1 in the fourth figure.)

To find the reciprocal of a number N outside the range from 1 to 10, note that moving the decimal point any number of places in either direction in column N is equivalent to moving it the same number of places in the **opposite direction** in the body of the table. For example:

$$\frac{1}{3.217} = 0.3108; \quad \frac{1}{3217.} = 0.000\,3108; \quad \frac{1}{0.003217} = 310.8$$

Explanation of Table of Circumferences (pp. 28–29)

This table gives the product of π times any number D from 1 to 10; that is, it is a table of multiples of π. (D = diameter.)

Moving the decimal point **one** place in column D is equivalent to moving it **one** place in the body of the table.

$$\text{Circumference} = \pi \times \text{diam.} = 3.141593 \times \text{diam.}$$

Conversely,

$$\text{Diameter} = \frac{1}{\pi} \times \text{circumf.} = 0.31831 \times \text{circumf.}$$

CIRCUMFERENCES BY HUNDREDTHS (*continued*)

Explanation of Table of Areas of Circles (pp. 30–31)

Moving the decimal point **one** place in column D is equivalent to moving it **two** places in the body of the table. (D = diameter.)

$$\text{Area of circle} = \frac{\pi}{4} \times (\text{diam.}^2) = 0.785398 \times (\text{diam.}^2)$$

Conversely,

$$\text{Diam.} = \sqrt{\frac{4}{\pi}} \times \sqrt{\text{area}} = 1.128379 \times \sqrt{\text{area}}$$

AREAS OF CIRCLES BY HUNDREDTHS (*continued*)

If given diameter is not found in this table, reduce diameter to feet and decimals of a foot by aid of the following auxiliary table, and then find area from pp. 30–31.

From Inches and Fractions of an Inch to Decimals of a Foot

Inches	1	2	3	4	5	6	7	8	9	10	11
Feet	.0833	.1667	.2500	.3333	.4167	.5000	.5833	.6667	.7500	.8333	.9167
Inches	⅛	¼	⅜	½	⅝	¾	⅞				
Feet	.0104	.0208	.0313	.0417	.0521	.0625	.0729				

Example. 5 ft. 7⅜ in. = 5.0 + 0.5833 + 0.0313 = 5.6146 ft.

SEGMENTS OF CIRCLES, GIVEN h/c

Given: h = height; c = chord. (For explanation of this table, see p. 38)

$\frac{h}{c}$	$\frac{\text{Diam.}}{c}$	Diff.	$\frac{\text{Arc}}{c}$	Diff.	$\frac{\text{Area}}{h \times c}$	Diff.	Central angle, v	Diff.	$\frac{h}{\text{Diam.}}$	Diff.

Explanation of Table of Volumes of Spheres (pp. 36–37).

Moving the decimal point **one** place in column *D* is equivalent to moving it **three** places in the body of the table. (*D* = diameter.)

$$\text{Volume of sphere} = \frac{\pi}{6} \times (\text{diam.}^3) = 0.523599 \times (\text{diam.}^3)$$

Conversely,

$$\text{Diam.} = \sqrt[3]{\frac{6}{\pi}} \times \sqrt[3]{\text{volume}} = 1.240701 \times \sqrt[3]{\text{volume}}$$

Explanation of Table on this page

Given, h = height of segment,
D = diam. of sphere.

To find the volume of the segment, form the ratio h/D and find from the table the value of (vol./D^3); then, by a simple multiplication,

vol. segment = $D^3 \times$ (vol./D^3)

The table gives also the ratio of the volume of the segment to the entire volume of the sphere.

NOTE. Area of zone = $\pi \times h \times D$. (Use Table of Multiples of π, p. 28)

Explanation of Table on p. 34

Given, h = height of segment,
c = chord.

To find the diam. of the circle, the length of arc, or the area of the segment, form the ratio h/c, and find from the table the value of (diam./c), (arc/c), or (area/hc); then, by a simple multiplication,

diam. = $c \times$ (diam./c),
arc = $c \times$ (arc/c),
area = $h \times c \times$ (area/hc).

The table gives also the angle subtended at the center, and the ratio of h to D. See p. 106.

Explanation of Table on p. 35

Given, h = height of segment,
D = diam. of circle.

To find the chord, the length of arc, or the area of the segment, form the ratio h/D, and find from the table the value of (chord/D), (arc/D), or (area/D^2); then, by a simple multiplication,

chord = $D \times$ (chord/D),
arc = $D \times$ (arc/D),
area = $D^2 \times$ (area/D^2).

The table gives also the angle subtended at the center, the ratio of the arc of the segment to the whole circumference, and the ratio of the area of the segment to the area of the whole circle. See p. 106.

NOTE. Vol. segm. = $\frac{1}{6}\pi h^2 (3D-2h)$.

REGULAR POLYGONS

n = number of sides;
v = $360°/n$ = angle subtended at the center by one side;

a = length of one side $= R\left(2 \sin \frac{v}{2}\right) = r\left(2 \tan \frac{v}{2}\right)$;

R = radius of circumscribed circle $= a\left(\frac{1}{2} \csc \frac{v}{2}\right) = r\left(\sec \frac{v}{2}\right)$;

r = radius of inscribed circle $= R\left(\cos \frac{v}{2}\right) = a\left(\frac{1}{2} \cot \frac{v}{2}\right)$;

$$\text{Area} = a^2\left(\tfrac{1}{4}\, n \cot \frac{v}{2}\right) = R^2\left(\tfrac{1}{2}\, n \sin v\right) = r^2\left(n \tan \frac{v}{2}\right).$$

BINOMIAL COEFFICIENTS

(For table giving binomial coefficients for fractional values of n, see p. 116).

$(n)_0 = 1$; $(n)_1 = n$; $(n)_2 = \frac{n(n-1)}{1 \times 2}$; $(n)_3 = \frac{n(n-1)(n-2)}{1 \times 2 \times 3}$; etc.; in general,

$(n)_r = \frac{n(n-1)(n-2)\ .\ .\ .\ (n-[r-1])}{1 \times 2 \times 3\ .\ .\ .\ \times r}$. Another notation: $\binom{n}{r} = (n)_r$.

Moving the decimal point n places to the right [or left] in the number requires adding $+n$ [or $-n$] in the body of the table (see p. 42).

$\log \pi = 0.4971$ $\log \pi/2 = 0.1961$ $\log \pi^2 = 0.9943$ $\log \sqrt{\pi} = 0.2486$
$\log e = 0.4343$ $\log (0.4343) = 0.6378 - 1$

These two pages give the common logarithms of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right [or left] in the number is equivalent to adding n [or $-n$] to the logarithm. Thus, $\log 0.017453 = 0.2419 - 2$, which may also be written $\bar{2}.2419$ or $8.2419 - 10$. See p. 91. Graphs, p. 174.

$$\log (ab) = \log a + \log b \qquad \log (a^N) = N \log a$$

$$\log \left(\frac{a}{b}\right) = \log a - \log b \qquad \log \left(\sqrt[N]{a}\right) = \frac{1}{N} \log a$$

* **Note**: Do not interpolate in this column.

$e = 2.71828$ $1/e = 0.367879$ $\log_{10} e = 0.4343$ $1/(0.4343) = 2.3026$

$\log_{10}(0.4343) = \bar{1}.6378$ $\log_{10}(e^n) = n(0.4343)$

For table of multiples of 0.4343, see p. 62. Graphs, p. 174.

HYPERBOLIC LOGARITHMS

	n	n (2.3026)	n (0.6974–3)
These two pages give the natural (hyperbolic, or Napierian) logarithms ($\log_e$) of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right [or left] in the number is equivalent to adding n times 2.3026 [or n times $\bar{3}.6974$] to the logarithm. Base $e = 2.71828+$	1	2.3026	0.6974–3
	2	4.6052	0.3948–5

10.0	2.3026									

Moving the decimal point *n* places to the right [or left] in the number requires ac *n* times 2.3026 [or *n* times (0.6974–3)] in the body of the table. See auxiliary tab multiples on top of the preceding page.

COMPOUND INTEREST. AMOUNT OF A GIVEN PRINCIPAL

The amount A at the end of n years of a given principal P placed at compound interest to-day is $A = P \times x$ or $A = P \times y$ or $A = P \times z$, according as the interest (at the rate of r per cent. per annum) is compounded annually, semi-annually, or quarterly; the factor x or y or z being taken from the following tables.

Values of x. (Interest compounded annually; $A = P \times x$.)

Years	$r = 2$	2½	3	3½	4	4½	5	6	7
1	1.0200	1.0250	1.0300	1.0350	1.0400	1.0450	1.0500	1.0600	1.0700

Formula: $z = [1 + (r/400)]^{4n}$.

AMOUNT OF AN ANNUITY

The amount S accumulated at the end of n years by a given annual payment Y set aside at the end of each year is $S = Y \times v$, where the factor v is to be taken from the following table. (Interest at r per cent. per annum, compounded annually.)

Values of v

Years	$r = 2$	2½	3	3½	4	4½	5	6	7
1	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000	1.0000

Formula: $v = \{[1 + (r/100)]^n - 1\} \div (r/100)$
$= (z - 1) \div (r/100)$.

PRINCIPAL WHICH WILL AMOUNT TO A GIVEN SUM

The principal P, which, if placed at compound interest to-day, will amount to a given sum A at the end of n years is $P = A \times x'$ or $P = A \times y'$ or $P = A \times z'$, according as the interest (at the rate of r per cent. per annum) is compounded annually, semi-annually, or quarterly: the factor x' or y' or z' being taken from the following tables.

Values of x'. (Interest compounded annually; $P = A \times x'$)

Formula: $z' = [1 + (r/400)]^{-4n} = 1/z$.

ANNUITY WHICH WILL AMOUNT TO A GIVEN SUM (SINKING FUND)

The annual payment, Y, which, if set aside at the end of each year, will amount with accumulated interest to a given sum S at the end of n years is $Y = S \times v'$, where the factor v' is given below. (Interest at r per cent. per annum, compounded annually.)

Formula: $v' = (r/100) + [[1 + (r/100)]^n - 1] = 1/s$.

PRESENT WORTH OF AN ANNUITY

The capital C, which, if placed at interest to-day, will provide for a given annual payment Y for a term of n years before it is exhausted is $C = Y \times w$, where the factor w is given below. (Interest at r per cent. per annum, compounded annually.)

Formula: $w = [1 - [1 + (r/100)]^{-n}] \div [r/100] = v/x.$

ANNUITY PROVIDED FOR BY A GIVEN CAPITAL

The annual payment Y provided for for a term of n years by a given capital C placed at interest to-day is $Y = C \times w'$. (Interest at r per cent. per annum, compounded annually; the fund supposed to be exhausted at the end of the term.)

WEIGHTS AND MEASURES

BY

LOUIS A. FISCHER

In the United States the measures of weight and length commonly employed are identical with the corresponding English units, but the capacity measures differ from those now in use in the British Empire, the U. S. gallon being defined as 231 cu. in. and the bushel as 2150.42 cu. in., whereas the corresponding British imperial units are, respectively, 277.418 cu. in., and 2219.344 cu. in. (1 imp. gal. = 1.2 U. S. gal., approx.; 1 imp. bu. = 1.03 U. S. bu., approx.).

The metric system of weights and measures was legalized and its use made permissive in the United States by an Act of Congress, passed in 1866. In 1872, by the concurrent action of the principal governments of the world, it was agreed to establish an International Bureau of Weights and Measures near Paris.

Prior to 1891 the British imperial yard was regarded as the real standard of the United States. In 1891, the Office of Weights and Measures (now Bureau of Standards) fixed the value of the United States yard in terms of the international meter, according to the ratio: one yard = 3600/3937 meters. At the same time, the pound was fixed in terms of the international kilogram, according to the relation: one pound = 453.59243 grams.

U. S. Customary Weights and Measures

Measures of Length

12 inches	= 1 foot
3 feet	= 1 yard
5½ yards = 16½ feet	= 1 rod, pole or perch
40 poles = 220 yards	= 1 furlong
8 furlongs = 1760 yards = 5280 feet	= 1 mile
3 miles	= 1 league
4 inches	= 1 hand
9 inches	= 1 span

Nautical Units

6080.2 feet	= 1 nautical mile
6 feet	= 1 fathom
120 fathoms	= 1 cable length
1 nautical mile per hr.	= 1 knot

Surveyor's or Gunter's Measure

7.92 inches	= 1 link
100 links = 66 ft. = 4 rods	= 1 chain
80 chains	= 1 mile
33⅓ inches	= 1 vara (Texas)

Measures of Area

144 square inches	= 1 square foot
9 square feet	= 1 square yard
30¼ square yards	= 1 square rod, pole or perch
160 square rods = 10 square chains = 43,560 sq. ft. = 5645 sq. varas (Texas)	= 1 acre
640 acres = 1 square mile	= 1 "section" of U. S. Govt. surveyed land
1 circular inch = area of circle 1 inch in diameter	= 0.7854 sq. in.
1 square inch	= 1.2732 cir. in.
1 circular mil	= area of circle 0.001 in. in diam.
1,000,000 cir. mils	= 1 cir. in.

Measures of Volume

1728 cubic inches	= 1 cubic foot
27 cubic feet	= 1 cubic yard
1 cord of wood	= 128 cu. ft.
1 perch of masonry	= 16½ to 25 cu. ft.

U. S. Customary Weights and Measures—*(continued)*

Measures of Volume

Liquid or Fluid Measure

4 gills	= 1 pint
2 pints	= 1 quart
4 quarts	= 1 gallon
7.4805 gallons	= 1 cubic foot

(There is no standard liquid "barrel.")

Apothecaries' Liquid Measure

60 minims	= 1 liquid dram or drachm
8 drams	= 1 liquid ounce
16 ounces	= 1 pint

Water Measure

The **Miner's Inch** is the quantity of water that will pass through an orifice 1 sq. in. in cross-section under a head of from 4 to 6½ in., as fixed by statutes, and varies from 1/40 cu. ft. to 1/50 cu. ft. per sec. The units now most in use are 1 cu. ft. per sec. and 1 gal. per sec., the U. S. Reclamation Service employing the former. See p. 260.

Dry Measure

2 pints	= 1 quart
8 quarts	= 1 peck
4 pecks	= 1 bushel

Shipping Measure

1 Register ton	= 100 cu. ft.
1 U. S. shipping ton	= 40 cu. ft.
	= 32.14 U. S. bu. / 31.14 imp. bu.
1 British shipping ton	= 42 cu. ft.
	= 32.70 imp. bu. / 33.75 U. S. bu.

Board Measure

1 board foot = 144 cu. in. = volume of board 1 ft. sq. and 1 in. thick.

No. of board feet in a log = $[\frac{1}{4}(d - 4)]^2L$, where d = diam. of log (usually taken inside the bark at small end), in., and L = length of log, ft. The 4 in. deducted are an allowance for slab. This rule is variously known as the Doyle, Conn. River, St. Croix, Thurber, Moore and Beeman, and the Scribner rule.

Weights
(The grain is the same in all systems)

Avoirdupois Weight

16 drams = 437.5 grains	= 1 ounce
16 ounces = 7000 grains	= 1 pound
100 pounds	= 1 cental
2000 pounds	= 1 short ton
2240 pounds	= 1 long ton
Also (in Great Britain):	
14 pounds	= 1 stone
2 stone = 28 lb.	= 1 quarter
4 quarters = 112 lb.	= 1 hundredweight (cwt.)
20 hundredweight	= 1 long ton

Troy Weight

24 grains	= 1 pennyweight (dwt.)
20 pennyweights = 480 grains	= 1 ounce
12 ounces = 5760 grains	= 1 pound

1 **Assay Ton** = 29,167 milligrams, or as many milligrams as there are troy ounces in a ton of 2000 lb. avoirdupois. Consequently, the number of milligrams of precious metal yielded by an assay ton of ore gives directly the number of troy ounces that would be obtained from a ton of 2000 lb. avoirdupois.

Apothecaries' Weight

20 grains	= 1 scruple ℈
3 scruples = 60 grains	= 1 dram ʒ
8 drams	= 1 ounce ℥
12 ounces = 5760 grains	= 1 pound

Weight for Precious Stones

1 carat = 200 milligrams

(Adopted by practically all important nations.)

Circular Measure

60 seconds	= 1 minute
60 minutes	= 1 degree
90 degrees	= 1 quadrant
360 degrees	= circumference
57.2957795 degrees (= 57° 17′44.806″)	= 1 radian (or angle having arc of length equal to radius)

METRIC SYSTEM

The fundamental unit of the metric system is the **meter**—the unit of length, from which the units of volume (**liter**) and of mass (**gram**) are derived. All other units are the decimal subdivisions or multiples of these. These three units are simply related: one cubic decimeter equals one liter, and one liter of water weighs one kilogram. The metric tables are formed by combining the words "meter," "gram," and "liter" with numerical prefixes.

All lengths, areas, and cubic measures in the following conversion tables are derived from the international meter. The customary weights are likewise derived from the kilogram. All capacities are based on the practical equivalent: 1 cubic decimeter equals 1 liter. (The liter is defined as the volume occupied by the mass of 1 kilogram of water under a pressure of 76 cm. of mercury and at the temperature of 4 deg. cent. According to the best information, 1 liter = 1.000027 cubic decimeters.)

The customary weights derived from the international kilogram are based on the value 1 avoirdupois lb. = 453.59243 grams. The value of the troy lb. is based on the same relation and also the equivalent 5760/7000 avoirdupois lb. equals 1 troy lb.

Metric Measures

Length			Area		
Unit	Symbol	Value in meters	Unit	Symbol	Value in sq. meters
Micron	μ	0.000001			
Millimeter	mm.	0.001	Sq. millimeter	$mm.^2$	0.000001
Centimeter	cm.	0.01	Sq. centimeter	$cm.^2$	0.0001
Decimeter	dm.	0.1	Sq. decimeter	$dm.^2$	0.01
Meter (unit)	m.	1.0	Sq. meter (centiare)	$m.^2$	1.0
Dekameter	dkm.	10.0	Sq. dekameter (are)	a.	100.0

SYSTEMS OF UNITS

The principal units of interest to mechanical engineers can all be derived from the three fundamental units of **force, length,** and **time.** These three fundamental units may be chosen at pleasure; each such choice gives rise to a "system" of units. The following table gives the units of the four "systems" most often met with in the literature.

The precise definitions of the fundamental units in these systems are as follows. (In these definitions the "standard pound body" and the "standard kilogram body" refer to two special lumps of metal, carefully preserved at London and Paris, respectively; the "standard locality" means sea level, 45 deg. latitude; or, more strictly, any locality in which the acceleration due to gravity has the value 980.665 cm. per sec.^{2} = 32.1740 ft. per sec.^{2}, which may be called the **standard acceleration.**

The **pound** (*force*) is the force required to support the standard pound body against gravity, *in vacuo*, in the standard locality; or, it is the force which, if applied to the standard pound body, supposed free to move, would give that body the "standard acceleration." The word "pound" is used for the unit of both force and mass, and consequently is ambiguous. To avoid uncertainty it is desirable to call the units "pound force" and "pound mass," respectively.

The **kilogram** (*force*) is the force required to support the standard kilogram against gravity, *in vacuo*, in the standard locality; or, it is the force which, if applied to the standard kilogram body, supposed free to move, would give that body the "standard acceleration." The word "kilogram" is used for the unit of both force and mass and consequently is ambiguous. To avoid uncertainty it is desirable to call the units "kilogram force" and "kilogram mass," respectively.

The **poundal** is the force which, if applied to the standard pound body, would give that body an acceleration of 1 ft. per sec.^{2}; that is, 1 poundal = 1/32.1740 of a pound force.

The **dyne** is the force which, if applied to the standard gram body, would give that body an acceleration of 1 cm. per sec.^{2}; that is, 1 dyne = 1/980.665 of a gram force.

Systems of Units

Name of unit	Dimensions of units in terms of F, L, T	British "gravitational" system, or "foot-pound-second" system	Metric "gravitational" system, or "kilogram-meter-second" system	Metric "absolute" system, or "C. G. S." system	British "absolute" system (little used)
Force	F	1 lb.	1 kg.	1 dyne	1 poundal
Length	L	1 ft.	1 m.	1 cm.	1 ft.
Time	T	1 sec.	1 sec.	1 sec.	1 sec.
Velocity	L/T	1 ft. per sec.	1 m. per sec.	1 cm. per sec.	1 ft. per sec.
Acceleration	L/T^2	1 ft. per sec.^{2}	1 m. per sec.^{2}	1 cm. per sec.^{2}	1 ft. per sec.^{2}
Pressure	F/L^2	1 lb. per ft.^{2}	1 kg. per m.^{2}	1 dyne per cm.^{2}	1 pdl. per ft.^{2}
Impulse or momentum	FT	1 lb.-sec.	1 kg.-sec.	1 dyne-sec.	1 pdl.-sec.
Work or energy	FL	1 ft.-lb.	1 kg.-m.	1 dyne-cm. = 1 "erg."	1 ft.-pdl.
Power	FL/T	1 ft.-lb. per sec.	1 kg.-m. per sec.	1 dyne-cm. per sec.	1 ft.-pdl. per sec.
Mass	$F/(L/T^2)$	1 lb. per (ft. per sec.^{2}) = 1 "slug."	1 kg. per (m. per sec.^{2}) = 1 "metric slug."	1 dyne per (cm. per sec.^{2}) = 1 gram mass.	1 pdl. per (ft. per sec.^{2}) = 1 pound mass.

NOTE. The "slug" (also called the "geepound," or the "engineer's unit of mass"), the "metric slug," and the "poundal" are never used in practice.

Other common units are as follows:

Work: 1 joule = 10^7 ergs = 10,000,000 dyne-cm.
1 kilowatt-hour = 3,600,000 joules = 3600×10^{10} dyne-cm.

Power: 1 horse power = 550 ft.-lb. per sec.
1 poncelet = 100 kg.-m. per sec.
1 force de cheval = 75 kg.-m. per sec.
1 watt = 1 joule per sec. = 10,000,000 dyne-cm. per sec.
1 kilowatt = 1000 watts = 10^{10} dyne-cm. per sec.

A new horse power of 550.220 ft.-lb. per sec., or 746 watts, has been proposed, but has not been accepted by mechanical engineers.

The *weight* of a body (in a given locality) always means a *force*, namely, the force, required to support the body against gravity (in that locality). When no particular locality is specified, the standard locality may be assumed. Thus, the "standard weight" of the pound body is 1 lb.; the "standard weight" of the kilogram body is 1 kg.

Heat Units. The units of heat commonly used are (1) the quantity of heat required to raise the temperature of 1 gram of water 1 deg. cent. at a mean temperature of 15 deg. cent., or (2) the heat required to raise the temperature of 1 lb. of water 1 deg. fahr. The former quantity is called the **gram-calorie** (small calorie), while the latter is known as the **British thermal unit** or B.t.u. The **kilogram-calorie** (large calorie), which is equal to 1000 g.-cal., is largely used in engineering work in metric countries. See also p. 295.

Mechanical Equivalent of Heat. See p. 311.* The value most commonly accepted among American engineers as the work equivalent of 1 **mean B.t.u.** is 777.5 ft.-lb., and the **mean gram-calorie** = 4.183 joules, which are the values used throughout this book. The U. S. Bureau of Standards does not recommend any special value; for its own purposes it takes the 59 deg. fahr. B.t.u. as 778.2 ft.-lb. and the 68 deg. B.t.u. as 777.5 ft.-lb. The 15 deg. calorie = 4.187 joules; 20 deg. calorie = 4.183 joules. There is an uncertainty of about 1 part in 1000 in these values.

TIME

Kinds of Time. Three kinds of time are recognized by astronomers, viz., sidereal, apparent solar, and mean solar time. The **sidereal day** is the interval between two consecutive transits of some fixed celestial object across any given meridian, or it is the interval required by the earth to make one complete revolution on its axis. This interval is constant but it is inconvenient as a time unit because the noon of the sidereal day occurs at all hours of the day and night. The **apparent solar day** is the interval between two consecutive transits of the sun across any given meridian. On account of the variable distance between the sun and earth, the variable speed of the earth in its orbit, the effect of the moon, etc., this interval is not constant and consequently cannot be kept by any simple mechanism, such as clocks or watches. To overcome the objection noted above, the **mean solar day** was devised. The mean solar day is the length of the average apparent solar day. Like the sidereal day it is constant, and like the apparent solar day its noon always occurs at approximately the same time of day. The astronomical day begins at mean solar noon and the hours run from one to twenty-four, while the civil day (mean solar) begins 12 hours earlier, at midnight, and the hours run from one to twelve, and then repeat from noon to midnight.

The Year. There are three different kinds of year used, the sidereal, the tropical, and the anomalistic. The **sidereal year** is the time taken by the earth to complete one revolution around the sun from a given star to the same star again. Its length is 365 days, 6 hours, 9 minutes, and 9 seconds. The **tropical year** is the time included between two successive passages of the vernal equinox by the sun, and since the equinox moves westward 50.″2 of arc a year, the tropical year is shorter by 20′23.″5 in time than the sidereal year. As the seasons depend upon the earth's position with respect to the equinox, the tropical year is the year of civil reckoning. The **anomalistic year** is the interval between two successive passages of the perihelion, namely, the time of the earth's nearest approach to the sun. The anomalistic year is only used in special calculations in astronomy.

The Calendar. The month depended originally upon the changes of the moon. The Mohammedan nations still use a lunar calendar with years of twelve lunar months, which alternately contain 355 and 356 days. According to their method of reckoning the same month falls in different seasons, and their calendars gain 1 year on ours every 33 years. The **Julian Calendar** (established 45 B. C.) discards all consideration of the moon and adopts 365¼ days as the true length of the year. It is still used in Russia and generally by the Greek Church. **Gregorian Calendar:** The true length of the tropical year is 365 days, 5 hr., 48 min., 45.5 sec., a difference of 11 min., 14.5 sec. by which the Julian year is too long. This amounts to a little more than 3 days in 400 years. To correct for this, those century years are made leap years which are divisible by 400 without remainder.

Standard Time. Prior to 1883 each city of the U. S. had its own time, which was determined by the time of passage of the sun across the local meridian. A system of standard time is used at present, according to which the United States, which extends from 65 deg. to 125 deg. West longitude, is divided into four sections, each of 15 deg. of longitude. The first or eastern section includes all territory between the Atlantic coast and an irregular line drawn from Detroit, Mich., through Pittsburg to Charleston, S. C., its most southern point. The time of this section is that of the 75-deg. meridian, which is 5 hr. slower than Greenwich time. The second (central) section includes all territory between the line mentioned, and an irregular line drawn from Bismarck, N. D., to the mouth of the Rio Grande. The third (mountain) section includes all territory between the last-named line and a line which passes through the western part of Idaho, Utah and Arizona. The fourth (Pacific) section covers the rest of the country to the Pacific Ocean. Standard time is uniform in each of these sections, but the time in one section differs by exactly 1 hr. from the section next to it. In cities situated on the border line of two sections, as, say, Pittsburg and Atlanta, the standard times of both sections are used, and in such cities when the time is given, it should be specified as eastern, central, etc. The system of standard time has been adopted in almost all civilized countries. All continental Europe, except Russia, uses a time 1 hr. faster than that of Greenwich; in Japan and Australia the time is 9 hr. faster.

TERRESTRIAL GRAVITY

By **standard gravity** is meant any locality where g_0 = 980.665 cm. per sec. per sec., or 32.1740 ft. per sec. per sec. This value, g_0, is assumed to be the value of g at sea level and latitude 45 deg.

Acceleration of Gravity

(U. S. Coast and Geodetic Survey, 1912)

Latitude, deg.	g		g/g_0	Latitude, deg.	g		g/g_0
	Cm./sec.²	Ft./sec.²			Cm./sec.²	Ft./sec.²	
0	978.0	32.088	0.9973	50	981.1	32.187	1.0004
10	978.2	32.093	0.9975	60	981.9	32.215	1.0013
20	978.6	32. 08	0.9979	70	982.6	32.238	1.0020
30	979.3	32.130	0.9986	80	983.1	32.253	1.0024
40	980.2	32.158	0.9995	90	983.2	32.258	1.0026

Correction for altitude above sea level: − 0.3 cm. per sec.² for each 1000 meters; − 0.003 ft. per sec.² for each 1000 feet.

SPECIFIC GRAVITY AND DENSITY

The **specific gravity of a solid or liquid** is the ratio of the mass of the body to the mass of an equal volume of water at some standard temperature. At the present time a temperature of 4 deg. cent. (39 deg. fahr.) is commonly used by physicists, but the engineer uses 60 deg. fahr. The specific gravity **of gases** is usually expressed in terms of hydrogen or air.

The **density** of a body is its mass per unit volume. If the gram is used as the unit of mass and the milliliter as the unit of volume, the figures representing the density are the same as the specific gravity of the body referred to water at 4 deg. cent. as unity. The customary unit is pounds per cu. ft.

The specific gravity of liquids is usually measured by means of an hydrometer (see p. 254).* Special arbitrary hydrometer scales are used in various trades and industries. The most common of these are the Baumé, Twaddell and Beck. Twaddell's hydrometer is used for liquids heavier than water. The number of degrees, N, which it indicates may be converted to specific gravities, G, by the formula $G = (5N + 1000)/1000$. The formula for the Beck hydrometer is $G = 170/(170 \pm N)$; for the Brix hydrometer $G = 400/(400 \pm N)$. In both of these the + sign is to be used for liquids lighter than water, the − sign for heavier liquids. For the salinometer (salometer), see p. 1734.* The specific gravities corresponding to the indications of the Baumé hydrometer are given in the following tables.

*See Marks' MECHANICAL ENGINEERS' HANDBOOK.

Specific Gravities at $\frac{60°}{60°}$ Fahr. Corresponding to Degrees Baumé for Liquids Lighter than Water

ARITHMETIC

NUMERICAL COMPUTATION

Number of Significant Figures. In any engineering computation, the data are ordinarily the results of measurement, and are correct only to a limited number of significant figures. Each of the numbers 3.840 and 0.003840 is said to be given "correct to four figures;" the true value lies in the first case between 3.8395 and 3.8405; in the second case, between 0.0038395 and 0.0038405. The **absolute error** is less than 0.001 in the first case, and less than 0.000001 in the second; but the **relative error** is the same in both cases, namely, an error of less than "one part in 3840."

If a number is written as 384000, the reader is left in doubt whether the number of correct significant figures is 3, 4, 5, or 6. This doubt can be removed by writing the number as 3.84×10^5 or 3.840×10^5 or 3.8400×10^5 or 3.84000×10^5.

In any numerical computation, the possible or desirable degree of accuracy should be decided on and the computation should then be so arranged that the required number of significant figures, and no more, is secured. Carrying out the work to a larger number of places than is justified by the data, is to be avoided, (1) because the form of the results leads to an erroneous impression of their accuracy, and (2) because time and labor are wasted in superfluous computation. The labor of working with six-place tables is nearly three times as great as that with four-place tables. In computations involving several steps, it is desirable to retain one extra figure until just before the final result is reached, in order to protect the last figure against the possible cumulative effect of small tabular errors. In **discarding superfluous figures,** if the first discarded figure is 5 or more, increase the preceding figure by 1. Thus, 3.14159, written correct to four figures, is 3.142; correct to three figures, 3.14. Again, 6.1297, correct to four figures, is 6.130.

Addition. In adding numbers, note that a doubtful final figure in any one number will render doubtful the whole column in which that figure lies; hence all figures to the right of that column are superfluous, and contribute nothing to the accuracy of the result.

0.2056x

14.25xxx
576.1xxxx
593.1

Subtraction. The "Austrian" or "shop" method is recommended. The mental process is as follows, the figures here printed in boldface type being the only ones written down:

[3 plus how many is 12?] 3 plus **9** is 12; 1 to carry.	14752
[7 plus how many is 15?] 7 plus **8** is 15; 1 to carry.	8463
5 plus **2** is 7. 8 plus **6** is 14.	**6289**

This method is especially useful when it is desired to subtract from a given number the sum of several other numbers.

7 plus 1 is 8; plus 5 is 13; plus 9 is 22; 2 to carry.	14752
5 plus 0 is 5; plus 2 is 7; plus 8 is 15; 1 to carry.	3125
3 plus 1 is 4; plus 1 is 5; plus 2 is 7.	101
5 plus 3 is 8; plus 6 is 14.	5237
	6289

The use of a wavy line to indicate subtraction is also recommended, as it will minimize the danger of adding when subtraction is intended.

Multiplication. In long examples in multiplication, the arrangement of work here illustrated is recommended, since it facilitates the abbreviation of the work by the omission, in practice, of all the figures on the right of the vertical line.

The **position of the decimal point** should be determined by reference to the first, or left-hand, figures of the numbers, rather than by "pointing off" so-and-so many places from the right-hand end. For the right-hand figures of a number are the least important ones, and in many cases are entirely unknown (especially when the slide rule or a computing machine is used). The mental process for determining the decimal point is as follows:

(*a*) If the multiplier is a number like 3.1416, with only one figure preceding the decimal point, think of this number as "a little over 3;" then the product must be "a little over three times the number which is being multiplied;" and this gives the position of the decimal point at once, by inspection.

(*b*) If the multiplier is a number like 3141.6 [or 0.000 003 141 6], think of this number as "about 3, with the point moved three places to the right" [or "about 3, with the point moved six places to the left"]; then think what the answer would be if the multiplier were simply "about 3," and shift the decimal point accordingly.

Multiplication Tables. Crelle's large volume (Berlin, G. Reimer) gives the product of every three-figure number by every three-figure number; Peters's (Berlin, G. Reimer), of every four-figure number by every two-figure number. The smaller table of H. Zimmermann (Berlin, Wm. Ernst) gives the product of every three-figure number by every two-figure number.

Division. In long division, where the numbers are given only approximately, the work can be much abbreviated without loss of accuracy by "cutting off" one figure of the divisor at each step, instead of "bringing down" a doubtful zero in the dividend. Thus, 3.1416 ÷ 2.3026 = 1.3644.

23026)	31416(1
	23026
2303)	8390(3
	6909
230)	1481(6
	1380
23)	101(4
	92
2)	9(4

To determine the **position of the decimal point** in a problem of fractional division, shift the point (mentally) in both numerator and denominator (the same number of places in each) until the denominator is a number in the "standard form," that is, a number with only one figure preceding the decimal point. (This will not change the value of the fraction.) Then estimate the approximate magnitude of the quotient by inspection. Thus:

$$\frac{0.2718}{3141.6} = \frac{0.000\ 2718}{3.1416} = \text{"about } 0.000\ 09\text{"} = 0.000\ 08652;$$

$$\frac{31.416}{0.002718} = \frac{31\ 416.}{2.718} = \text{"about } 10\ 000\text{"} = 11\ 558.$$

Reciprocals. The reciprocal of N is $1/N$. Instead of dividing by a long number N, it is often better to multiply by the reciprocal of N. The table of reciprocals on pp. 24–27 gives the reciprocal of any number, correct to four figures. Barlow's Table (Spon & Chamberlain, New York) gives the reciprocal of every four-figure number correct to seven figures (but without facilities for interpolation). The reciprocals of numbers having more than four figures are best found by the use of a large table of logarithms.

Reciprocals of 1 ± x when x is Small.

$$1/(1+x) = 1 - x + [\text{error} < x^2, \text{ if } x \text{ is between 0 and 1}],$$
$$= 1 - x + x^2 - [\text{error} < x^3, \text{ if } x \text{ is between 0 and 1}].$$
$$1/(1-x) = 1 + x + [\text{error} < x^2 + 2x^3, \text{ if } x \text{ is between 0 and } \tfrac{1}{2}],$$
$$= 1 + x + x^2 + [\text{error} < x^3 + 2x^4, \text{ if } x \text{ is between 0 and } \tfrac{1}{2}].$$

NOTE. $1/(a \pm b) = (1/a)[1/(1 \pm x)]$, where $x = b/a$.

Notation by Powers of 10. All questions concerning the position of the decimal point are readily answered if each number is expressed in the "standard form," that is, as the product of two factors, one of which is a number with only one figure preceding the decimal point, while the other is a positive or negative power of 10. Thus, 3.1416×10^3 means 3.1416 with the point moved three places to the right, that is, 3141.6. Again, 3.1416×10^{-6} means 3.1416 with the point moved six places to the left, that is, 0.000 003 1416. This notation by powers of 10 should always be used in dealing with very large or very small numbers. Among electrical engineers its use is very general, even for numbers of moderate size.

Square Root. (*a*) If four figures of the root are sufficient, take the answer directly from the table of square roots, pp. 12–15. (*b*) To obtain a root of six or seven figures from the table, use the formula: $\sqrt{N} = a + [(N - a^2)/2a]$ (approx.), where a is the nearest value of $\sqrt{N}$ obtainable from the table, with three or four ciphers annexed. Here a^2 must be found exactly, by direct multiplication, so that at least three significant figures of the difference $N - a^2$ shall be known correctly; but this done, the division of $N - a^2$ by $2a$ should be carried to only three figures (logarithms or slide rule may be used).

NOTE. The simplest way to obtain any root of a seven-figure number correct to seven figures is to use a seven-place table of logarithms, if such a table is at hand.

Square Roots of 1 ± x when x is Small.

$$(1+x)^{\frac{1}{2}} = 1 + \tfrac{1}{2}x - [\text{error less than } \tfrac{1}{8}x^2 \text{ if } 0 < x < 1]$$
$$= 1 + \tfrac{1}{2}x - \tfrac{1}{8}x^2 + [\text{error} < \tfrac{1}{16}x^3 \text{ if } 0 < x < 1]$$
$$(1-x)^{\frac{1}{2}} = 1 - \tfrac{1}{2}x - [\text{error} < \tfrac{1}{8}x^2 + \tfrac{1}{10}x^3 \text{ if } 0 < x < \tfrac{1}{2}]$$
$$= 1 - \tfrac{1}{2}x - \tfrac{1}{8}x^2 - [\text{error} < \tfrac{1}{16}x^3 + \tfrac{1}{10}x^4 \text{ if } 0 < x < \tfrac{1}{2}]$$

NOTE. $\sqrt{a+b} = \sqrt{a}\,(1+x)^{\frac{1}{2}}$, where $x = b/a$.

Cube Root. (*a*) If four figures of the root are sufficient, take the answer directly from the table of cube roots, pp. 16–21. (*b*) To obtain a root of six or seven figures from the table, use the formula: $\sqrt[3]{N} = a + [(N - a^3)/3a^2]$ (approx.), where a is the nearest value of $\sqrt[3]{N}$ obtainable from the table, with three or four ciphers annexed. Here a^3 must be found correct to seven or eight figures, by direct multiplication, so that at least three significant figures of the difference $N - a^3$ shall be known; but this done, the division of $N - a^3$ by $3a^2$ should be carried to only three or four figures (logarithms or the slide rule may be used).

NOTE. The simplest way to obtain any root of a seven-figure number correct to seven figures is to use a seven-place table of logarithms, if such a table is at hand.

Cube Roots of $1 \pm x$ when x is Small.

$$(1+x)^{1/3} = 1 + \tfrac{1}{3}x - [\text{error} < \tfrac{1}{9}x^2 \text{ if } 0 < x < 1],$$
$$= 1 + \tfrac{1}{3}x - \tfrac{1}{9}x^2 + [\text{error} < \tfrac{1}{16}x^3 \text{ if } 0 < x < 1],$$
$$(1-x)^{1/3} = 1 - \tfrac{1}{3}x - [\text{error} < \tfrac{1}{9}x^2 + \tfrac{1}{10}x^3 \text{ if } 0 < x < \tfrac{1}{2}],$$
$$= 1 - \tfrac{1}{3}x - \tfrac{1}{9}x^2 - [\text{error} < \tfrac{1}{16}x^3 + \tfrac{1}{18}x^4 \text{ if } 0 < x < \tfrac{1}{2}].$$

NOTE. $\sqrt[3]{a+b} = \sqrt[3]{a}(1+x)^{1/3}$, where $x = b/a$.

LOGARITHMS

Tables of Logarithms. The use of a table of logarithms greatly reduces the labor of multiplication, division, raising to powers, and extracting roots. The table on pp. 42–43 is carried out to four significant figures, and the following explanations should be sufficient to permit the use of the table readily, even by one without previous experience. For algebraic theory, see p. 113.

If more than four-figure accuracy is required, recourse must be had to a larger table. Five-place tables are available in great variety; the Macmillan Tables, 1913, are perhaps as convenient as any. If more than five figures are required, use Bremiker's six-place table, or proceed at once to a seven-place table: Schrön (Vieweg und Sohn, Braunschweig); Bruhns; Vega-Bremiker. If extreme accuracy is required, use the eight-place table by Bauschinger and Peters (Engelmann, Leipzig). Logarithmic paper, see p. 176.

To Find the Logarithm of Any Given (Positive) Number.

(*a*) WHEN THE GIVEN NUMBER IS BETWEEN 1 AND 10.

An inspection of the table on pp. 42–43 shows that as the number increases from 1 to 9.99. . . the logarithm of that number increases continuously from 0 to 0.999. . . For example, log 2.97 = 0.4728; log 2.98 = 0.4742.

If the given number contains four significant figures, it is necessary to interpolate between the tabulated values, as follows:

To find log 2.973, notice that this number is $\frac{3}{10}$ of the way from 2.97 to 2.98; hence its logarithm will be (approximately) $\frac{3}{10}$ of the way from 0.4728 to 0.4742. The difference here is 14 units, and $\frac{3}{10}$ of this difference is 4 (to the nearest unit); hence, by adding this 4 to 4728, log 2.973 = 0.4732. This process of interpolating should be performed mentally; the step of finding the tabular difference will be facilitated by a glance at the last column on the right, which gives, for each line of the table, the average of the differences along that line.

Again, to find log 4.098: From table, log 4.09 = 0.6117; adding $\frac{8}{10}$ of the difference (11), or about 9, gives: log 4.098 = 0.6126. Or better, since $\frac{8}{10}$ of the way forward is equal to $\frac{2}{10}$ of the way back, find in table log 4.10 = 0.6128, and *subtract* $\frac{2}{10}$ of 11, or 2, giving log. 4.098 = 0.6126. It should be noted that any interpolated value may be in error by 1 in the last place.

If the given number contains more than four significant figures, it should be cut down to four figures (see p. 88), since the later figures will not affect the result in four-place computations.

(*b*) WHEN THE GIVEN NUMBER IS LESS THAN 1 OR MORE THAN 10, it is simply necessary to notice that every such number can be regarded as obtainable from some number between 1 and 10 by merely shifting the decimal point (see p. 90); and that according to the rule at the foot of the table, moving the decimal point n places to the right [or left] in the number-column is equivalent to adding n [or $-n$] to the logarithm in the body of the table.

For example, to find log 2973. Here $2973 = 2.973 \times 10^3$ (*i.e.*, 2.973 with the decimal point moved 3 places to the right). From the table, log 2.973 = 0.4732. Hence, log 2973 = 0.4732 + 3, which may be written as 3.4732.

Again, to find log 0.0002973. Here $0.0002973 = 2.973 \times 10^{-4}$ (*i.e.*, 2.973 with the decimal point moved 4 places to the left). From the table, log 2.973 = 0.4732. Hence, log 0.0002973 = 0.4732 − 4. (This may be written as $\bar{4}.4732$, if desired, and is equal of course, to − 3.5268; this latter form, however, is not convenient in practice.)

It is thus evident that the logarithm of every positive number may be regarded as consisting of two parts: a decimal fraction, which is always positive (or zero); and a whole number, which may be positive, negative, or zero. The fractional part is called the **mantissa**, and is found from the table; the whole-number part is called the **characteristic**, and is determined by inspection.

To Find the Number Corresponding to a Given Logarithm.

(*a*) WHEN THE GIVEN LOGARITHM IS A POSITIVE DECIMAL FRACTION (CHARACTERISTIC ZERO), simply reverse the process for finding the logarithm of a number between 1 and 10.

For example, given log N = 0.4732; to find N. In the body of the table it is seen that 0.4732 lies a little beyond 0.4728; hence N must lie a little beyond 2.97. By taking differences it is found that 4728 is in fact $4/14$ of the way from 0.4728 to the next higher logarithm; therefore N must be $4/14$ of the way from 2.97 to the next higher number. But $4/14$ of 1 is 0.3 (to the nearest tenth), hence N = 2.973.

Again, given log N = 0.6126; to find N. Here, 0.6126 is $9/11$ of the way from 0.6117 to the next higher logarithm; therefore N must be $9/11$ of the way from 4.09 to the next higher number. But $9/11$ of 1 is 0.8 (to the nearest tenth), hence N = 4.098.

(*b*) WHEN THE GIVEN LOGARITHM HAS ANY GIVEN VALUE (CHARACTERISTIC NOT ZERO), proceed as follows: First, be sure the given logarithm is in the "standard form," that is, a positive decimal fraction (mantissa) plus a positive or negative whole number (characteristic). For example, if log N is originally given in the form log N = − 3.5268, this must first be reduced to the (equivalent) form log N = 0.4732 − 4 (or $\bar{4}.4732$), before entering the table. Having the logarithm given in the standard form, suppose for the moment that the characteristic is zero, and find in the table the number corresponding to the given mantissa; then move the decimal point to the right or left according as the value of the characteristic is positive or negative.

For example, given log N = 0.4732 + 3; to find N. From the table, the number corresponding to 0.4732 is 2.973. The characteristic (+ 3) directs that the decimal point be moved 3 places to the right; hence $N = 2.973 \times 10^3 = 2973$.

Again, given log N = 0.4732 − 4; to find N. From the table, the number corresponding to 0.4732 is 2.973. The characteristic (− 4) indicates that the decimal point is to be moved 4 places to the left; hence $N = 2.973 \times 10^{-4} = 0.0002973$.

The number corresponding to a given logarithm is called its **antilogarithm.** Thus, if log 2973 = 0.4732 + 3, then 2973 = antilog (0.4732 + 3).

NOTE 1. In most tables of logarithms the decimal point is omitted, the tables being in fact not tables of logarithms, but tables of mantissas. This omission is of no consequence to the experienced computer, but is often perplexing to one who makes only occasional use of such tables.

NOTE 2. Many computers prefer to write negative characteristics in the form of some positive number minus some multiple of 10; thus, 0.4732 − 4 = 6.4732 − 10; 0.4732 − 13 = 7.4732 − 20; etc.

Fundamental Properties of Logarithms. The usefulness of logarithms in computation depends on the following properties:

$$(1)\ \log(ab) = \log a + \log b; \quad (3)\ \log(a^n) = n \log a;$$
$$(2)\ \log(a/b) = \log a - \log b; \quad (4)\ \log \sqrt[n]{a} = (1/n) \log a;$$
$$(5)\ \log 10^n = n$$

It is to be noted also that log 1 = 0, log 10 = 1, and log $(1/n)$ = −log n

To Multiply by Logarithms. Find from the table the log. of each factor, and add; the result will be the log. of the product. Then find the product itself from the table.

EXAMPLE. To find $x = (4.098)(0.0002973)(72.1)$.

Answer: $x = 8.784 \times 10^{-2} = 0.08784$

$$\begin{array}{lll} \log\ 4.098 & = 0.6126 & \\ \log\ 0.0002973 & = 0.4732 - 4 & \\ \log\ 72.1 & = \underline{0.8579 + 1} & \\ \log\ x & = 1.9437 - 3 = 0.9437 - 2. & \end{array}$$

To Divide by Logarithms. First Method: Find from the table the log. of the numerator and the log. of the denominator, and subtract the second from the first; the result will be the logarithm of the quotient. Then find the quotient itself from the table.

EXAMPLE. To find $x = \dfrac{4.098}{0.0002973}$

Answer: $x = 1.378 \times 10^4 = 13780$

$$\begin{array}{ll} \log\ 4.098 & = 0.6126 \\ \log\ 0.0002973 & = \underline{0.4732 - 4} \\ \log\ x & = 0.1394 + 4 \end{array}$$

In order **to avoid negative mantissas** in cases where a larger mantissa would have to be subtracted from a smaller, modify the upper logarithm by adding and subtracting 1.

EXAMPLE. To find $x = \dfrac{0.0291}{63.4}$.

Answer: $x = 4.590 \times 10^{-4} = 0.0004590.$

$$\begin{array}{ll} \log 0.0291 & = 0.4639 - 2 = 1.4639 - 3 \\ \log 63.4 & = 0.8021 + 1 = \underline{0.8021 + 1} \\ \log x & \qquad\qquad\qquad\ = 0.6618 - 4 \end{array}$$

But if the logarithms are written with the characteristics in front, and the "shop method" of subtraction is used (see p. 88), then no such special device is here required. Thus:

$$\begin{array}{ll} \log\ 0.0291 & = \bar{2}.4639 \\ \log\ 63.4 & = \underline{1.8021} \\ \log\ x & = \bar{4}.6618 \end{array}$$

To Divide by Logarithms. Second Method: Instead of subtracting the log. of a number, it is often convenient to add the **cologarithm** of that number; the colog. of N being defined by: $\operatorname{colog} N = \log (1/N) = -\log N$.

To find the colog. of a number, write the log. of the number in the standard form, and subtract it from $1.0000 - 1$, as in the following examples:

$$\begin{array}{rl} & 1.0000 - 1 \\ \log 69.5 = & \underline{0.8420 + 1} \\ \operatorname{colog} 69.5 = & 0.1580 - 2 \end{array} \qquad \begin{array}{rl} & 1.0000 - 1 \\ \log 0.0002973 = & \underline{0.4732 - 4} \\ \operatorname{colog} 0.0002973 = & 0.5268 + 3 \end{array}$$

This subtraction should be performed mentally. Thus, to subtract the mantissa, subtract each digit from 9 until the last non-zero digit is arrived at, and subtract this from 10; to subtract the characteristic, follow the regular rule of algebra ("reverse the sign and add"). Hence, if the logarithm itself is already written down, or can be read off from the table without interpolation, the cologarithm can be written down at once, by inspection. The use of cologarithms is not essential in logarithmic computation, but it often facilitates a compact arrangement of the work, especially in cases where the denominator of a fraction is itself the product of two or more factors.

To Find the nth Power of a Number by Logarithms. Find from the table the log. of the number, and multiply it by n; the result will be the logarithm of the nth power of that number. Then find the power itself from the tables.

EXAMPLE 1. Find $x = (0.0291)^3$

Answer: $x = 2.464 \times 10^{-5} = 0.00002464.$

$$\begin{array}{ll} \log 0.0291 & = 0.4639 - 2 \\ & \qquad\qquad\ \underline{\ \ 3\ \ } \\ \log x & = 1.3917 - 6 = 0.3917 - 5. \end{array}$$

EXAMPLE 2. Find $x = (0.0291)^{1.41}$

Answer: $x = 6.825 \times 10^{-3}$

$= 0.006825$

$$\begin{array}{rrr} \log 0.0291 & = 0.4639 - 2 = & -1.5361 \\ & & 1.41 \\ \hline & & 15361 \\ & & 61444 \\ & & 15361 \\ \hline \log x & = & -2.1659 \\ & = & 0.8341 - 3 \end{array}$$

To Find the nth Root of a Number by Logarithms. Find from the table the log. of the number, and divide it by n; the result will be the log. of the nth root of that number. Then find the root itself from the table.

EXAMPLE. Find $x = \sqrt[3]{4.098}$ $\qquad \log 4.098 = 0.6126$

Answer: $x = 1.600$ $\qquad \log x = 0.2042$

In order **to avoid fractional characteristics,** if the characteristic is not divisible by n, make it so divisible by adding and subtracting a suitable number before dividing.

EXAMPLE. Find $x = \sqrt[3]{0.0004590}.$ $\qquad \log 0.0004590 = 0.6618 - 4$

Answer: $x = 7.714 \times 10^{-2}$ $\qquad 3)2.6618 - 6$

$= 0.07714$ $\qquad \log x = 0.8873 - 2$

But if the characteristic is positive, it is simpler to write it in front of the mantissa, and then divide directly.

THE SLIDE RULE

The slide rule is an indispensable aid in all problems in multiplication, division, proportion, squares, square roots, etc., in which a limited degree of accuracy is sufficient. The ordinary 10-in. Mannheim rule (see below) costs \$3 to \$4.50 and gives three significant figures correctly; the 20-in. rule (\$12.50) gives from three to four figures; the Fuller spiral rule (\$30) or the Thacher cylindrical rule (\$35) gives from four to five figures. For many problems the slide rule gives results more rapidly than a table of logarithms; it requires, however, more care in placing the decimal point in the answer. In all work with the slide rule, the position of the decimal point should be determined by inspection (see p. 89), only the sequence of digits being obtained from the instrument itself. Rapidity in the use of the instrument depends mainly on the skill with which the eye can estimate the values of the various divisions on the scale; expertness in this respect comes only with practice. The following explanations should be sufficient to permit the use of the ordinary slide rule successfully without previous experience and without knowledge of logarithms.

Multiplication and Division with a (Theoretical) Complete Logarithmic Scale. Consider a *complete* logarithmic scale (D, Fig. 1), assumed to extend indefinitely in both directions, only the main section, from 1 to 10, however, being usually available. Note that the divisions within the several sections are indentical, except that the numeral attached to each division of any one section is ten times the numeral attached to the corresponding division in the preceding section. [The distances laid off from 1 are proportional to the logarithms of the corresponding numbers, the distance from 1 to 10 being taken as unity.] Consider also a duplicate scale, C, numbered from 1 to 10, and arranged to slide along the fixed scale D as in the figures. By means of such a scale D, and slide C, any two numbers between 1 and 10 (and hence any two numbers whatever, with proper attention to the decimal point) can be multiplied or divided, as in the following examples.

To MULTIPLY 4 BY 6. In Fig. 1, starting with point 1 of the fixed scale, run the eye along from 1 to 4; then set the 1 of the slide opposite this point 4, and *run the eye forward along the slide from* 1 *to* 6; the point thus reached on the fixed scale is 24, which is equal to 4 × 6. This process gives the distance from 1 to 4 *plus* the distance from 1 to 6, and is, in fact, a mechanical method of adding the logarithms of these numbers; hence the result is the product of the numbers. Conversely,

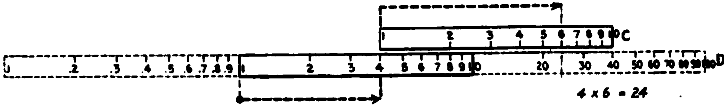

FIG. 1.

To DIVIDE 4 BY 6. In Fig. 2, starting with the point 1 of the fixed scale, run the eye along from 1 to 4; then set the 6 of the slide opposite the point 4, and *run the eye backward along the slide from* 6 *to* 1; the point thus reached on the fixed scale is 0.667, which is equal to 4 ÷ 6. This process gives the distance from 1 to 4 *minus* the distance from 1 to 6; and is, in fact, a mechanical method of subtracting the logarithms of these numbers; hence the result is their quotient.

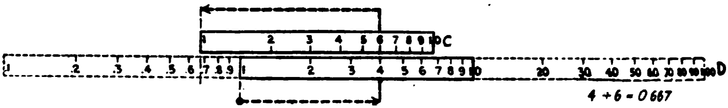

FIG. 2.

Multiplication and Division, Using Only a Single Section of the Scale. If only the main section of scale D is available (as is usually the case in practice), the result of multiplication may fall beyond the scale, as it does in Fig. 1. In such cases *divide the first factor by* 10 *before beginning to multiply*; this will bring the result within the scale, without affecting the sequence of digits.

For example, to multiply 4 by 6. Having found that the setting shown in Fig. 1 is not successful, *reset the slide as in Fig.* 3, *with* 10 *instead of* 1 *opposite* 4; run the eye backward along the slide from 10 to 1, thus reaching the (unrecorded) point corresponding to 4 ÷ 10; then, continuing from this point, run the eye forward along the slide from 1 to 6, as before; the point finally reached on the main scale is 2.4, which has the same sequence of digits as the required value 24. After a little practice, this preliminary step of dividing by 10 will be performed almost intuitively. Whether or not this step is necessary in any given case, can be determined only by trial.

The **general rule for multiplication** may be stated as follows, if preferred: To find the product of two factors, find one factor on the fixed scale; opposite this, set (tentatively) point 1 of the slide; on the slide find the second factor, and opposite this read the product on the main scale, if possible. If the product falls beyond the scale, begin over again, using point 10 of the slide instead of point 1.

In division also, the result may fall beyond the main section of the scale, as it does in Fig. 2. In such cases, it suffices merely to *multiply the result by* 10 in order to bring it within the scale; this will not affect the sequence of digits.

For example, to divide 4 by 6, set the slide as in Fig. 4, and follow out mentally the steps indicated by the arrows. It will be noticed that the supplementary step of multiplying by 10 is performed by simply running the eye along the slide from 1 to 10 without resetting the slide; for this reason, division on the slide rule is slightly easier than multiplication.

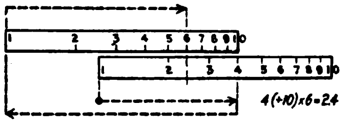

Fig. 3.

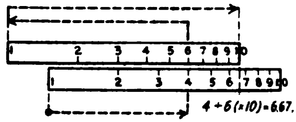

Fig. 4.

The Ordinary Mannheim Slide Rule has four scales, A, B, C, D, as shown in Fig. 5. Scales C and D are essentially the same as the C and D scales described above, and the principle just explained shows how they are used in multiplication and division. The fact that the D scale covers only the main section from 1 to 10 (all decimal points being omitted) is practically no restriction on the scope of the scale, as is seen in the preceding examples. A runner is provided, so that intermediate positions reached in the course of an extended computation may be indicated temporarily on the scale without the necessity of reading off their numerical values. The best runners are those which have no side frame to obscure the numerals.

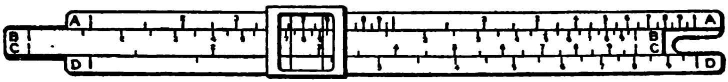

Fig. 5.

In problems involving successive multiplications and divisions, arrange the work so that multiplication and division are performed alternately.

For example, to calculate $\frac{a \times b \times c}{d \times e}$, divide the product $a \times b$ by d; multiply this quotient by c; and divide this product by e. Each operation will require only one shifting either of the slide (for multiplication) or of the runner (for division).

To multiply a number of different quantities by a *constant multiplier*, x, set the point 1 of slide opposite x, and read, by aid of the runner, the products of x by all the quantities which do not fall beyond the scale; then reset the slide, setting 10 instead of 1 opposite x, and read the products of x by all the remaining quantities.

To divide a number of different quantities by a *constant divisor*, y, first find (by the slide rule) the quotient $1 \div y$, and then use this as a constant multiplier.

Scales A and B are exactly like scales C and D, except that they cover two sections of the complete logarithmic scale, the graduations being only half as fine. Either pair of scales may be used for multiplication and division; C and D give more accurate readings, but have the disadvantage that in the case of multiplication the slide must often be shifted to the other end in order to keep the result on the scale—an inconvenience which is not present when the less accurate scales A and B are employed.

By the use of both pairs of scales, problems in squares and square roots may be readily solved; for every number on A, except for the decimal point, is the square of the number directly below it on D (use the runner).

A scale of sines, tangents, and logarithms is often printed on the back of the slide. For further details concerning the use of the slide rule in various problems, see the instruction books furnished with each instrument: Wm. Cox, "Manual of the Mannheim Slide Rule;" F. A. Halsey, "Manual of the Slide Rule;" etc.

Other Types of Slide Rules. The **duplex slide rule** ($5 to $18 according to length) shows on one face the regular *A, B, C, D* scales, and on the other face the scales *A, B′, C′, D* (where *B′* and *C′* are the same as *B* and *C*, only numbered in the reverse order), with a runner encircling the whole scale. This arrangement makes possible the solution of more complicated problems with fewer settings of the slide, but if the rule is to be used only for simple problems, the multiplicity of scales is rather confusing. Less complicated is the **polyphase rule**, which is like a Mannheim rule with the addition of a single inverted scale, *C′*, printed in the middle of the slide. The **log log duplex slide rule** (10 in., $8) is especially adapted for handling complex problems involving fractional powers or roots, hyperbolic logarithms, etc. A number of **circular slide rules** are on the market, the best of which are operated by a milled thumbnut, like the stem wind of a watch. The advantage of the circular rule, aside from its compact size (some models are scarcely larger than a watch), lies in the fact that the scale is endless, so that the slide never has to be reset in order to bring the result within the scale. A disadvantage is found in the necessity of reading the figures in oblique positions, or else continually turning the instrument as a whole in the hand. The **Fuller and Thacher rules** already mentioned are invaluable for problems requiring greater accuracy than can be obtained with the ordinary rules. There are also many **special slide rules**, adapted to various special types of computation, such as calculating discharge of water through pipes, horse power of engines, dimensions of lumber, stadia measurements, etc. One of the most recent devices of this kind is the **Ross meridiograph** (L. Ross, San Francisco, Cal.), which is a circular slide rule for solving certain cases of spherical triangles. The **Eichhorn trigonometrical slide rule** solves any plane triangle.

COMPUTING MACHINES

For certain purposes computing machines have ceased to be luxuries and have become almost necessities; but they are expensive, and should be selected with reference to the special work which is to be done. The machines may be classified roughly into three groups, as follows:

Adding Machines, Non-listing. Of the machines of this kind, the most convenient in the hands of a careful operator is the well-known **Comptometer** (Felt & Tarrant Co., Chicago, Ill.; $250 to $350 according to size), or the recent **Burroughs non-listing** adding machine (Detroit, Mich., $175). To add a number, simply press a key in the proper column; the result appears on the dials in front of the keyboard. Multiplication as well as addition can be performed on this machine with great rapidity, and division also after a little practice. Weight, about 15 lb. Much less rapid, but less expensive and requiring somewhat less skill in operation, is the **Barrett adding machine** (Philadelphia, Pa.) with multiplying attachment. Other key-operated machines are the **Mechanical Accountant** (Providence, R. I.), and the **Austin** (Baltimore, Md.). The **American adding machine** (American Can Co., Chicago, Ill.; $39.50) is operated by pulling up a finger-lever for each digit. Small machines, operated by the use of a stylus, are the **Rapid computer** (Benton Harbor, Mich., $25); the **Gem** (Automatic Adding Machine Co., New York; $10), the **Arithstyle** (New York, $36) and the **Triumph** (Brooklyn, N. Y., $35). These machines, while much less rapid than the key-operated machines, are useful in simple addition. The **Underwood typewriter** is now supplied with a complete electrically driven adding machine attached, and the **Wahl adding attachment** is supplied on the Remington and other typewriters. **Ray Subtracto-Adder** (Richmond, Va., $25).

Adding and Listing Machines. The machines of this group not only add, but also print the items, totals and sub-totals. The **Burroughs** (Detroit, Mich.), the **Wales** (Adder Machine Co., Wilkes-Barre, Pa.), the **Comptograph** (Chicago, Ill.) and the **White** (New Haven, Conn.), resemble each other in having an 81-key keyboard; the **Dalton** (Cincinnati, Ohio) and the **Commercial** (White Adding Machine Co., New Haven, Conn.) have a 10-key and a 9-key keyboard respectively, admitting of operation by the touch method. On all these machines, in order to add a number, first depress the proper keys and then pull a handle (or, in the case of electrically driven machines, press a button) to record the item. Multiplication cannot be performed conveniently, except on the Dalton. Subtraction can be performed only by adding the complement, except on the Commercial and on one type of the Burroughs. The prices range from $125 to $600, according to size and style, new models being constantly devised for special commercial purposes. A new and more portable machine of the 81-key type is the **Barrett** adding and listing machine (Philadelphia, Pa., $250). A cheaper machine, with a 10-key keyboard, is the **Standard** (St. Louis, Mo.). The new **American** adding and listing machine (American Can Co., Chicago, Ill.), operated by pulling up a finger-lever for each digit, costs only $88. The **Ellis** (Newark, N. J.) is an elaborate adding and listing machine having a complete typewriter incorporated with it. **The Elliott-Fisher bookkeeping machine** (Harrisburg, Pa.) and the **Moon-Hopkins billing machine** (St. Louis, Mo.) are intended primarily for commercial use; the latter is a complicated electric machine ($750) which combines many of the features of an adding and listing machine with those of a calculating machine.

Calculating Machines (so-called). Machines of this third group are intended primarily for multiplication and division; the types which have a keyboard can be used effectively for addition and subtraction also. They are all non-listing. The earliest commercially successful types were the Thomas and the Brunsviga. In both these types the multiplicand is set up by moving pegs in slots, or (in the newest models) by depressing keys, and the multiplication is effected by turning a handle for each digit of the multiplier—twice for a digit 2, three times for a digit 3, etc.; the result then appears on the dials. In the Thomas type the handle always turns in the same direction, the change from multiplication to division being effected by a shift key. In the Brunsviga type the handle is turned forward for multiplication and backward for division. Among the best examples of the Thomas type now on the American market are the **Tim**, with a single row of dials, the **Unitas**, with a double row of dials (both sold by Oscar Müller Co., New York City; also with keyboard and electric drive), and the **Reuter** (Philadelphia, Pa.). Prices, $300 upward. Another machine of this type, with keyboard, is the **Record** (U. S. Adding Machine Co., New York City). The **Brunsviga** is represented by Carl H. Reuter, Philadelphia, Pa.; various models. Of somewhat similar type are the **Triumphator** (New York City; $250), and **Colt's calculator** (Culmer Engineering Co., New York City). A new machine, on the same principle, but with keyboard, is the **Monroe** (made in Orange, N. J.; $250). The **Millionaire** (W. A. Morschhauser, New York City; $400), is from the mechanical point of view, the only true multiplying machine on the market (except the Moon-Hopkins). After the multiplicand is set up on the pegs, the digits of the multiplier are indicated successively by moving a pointer, the handle being turned only once for each digit. Further, the movement of the carriage is automatic. The newest models have keyboard and electric drive. The **Ensign electric calculating machine** (Boston, Mass.; $400) is a new machine with an 81-key keyboard on which it adds like an adding machine, and a secondary 10-key keyboard by means of which it multiplies and divides quite as rapidly as any of the calculating machines, the proper key being pressed just once for each digit of the multiplier. The **National calculator** (New York), and the **Lamb calculator** (Calculator Mfg. Co., New York) are less expensive machines devised for figuring payrolls and labor costs. A still simpler device for the same purpose is the **Calculacard** (New York). The machine called the **Calculagraph** (New York) is a time clock which automatically computes labor costs.

For graphical methods of computation, see pp. 106, 119, 170, 173–185.

FINANCIAL ARITHMETIC

For the facts which are commonly required in regard to compound interest, sinking funds, etc., see the headings of the tables on pp. 64–68.

ELEMENTARY GEOMETRY AND MENSURATION

GEOMETRICAL THEOREMS

(For geometrical constructions, see p. 101)

Right Triangles. $a^2 + b^2 = c^2$. (See Fig. 1). $\angle A + \angle B = 90°$. $p^2 = mn$. $a^2 = mc$. $b^2 = nc$. See also p. 105 and p. 132.

Oblique Triangles. (See also pp. 105, 134.) Sum of angles = 180°. An exterior angle = sum of the two opposite interior angles. (Fig. 1.)

The medians, joining each vertex with the middle point of the opposite side, meet in the center of gravity G (Fig. 2), which trisects each median.

The altitudes meet in a point called the orthocenter, O.

The perpendiculars erected at the midpoints of the sides meet in a point C, the center of the circumscribed circle. [In any triangle G, O, and C lie in line, and G is two-thirds of the way from O to C.]

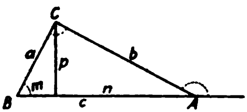

FIG. 1.

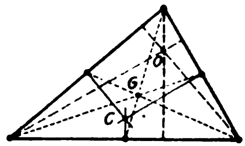

FIG. 2.

The bisectors of the angles meet in the center of the inscribed circle (Fig. 3).

The largest side of a triangle is opposite the largest angle; it is less than the sum of the other two sides, and greater than their difference.

FIG. 3.

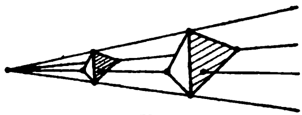

FIG. 4.

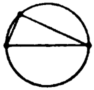
Similar Figures. Any two similar figures, in a plane or in space, can be placed in "perspective," that is, so that straight lines joining corresponding points of the two figures will pass through a common point (Fig. 4). That is, of two similar figures, one is merely an enlargement of the other. Assume that each length in one figure is k times the corresponding length in the other; then each area in the first figure is k^2 times the corresponding area in the second, and each volume in the first figure is k^3 times the corresponding volume in the second. If two lines are cut by a set of parallel lines (or parallel planes), the corresponding segments are proportional.

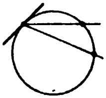
The Circle. (See also pp. 106, 137.) An angle inscribed in a semicircle is a right angle (Fig. 5). An angle inscribed in a circle, or an angle between a chord and a tangent, is measured by half the intercepted arc (Fig. 6). An angle formed by any two lines which meet a circle is measured by half the sum or half the difference of the intercepted arcs, according as the point of intersection of the lines lies inside (Fig. 7) or outside the circle (Fig. 8).

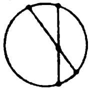
A tangent is perpendicular to the radius drawn to the point of contact.

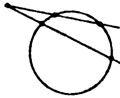
If a variable line through A (Figs. 9 and 10) cuts a circle in P and Q, then

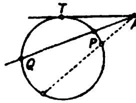
$\overline{AP} \times \overline{AQ}$ is constant; in particular, if A is an external point, $\overline{AP} \times \overline{AQ} = \overline{AT}^2$, where $\overline{AT}$ is the tangent from A.











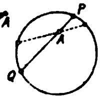


FIG. 5. FIG. 6. FIG. 7. FIG. 8. FIG. 9. FIG. 10.

The radical axis (Fig. 11) of two circles is a straight line such that the tangents drawn from any point of this line to the two circles are of equal length. If the two circles intersect, the radical axis passes through their points of intersection. In any case, the radical axis bisects the common tangents of the two circles. The three radical axes of a set of three circles meet in a common point. (For equations, see p. 137.)

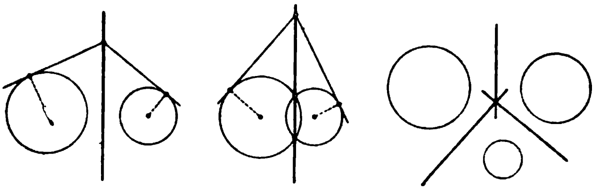

FIG. 11.

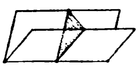
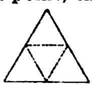
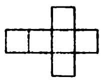
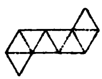
Dihedral Angles. The dihedral angle between two planes is measured by a plane angle formed by two lines, one in each plane, perpendicular to the edge (Fig. 12). (For solid angles, see p. 110.)

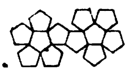
In a **tetrahedron**, or triangular pyramid, the four medians, joining each vertex with the center of gravity of the opposite face, meet in a point, the center of gravity of the tetrahedron; this point is 3/4 of the way from any vertex to the center of gravity of the opposite face. The four perpendiculars erected at the circumcenters of the four faces meet in a point, the center of the circumscribed sphere. The four altitudes meet in a point called the orthocenter of the tetrahedron. The planes bisecting the six dihedral angles meet in a point, the center of the inscribed sphere.











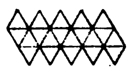


FIG. 12. FIG. 13. FIG. 14. FIG. 15. FIG. 16. FIG. 17.

Regular Polyhedra (see also p. 110): Regular tetrahedron (Fig. 13), bounded by four equilateral triangles; cube (Fig. 14), bounded by six squares; octahedron (Fig. 15), bounded by eight equilateral triangles; dodecahedron (Fig. 16), bounded by twelve regular pentagons; icosahedron (Fig. 17), bounded by twenty equilateral triangles. Figs. 13–17 show how these solids can be made by cutting the surface out of paper and folding it together.

The Sphere. (See also p. 109.) If AB is a diameter, any plane perpendicular to AB cuts the sphere in a circle, of which A and B are called the poles. A great circle on the sphere is formed by a plane passing through the center. A spherical triangle is bounded by arcs of great circles (see p.

134). In two polar triangles, each angle in one is the supplement of the corresponding side in the other. In two symmetrical triangles, the sides and angles of one are equal to the corresponding sides and angles of the other, but arranged in the reverse order (like right-handed and left-handed gloves).

GEOMETRICAL CONSTRUCTIONS

To Bisect a Line AB (Fig. 18). (*a*) From A and B as centers, and with equal radii, describe arcs intersecting in P and Q, and draw PQ, which will bisect AB in M.

(*b*) Lay off $AC = BD$ = approximately half of AB, and then bisect CD.

To Draw a Parallel to a Given Line l Through a Given Point A (Fig. 19). With point A as center draw an arc just touching the line l; with any point O of the line as center, draw an arc BC with the same radius. Then a line through A touching this arc will be the required parallel. Or, use a straight edge and triangle. Or, use a sheet of celluloid with a set of lines parallel to one edge and about ¼ in. apart ruled upon it.

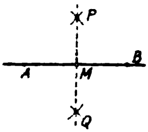

FIG. 18.

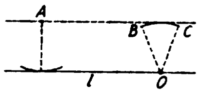

FIG. 19.

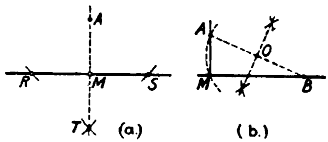

FIG. 20.

To Draw a Perpendicular to a Given Line from a Given Point A Outside the Line (Fig. 20). (*a*) With A as center, describe an arc cutting the line in R and S, and bisect RS in M. Then M is the foot of the perpendicular. (*b*) If A is nearly opposite one end of the line, take any point B of the line and bisect AB in O; then with O as center, and OA or OB as radius, draw an arc cutting the line in M. Or, (*c*) use a straight edge and triangle.

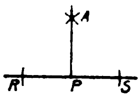

FIG. 21.

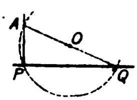

FIG. 22.

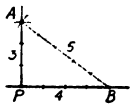

FIG. 23.

To Erect a Perpendicular to a Given Line at a Given Point P. (*a*) Lay off $PR = PS$ (Fig. 21), and with R and S as centers draw arcs intersecting at A. Then PA is the required perpendicular. (*b*) If P is near the end of the line, take any convenient point O (Fig. 22) above the line as center, and with radius OP draw an arc cutting the line in Q. Produce QO to meet the arc in A; then PA is the required perpendicular. (*c*) Lay off $PB = 4$ units of any scale (Fig. 23); from P and B as centers lay off $PA = 3$ and $BA = 5$; then APB is a right angle.

To Divide a Line AB into n Equal Parts (Fig. 24). Through A draw a line AX at any angle, and lay off n equal steps along this line. Connect the last of these divisions with B, and draw parallels through the other divisions. These parallels will divide the given line into n equal parts. A similar method may be used to divide a line into parts which shall be proportional to any given numbers.

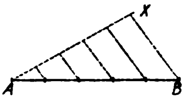

FIG. 24.

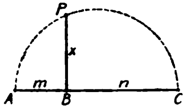

FIG. 25.

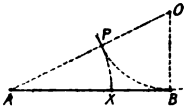

FIG. 26.

To Construct a Mean Proportional (or Geometric Mean) Between Two Lengths, m and n (Fig. 25). Lay off $AB = m$ and $BC = n$ and construct a semicircle on AC as diameter. Let the perpendicular erected at B meet the circumference at P. Then $BP = \sqrt{mn}$. (See p. 115.)

To Divide a Line AB in Extreme and Mean Ratio (the "golden section"). At one end, B, of the given line (Fig. 26), erect a perpendicular, BO, equal to half AB, and join OA. Along OA lay off $OP = OB$, and along AB lay off $AX = AP$. Then X is the required point of division; that is, $\overline{AX}^2 = AB \times BX$. Numerically, $AX = \frac{1}{2}(\sqrt{5} - 1)(AB) = 0.618(AB)$.

To Bisect an Angle AOB (Fig. 27). Lay off $OA = OB$. From A and B as centers, with any convenient radius, draw arcs meeting in M; then OM is the required bisector.

To draw the bisector of an angle when the vertex of the angle is not accessible (Fig. 28). Parallel to the given lines a, b, and equidistant from them, draw two lines a', b' which intersect; then bisect the angle between a' and b'.

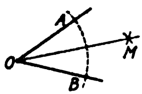

FIG. 27.

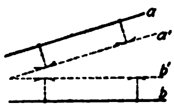

FIG. 28.

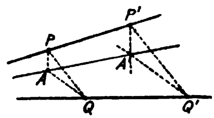

FIG. 29.

To Draw a Line Through a Given Point A and in the Direction of the Point of Intersection of Two Given Lines, when this point of intersection is inaccessible (Fig. 29). Draw any two parallel lines PQ and $P'Q'$ as in the figure; through P' draw a line parallel to PA, and through Q' draw a line parallel to QA; let these lines intersect in A', and draw the line AA'. This line AA' will (if produced) pass through the intersection of the two given lines.

To Construct, Approximately, the Length of a Circular Arc (Rankine). In Fig. 30 draw a tangent at A. Prolong the chord BA to C, making $AC = \frac{1}{2} AB$. With C as center, and radius CB, draw arc cutting the tangent in D. Then AD = arc AB, approximately (error about 4 min. in an arc of 60 deg.). Conversely, to find an arc AB on a given circle to equal a given length AD, take E one-fourth of the way from A to D, and with E as center and radius ED draw an arc cutting the circumference in B. Then arc $AB = AD$, approximately.

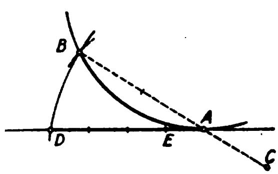

FIG. 30.

To Inscribe a Hexagon in a Circle (Fig. 31). Step around the circumference with a chord equal to the radius. Or, use a 60-deg. triangle.

To Circumscribe a Hexagon About a Circle (Fig. 32). Draw a chord AB equal to the radius. Bisect the arc AB in T. Draw the tangent at T (parallel to AB), meeting OA and OB in P and Q. Then draw a circle with radius OP or OQ and inscribe in it a hexagon, one side being PQ.

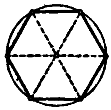

Fig. 31.

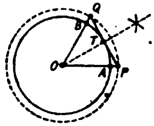

Fig. 32.

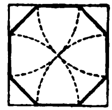

Fig. 33.

To Inscribe an Octagon in a Square (Fig. 33). From the corners as centers, and with radius equal to half the diagonal, draw four arcs, cutting the sides in eight points. The points will be the vertices of the octagon.

To Inscribe an Octagon in a Circle. Draw two perpendicular diameters, and bisect each of the quadrant arcs.

To Circumscribe an Octagon About a Circle. Draw a square about the circle, and draw the tangents to the circle at the points where the circle is cut by the diagonals of the square.

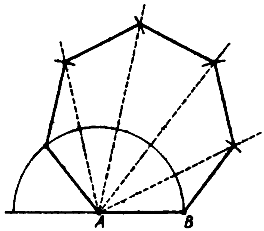

Fig. 34.

To Construct a Polygon of n Sides, One Side AB being Given (Fig. 34). With A as center and AB as radius, draw a semicircle, and divide it into n parts, of which $n - 2$ parts (counting from B) are to be used. Draw rays from A through these points of division, and complete the construction as in the figure (in which $n = 7$). Note that the center of the polygon must lie in the perpendicular bisector of each side.

To Draw a Tangent to a Circle from an external point A (Fig. 35). Bisect AC in M; with M as center and radius MC, draw arc cutting circle in P; then P is the required point of tangency.

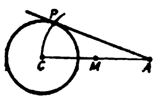

Fig. 35.

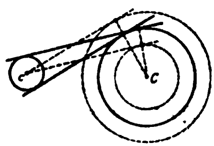

Fig. 36.

To Draw a Common Tangent to Two Given Circles (Fig. 36). Let C and c be the centers and R and r the radii ($R > r$). From C as center, draw two concentric circles with radii $R + r$ and $R - r$; draw tangents to these circles from c; then draw parallels to these lines at distance r. These parallels will be the required common tangents.

To Draw a Circle Through Three Given Points A, B, C, or to find the center of a given circular arc (Fig. 37). Draw the perpendicular bisectors of AB and BC; these will meet in the center, O.

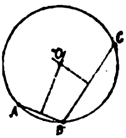

Fig. 37.

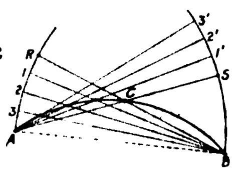

Fig. 38.

To Draw a Circular Arc Through Three Given Points When the Center is not Available (Fig. 38). With A and B as centers, and chord

AB as radius, draw arcs, cut by *BC* in *R* and by *AC* in *S*. Divide *RA* into *n* equal parts, 1, 2, 3, . . . Divide *BS* into the same number of equal parts, and continue these divisions at 1′, 2′, 3′, . . . Connect *A* with 1′, 2′, 3′, . . . and *B* with 1, 2, 3, . . . Then the points of intersection of corresponding lines will be points of the required arc. (Cônstruction valid only when $CA = CB$.)

To Draw a Circle Through Two Given Points, A, B, and Touching a Given Line, l (Fig. 39). Let *AB* meet line *l* in *C*. Draw any circle through *A* and *B*, and let *CT* be tangent to this circle from *C*. Along *l*, lay off *CP* and *CQ* equal to *CT*. Then either *P* or *Q* is the required point of tangency. (Two solutions.) Note that the center of the required circle lies in the perpendicular bisector of *AB*.

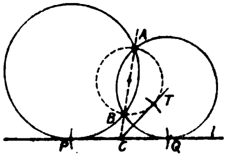

FIG. 39.

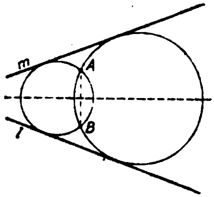

FIG. 40.

To Draw a Circle Through One Given Point, A, and Touching Two Given Lines, l and m (Fig. 40). Draw the bisector of the angle between *l* and *m*, and let *B* be the reflection of *A* in this line. Then draw a circle through *A* and *B* and touching *l* (or *m*), as in preceding construction. (Two solutions.)

To Draw a Circle Touching Three Given Lines (Fig. 41). Draw the bisectors of the three angles; these will meet in the center *O*. (Four solutions.) The perpendiculars from *O* to the three lines give the points of tangency.

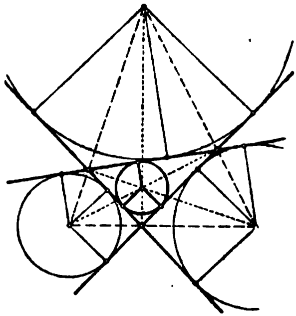

FIG. 41.

To Draw a Circle Through Two Given Points A, B, and Touching a Given Circle (Fig. 42). Draw any circle through *A* and *B*, cutting the given circle in *C* and *D*. Let *AB* and *CD* meet in *E*, and let *ET* be tangent from *E* to the circle just drawn. With *E* as center, and radius *ET*, draw an arc cutting the given circle in *P* and *Q*. Either *P* or *Q* is the required point of contact. (Two solutions.)

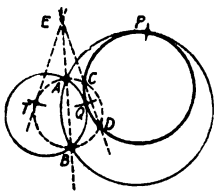

FIG. 42.

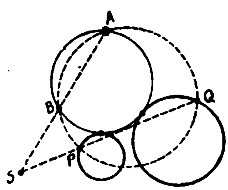

FIG. 43.

To Draw a Circle Through One Given Point, A, and Touching Two Given Circles (Fig. 43). Let *S* be a center of similitude for the two given circles, that is, the point of intersection of two external (or internal) common tangents. Through *S* draw any line cutting one circle in two points, the nearer of which shall be called *P*, and the other in two points, the more remote of which shall be called *Q*. Through *A*, *P*, *Q* draw a circle cutting SA in B. Then draw a circle through A and B and touching one of the given circles (see preceding construction). This circle will touch the other given circle also. (Four solutions.)

To Draw an Annulus Which Shall Contain a Given Number of Equal Contiguous Circles (Fig. 44). (An annulus is a ring-shaped area enclosed between two concentric circles.) Let $R + r$ and $R - r$ be the inner and outer radii of the annulus, r being the radius of each of the n circles. Then the required relation between these quantities is given by $r = R \sin(180°/n)$, or $r = (R + r)[\sin(180°/n)]/[1 + \sin(180°/n)]$.

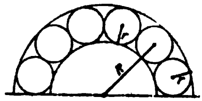

FIG 44.

For **methods of constructing ellipses and other curves,** see pp. 139–156.

LENGTHS AND AREAS OF PLANE FIGURES

Right Triangle (Fig. 45). $a^2 + b^2 = c^2$.
Area $= \frac{1}{2}ab = \frac{1}{2}a^2 \cot A = \frac{1}{2}b^2 \tan A = \frac{1}{4}c^2 \sin 2A$.

Equilateral Triangle (Fig. 46). Area $= \frac{1}{4}a^2\sqrt{3} = 0.43301a^2$.

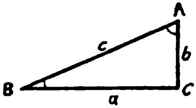

FIG. 45.

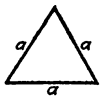

FIG. 46.

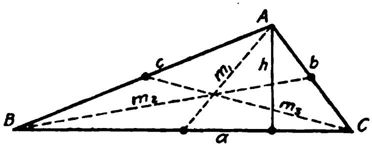

FIG. 47.

Any Triangle (Fig. 47). $s = \frac{1}{2}(a + b + c)$, $t = \frac{1}{2}(m_1 + m_2 + m_3)$,

$r = \sqrt{(s - a)(s - b)(s - c)/s}$ = radius inscribed circle,

$R = \frac{1}{2}a/\sin A = \frac{1}{2}b/\sin B = \frac{1}{2}c/\sin C$ = radius circumscribed circle;

Area $= \frac{1}{2}$ base $\times$ altitude $= \frac{1}{2}ah = \frac{1}{2}ab \sin C = rs = abc/4R$

$= \sqrt{s(s - a)(s - b)(s - c)} = \frac{4}{3}\sqrt{t(t - m_1)(t - m_2)(t - m_3)}$

$= r^2 \cot \frac{1}{2}A \cot \frac{1}{2}B \cot \frac{1}{2}C = 2R^2 \sin A \sin B \sin C$

$= \pm\frac{1}{2}\{(x_1y_2 - x_2y_1) + (x_2y_3 - x_3y_2) + (x_3y_1 - x_1y_3)\}$, where (x_1, y_1), (x_2, y_2), (x_3, y_3) are co-ordinates of vertices. See also p. 134.

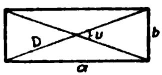

FIG. 48.

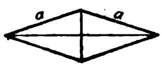

FIG. 49.

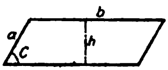

FIG. 50.

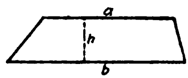

FIG. 51.

Rectangle (Fig. 48). Area $= ab = \frac{1}{2}D^2 \sin u$. [$u$ = angle between diagonals D, D.]

Rhombus (Fig. 49). Area $= a^2 \sin C = \frac{1}{2}D_1D_2$. [$C$ = angle between two adjacent sides; D_1, D_2 = diagonals.]

Parallelogram (Fig. 50). Area $= bh = ab \sin C = \frac{1}{2}D_1D_2 \sin u$. [$u$ = angle between diagonals D_1 and D_2; $D_1^2 + D_2^2 = 2(a^2 + b^2)$].

Trapezoid (Fig. 51). Area $= \frac{1}{2}(a + b)h = \frac{1}{2}D_1D_2 \sin u$. [Bases a and b are parallel; u = angle between diagonals D_1 and D_2.]

Quadrilateral Inscribed in a Circle (Fig. 52). Area $= \frac{1}{2}D_1D_2 \sin u = \sqrt{(s-a)(s-b)(s-c)(s-d)} = \frac{1}{2}(ac+bd)\sin u$; $s = \frac{1}{2}(a+b+c+d)$.

Any Quadrilateral (Fig. 53). Area $= \frac{1}{2}D_1D_2 \sin u$.

NOTE. $a^2+b^2+c^2+d^2 = D_1^2+D_2^2+4m^2$, where m = distance between midpoints of D_1 and D_2.

Polygons. See table, p. 39.

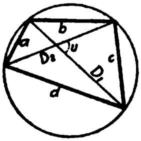

FIG. 52.

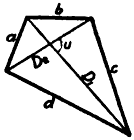

FIG. 53.

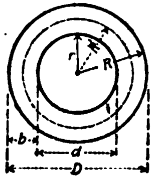

FIG. 54.

FIG. 55.

Circle. Area $= \pi r^2 = \frac{1}{2}Cr = \frac{1}{4}Cd = \frac{1}{4}\pi d^2 = 0.785398d^2$ (table, p. 30). Here r = radius, d = diam., C = circumference $= 2\pi r = \pi d$ (table, p. 28).

Annulus (Fig. 54). Area $= \pi(R^2 - r^2) = \pi(D^2 - d^2)/4 = 2\pi R'b$, where R' = mean radius $= \frac{1}{2}(R+r)$, and $b = R - r$.

Sector (Fig. 55). Area $= \frac{1}{2}rs = \pi r^2(A/360°) = \frac{1}{2}r^2$ rad A, where rad A = radian measure of angle A, and s = length of arc $= r$ rad A (table, p. 44).

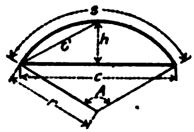

FIG. 56.

Segment (Fig. 56). Area $= \frac{1}{2}r^2$ (rad $A - \sin A$) $= \frac{1}{2}[r(s-c)+ch]$, where rad A = radian measure of angle A (table, pp. 34–35, 44). For small arcs, $s = \frac{1}{3}(8c' - c)$, where c' = chord of half the arc. (Huygens's approximation.) NOTE. $c = 2\sqrt{h(d-h)}$; $c' = \sqrt{dh}$ or $d = c'^2/h$, where d = diameter of circle; $h = r(1 - \cos \frac{1}{2}A)$, $s = 2r$ rad $\frac{1}{2}A$.

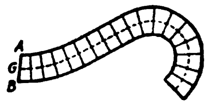

FIG. 57.

Ribbon bounded by two parallel curves (Fig. 57). If a straight line AB moves so that it is always perpendicular to the path traced by its middle point G, then the **area** of the ribbon or strip thus generated is equal to the length of AB times the length of the path traced by G. (It is assumed that the radius of curvature of G's path is never less than $\frac{1}{2}AB$, so that successive positions of the generating line will not intersect.)

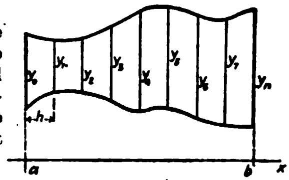

FIG. 58.

Simpson's Rule (Fig. 58). Divide the given area into n panels (where n is some even number) by means of $n+1$ parallel lines, called ordinates, drawn at constant distance h apart; and denote the lengths of these ordinates by $y_0, y_1, y_2, \ldots, y_n$. (Note that y_0 or y_n may be zero.) Then Area $= \frac{1}{3}h[(y_0+y_n)+4(y_1+y_3+y_5\ldots)+2(y_2+y_4+y_6\ldots)]$, approx. The greater the number of divisions, the more accurate the result. Note: Taking $y = f(x)$, where x varies from $x = a$ to $x = b$, and $h = (b-a)/n$, then the error $= -\frac{1}{180}\frac{(b-a)^5}{n^4}f''''(X)$, where $f''''(X)$ is the value of the fourth derivative of $f(x)$ for some (unknown) value, $x = X$, between a and b.

Ellipse (Fig. 59; see also p. 140). Area of ellipse $= \pi ab$. Area of shaded segment $= xy + ab \sin^{-1}(x/a)$. Length of perimeter of ellipse $= \pi(a + b)K$, where $K = [1 + \frac{1}{4}m^2 + \frac{1}{64}m^4 + \frac{1}{256}m^6 + \ldots]$, $m = (a - b)/(a + b)$.

For m =	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
K =	1.002	1.010	1.023	1.040	1.064	1.092	1.127	1.168	1.216	1.273

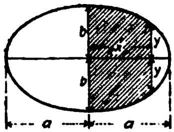

FIG. 59.

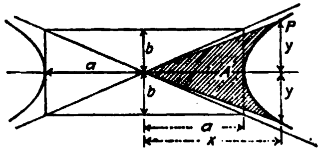

FIG. 60.

Hyperbola (Fig. 60; see also p. 144). In any hyperbola, shaded area $A = ab \log_e\left(\frac{x}{a} + \frac{y}{b}\right)$. In an equilateral hyperbola $(a = b)$, area $A = a^2 \sinh^{-1}(y/a) = a^2 \cosh^{-1}(x/a)$. For tables of hyperbolic functions, see p. 60. Here x and y are co-ordinates of point P.

Parabola (Fig. 61; see also p. 138). Shaded area $A = \frac{2}{3}ch$. In Fig. 62, length of arc $OP = s = \frac{1}{2}PT + \frac{1}{2}p \log_e \cot \frac{1}{2}u$. Here c = any chord; p = semi-latus rectum; PT = tangent at P. Note: $OT = OM = x$.

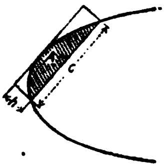

FIG. 61,

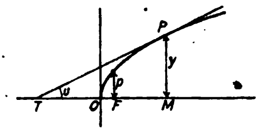

FIG. 62.

Other Curves. For lengths and areas, see pp. 147–156.

SURFACES AND VOLUMES OF SOLIDS

Regular Prism (Fig. 63). Volume $= \frac{1}{2}nrah = Bh$. Lateral area $= nah = Ph$. Here n = number of sides; B = area of base; P = perimeter of base.

Right Circular Cylinder (Fig. 64). Volume $= \pi r^2 h = Bh$. Lateral area $= 2\pi rh = Ph$. Here B = area of base; P = perimeter of base.

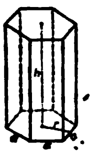

FIG. 63.

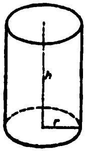

FIG. 64.

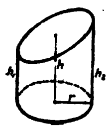

FIG. 65.

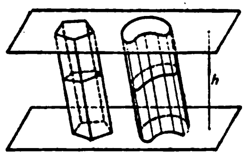

FIG. 66.

Truncated Right Circular Cylinder (Fig. 65). Volume $= \pi r^2 h = Bh$. Lateral area $= 2\pi rh = Ph$. Here h = mean height $= \frac{1}{2}(h_1 + h_2)$; B = area of base; P = perimeter of base.

Any Prism or Cylinder (Fig. 66). Volume $= Bh = Nl$. Lateral area $= Ql$. Here l = length of an element or lateral edge; B = area of base; N = area of normal section; Q = perimeter of normal section.

Any Truncated Prism or Cylinder (Fig. 67). Volume $= Nl$. Lateral area $= Qk$. Here l = distance between centers of gravity of areas of the two bases; k = distance between centers of gravity of perimeters of the two bases; N = area of normal section; Q = perimeter of normal section. For a truncated triangular prism with lateral edges a,b,c, $l = k = \frac{1}{3}(a + b + c)$. Note: l and k will always be parallel to the elements.

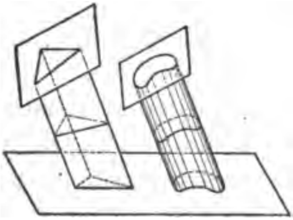

FIG. 67.

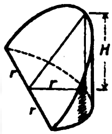

FIG. 68.

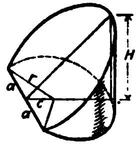

FIG. 69.

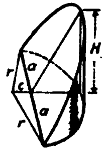

FIG. 70.

Special Ungula of a right circular cylinder. (Fig. 68.). Volume $= \frac{2}{3}r^2H$. Lateral area $= 2rH$. r = radius. (Upper surface is a semi-ellipse.)

Any Ungula of a right circular cylinder. (Figs. 69 and 70.) Volume $= H(\frac{2}{3}a^3 \pm cB)/(r \pm c) = H[a(r^2 - \frac{1}{3}a^2) \pm r^2c \text{ rad } u]/(r \pm c)$. Lateral area $= H(2ra \pm cs)/(r \pm c) = 2rH(a \pm c \text{ rad } u)/(r \pm c)$. If base is greater (less) than a semicircle, use $+$ $(-)$ sign. r = radius of base; B = area of base; s = arc of base; u = half the angle subtended by arc s at center; rad u = radian measure of angle u (see table, p. 44).

Hollow Cylinder (right and circular). Volume $= \pi h(R^2 - r^2) = \pi hb(D - b) = \pi hb(d + b) = \pi hbD' = \pi hb(R + r)$. Here h = altitude; $r,R(d,D)$ = inner and outer radii (diameters); b = thickness $= R - r$; D' = mean diam. $= \frac{1}{2}(d + D) = D - b = d + b$.

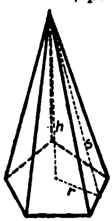

FIG. 71.

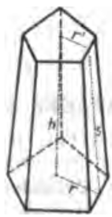

FIG. 72.

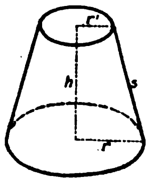

FIG. 73.

Regular Pyramid (Fig. 71). Volume $= \frac{1}{3}$ altitude $\times$ area of base $= \frac{1}{6}hran$. Lateral area $= \frac{1}{2}$ slant height $\times$ perimeter of base $= \frac{1}{2}san$. Here r = radius of inscribed circle; a = side (of regular polygon); n = number of sides; $s = \sqrt{r^2 + h^2}$. Vertex of pyramid directly above center of base.

Right Circular Cone. Volume $= \frac{1}{3}\pi r^2h$. Lateral area $= \pi rs$. Here r = radius of base; h = altitude; s = slant height $= \sqrt{r^2 + h^2}$.

Frustum of Regular Pyramid (Fig. 72).

Volume $= \frac{1}{6}hran[1 + (a'/a) + (a'/a)^2]$.

Lateral area = slant height $\times$ half sum of perimeters of bases = slant height $\times$ perimeter of mid-section $= \frac{1}{2}sn(r + r')$. Here r,r' = radii of inscribed circles; $s = \sqrt{(r - r')^2 + h^2}$; a, a' = sides of lower and upper bases; n = number of sides.

Frustum of Right Circular Cone (Fig. 73). Volume = $\frac{1}{3}\pi r^2 h[1 + (r'/r) + (r'/r)^2] = \frac{1}{3}\pi h(r^2 + rr' + r'^2) = \frac{1}{4}\pi h[(r + r')^2 + \frac{1}{3}(r - r')^2]$. Lateral area $= \pi s(r + r')$; $s = \sqrt{(r - r')^2 + h^2}$.

Any Pyramid or Cone. Volume $= \frac{1}{3}Bh$. B = area of base; h = perpendicular distance from vertex to plane in which base lies.

Any Pyramidal or Conical Frustum (Fig. 74). Volume = $\frac{1}{3}h(B + \sqrt{BB'} + B') = \frac{1}{3}hB[1 + (P'/P) + (P'/P)^2]$. Here B, B' = areas of lower and upper bases; P, P' = perimeters of lower and upper bases.

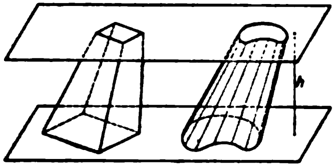

FIG. 74.

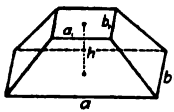

FIG. 75.

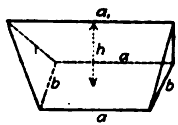

FIG. 76.

Obelisk (Frustum of a rectangular pyramid. Fig. 75).
Volume $= \frac{1}{6}h[(2a + a_1)b + (2a_1 + a)b_1] = \frac{1}{6}h[ab + (a + a_1)(b + b_1) + a_1b_1]$.

Wedge (Rectangular base; a_1 parallel to a, a and at distance h above base. Fig. 76). Volume $= \frac{1}{6}hb(2a + a_1)$.

Sphere. Volume $= V = \frac{4}{3}\pi r^3 = 4.188790r^3 = \frac{1}{6}\pi d^3 = 0.523599d^3$ (table, p. 36) = $\frac{2}{3}$ volume of circumscribed cylinder. Area $= A = 4\pi r^2$ = four great circles (table, p. 30) $= \pi d^2 = 3.14159d^2$ = lateral area of circumscribed cylinder. Here r = radius; $d = 2r$ = diameter $= \sqrt[3]{6V/\pi} = 1.24070\sqrt[3]{V} = \sqrt{A/\pi} = 0.56419\sqrt{A}$.

Hollow Sphere, or spherical shell. Volume = $\frac{4}{3}\pi(R^3 - r^3) = \frac{1}{6}\pi(D^3 - d^3) = 4\pi R_1^2 t + \frac{1}{3}\pi t^3$. Here R, r = outer and inner radii; D, d = outer and inner diameters; t = thickness $= R - r$; R_1 = mean radius = $\frac{1}{2}(R + r)$.

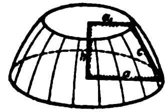

FIG. 77.

Spherical Segment of One Base. Zone (spherical "cap" of Fig. 78). Volume $= \frac{1}{6}\pi h(3a^2 + h^2) = \frac{1}{3}\pi h^2(3r - h)$ (table, p. 38). Lateral area (of zone) $= 2\pi rh = \pi(a^2 + h^2)$. Note: $a^2 = h(2r - h)$, where r = radius of sphere.

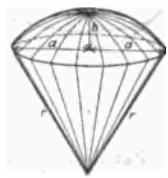

FIG. 78.

Any Spherical Segment. Zone (Fig. 77). Volume $= \frac{1}{6}\pi h(3a^2 + 3a_1^2 + h^2)$. Lateral area (zone) $= 2\pi rh$. Here r = radius of sphere. If the inscribed frustum of a cone be removed from the spherical segment, the volume remaining is $\frac{1}{6}\pi hc^2$, where c = slant height of frustum $= \sqrt{h^2 + (a - a_1)^2}$.

Spherical Sector (Fig. 78). Volume $= \frac{1}{3}r \times$ area of cap $= \frac{2}{3}\pi r^2 h$. Total area = area of cap + area of cone $= 2\pi rh + \pi ra$. Note: $a^2 = h(2r - h)$.

Spherical Wedge bounded by two plane semicircles and a **lune.** (Fig. 79.) Volume of wedge ÷ volume of sphere = $u/360°$. Area of lune ÷ area of sphere = $u/360°$. u = dihedral angle of the wedge.

Spherical Triangle bounded by arcs of three great circles. (Fig. 80.) Area of triangle = $\pi r^2 E/180°$ = area of octant $\times E/90°$. E = spherical excess = $180° - (A + B + C)$, where A, B, and C are angles of the triangle. See also p. 134.

Solid Angles. Any portion of a spherical surface subtends what is called a **solid angle** at the center of the sphere. If the area of the given portion of spherical surface is equal to the square of the radius, the subtended solid angle is called a **steradian,** and this is commonly taken as the unit. The entire solid angle about the center is called a **steregon,** so that 4π steradians = 1 steregon. A so-called "solid right angle" is the solid angle subtended by a quadrantal (or trirectangular) spherical triangle, and a "spherical degree" (now little used) is a solid angle equal to $1/90$ of a solid right angle. Hence 720 spherical degrees = 1 steregon, or π steradians = 180 spherical degrees. If u = the angle which an element of a cone makes with its axis, then the solid angle of the cone contains $2\pi(1 - \cos u)$ steradians.

FIG. 79.

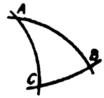

FIG. 80.

Regular Polyhedra. A = area of surface; V = volume; a = edge.

Name of solid (see p. 100)	Bounded by	A/a^2	V/a^3
Tetrahedron	4 triangles	1.7321	0.1179
Cube	6 squares	6.0000	1.0000
Octahedron	8 triangles	3.4641	0.4714
Dodecahedron	12 pentagons	20.6457	7.6631
Icosahedron	20 triangles	8.6603	2.1817

Ellipsoid (Fig. 81). Volume = $\frac{4}{3}\pi abc$, where a, b, c = semi-axes.

Spheroid (or ellipsoid of revolution). The volume of any segment made by two planes perpendicular to the axis of revolution may be found accurately by the prismoidal formula (p. 111).

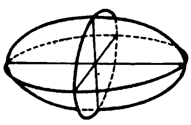

FIG. 81.

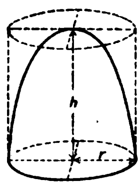

FIG. 82.

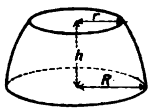

FIG. 83.

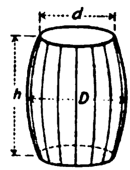

FIG. 84.

Paraboloid of Revolution (Fig. 82). Volume = $\frac{1}{2}\pi r^2 h$ = $\frac{1}{2}$ volume of circumscribed cylinder.

Segment of Paraboloid of Revolution (Bases perpendicular to axis, Fig. 83). Volume of segment = $\frac{1}{2}\pi(R^2 + r^2)h$.

Barrels or Casks (Fig. 84). Volume = $\frac{1}{12}\pi h(2D^2 + d^2)$ approx. for circular staves. Volume = $\frac{1}{15}\pi h(2D^2 + Dd + \frac{3}{4}d^2)$ exactly for parabolic staves.

For a standing cask, partially full, compute contents by the prismoidal formula, p. 111. Roughly, the number of gallons, G, in a cask is given by $G = 0.0034n^2h$, where n = number of inches in the mean diameter, or $\frac{1}{2}(D + d)$, and h = number of inches in the height.

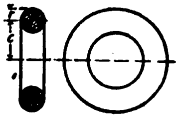

FIG. 85.

Torus, or Anchor Ring (Fig. 85). Volume $= 2\pi^2cr^2$. Area $= 4\pi^2cr$ (Proof by theorems of Pappus).

Theorems of Pappus. 1. Assume that a plane figure, area A, revolves about an axis in its plane but not cutting it; and let s = length of circular arc traced by its center of gravity. Then volume of the solid generated by A is $V = As$. For a complete revolution, $V = 2\pi rA$, where r = distance from axis to center of gravity of A.

2. Assume that a plane curve, length l, revolves about an axis in its plane but not cutting it; and let s = length of circular arc traced by its center of gravity. Then area of the surface generated by l is $S = ls$. For a complete revolution, $S = 2\pi rl$, where r = distance from axis to center of gravity of l.

NOTE. If V_1 or S_1 about any axis is known, then V_2 or S_2 about any parallel axis can be readily computed when the distance between the axes is known.

Generalized Theorems of Pappus. Consider any curved path of length s. If (1) a plane figure, area A [or (2) a plane curve, length l] moves so that its center of gravity slides along this curved path (Fig. 86), while the plane of A [or l] remains always perpendicular to the path, then (1) the volume generated by A is $V = As$ [and (2) the area generated by l is $S = ls$]. The path is assumed to curve so gradually that successive positions of A [or l] will not intersect.

FIG. 86.

The Prismoidal Formula (Fig. 87). Volume $= \frac{1}{6}h(A + B + 4M)$, where h = altitude, A and B = areas of bases and M = area of a plane section midway between the bases. This formula is exactly true for any solid lying between two parallel planes and such that the area of a section at distance x from one of these planes is expressible as a polynomial of not higher than the third degree in x. It is approximately true for many other solids.

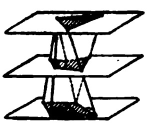

FIG. 87.

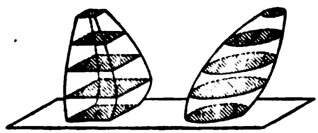

FIG. 88.

Simpson's Rule may be applied to finding volumes, if the ordinates y_1, y_2, be interpreted as the areas of plane sections, at constant distance h apart (p. 106).

Cavalieri's Theorem. Assume two solids to have their bases in the same plane. If the plane section of one solid at every distance x above the base is equal in area to the plane section of the other solid at the same distance x above the base, then the volumes of the two solids will be equal. See Fig. 88.

ALGEBRA

FORMAL ALGEBRA

Notation. The main points of separation in a simple algebraic expression are the + and − signs. Thus, $a + b \times c - d \div x + y$ is to be interpreted as $a + (b \times c) - (d \div x) + y$. In other words, the range of operation of the symbols $\times$ and $\div$ extends only so far as the next + or − sign. As between the signs $\times$ and $\div$ themselves, $a \div b \times c$ means, properly speaking, $a \div (b \times c)$; that is, the $\div$ sign is the stronger separative; but this rule is not always strictly followed, and in order to avoid ambiguity it is better to use the parentheses.

The range of influence of exponents and radical signs extends only over the next adjacent quantity. Thus, $2ax^3$ means $2a(x^3)$, and $\sqrt{2}ax$ means $(\sqrt{2})\,(ax)$. Instead of $\sqrt{2}ax$, it is safer, however, to write $\sqrt{2}\cdot ax$, or, better, $ax\sqrt{2}$.

Any expression within parentheses is to be treated as a single quantity. A horizontal bar serves the same purpose as parentheses.

The notation $a \cdot b$, or simply ab, means $a \times b$; and $a:b$, or a/b, means $a \div b$.

The symbol $|a|$ means the "absolute value of a," regardless of sign; thus, $|-2| = |+2| = 2$.

The symbol $n!$ (where n is a whole number) is read: "n factorial," and means the product of the natural numbers from 1 to n, inclusive. Thus $1! = 1$; $2! = 1 \times 2$; $3! = 1 \times 2 \times 3$; $4! = 1 \times 2 \times 3 \times 4$; etc.

The symbol $\neq$ or $\ne$ means "not equal to"; $\pm$ means "plus or minus."

The symbol $\approx$ is sometimes used for "approximately equal to."

Addition and Subtraction. $a + b = b + a$.

$(a + b) + c = a + (b + c)$. $a - (-b) = a + b$. $a - a = 0$.

$a + (x - y + z) = a + x - y + z$. $a - (x - y + z) = a - x + y - z$.

A minus sign preceding a parenthesis operates to reverse the sign of every term within, when the parentheses are removed.

Multiplication and Simple Factoring. $ab = ba$. $(ab)c = a(bc)$. $a(b + c) = ab + ac$. $a(b - c) = ab - ac$. Also, $a \times (-b) = -ab$, and $(-a) \times (-b) = ab$; "unlike signs give minus; like signs give plus."

$(a + b)(a - b) = a^2 - b^2$.

$(a + b)^2 = a^2 + 2ab + b^2$, $(a - b)^2 = a^2 - 2ab + b^2$.

$(a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$, $(a - b)^3 = a^3 - 3a^2b + 3ab^2 - b^3$; etc.

(See table of binomial coefficients, p. 39; also p. 114.)

$a^2 - b^2 = (a - b)(a + b)$, $a^3 - b^3 = (a - b)(a^2 + ab + b^2)$.

$a^n - b^n = (a - b)(a^{n-1} + a^{n-2}b + a^{n-3}b^2 + \ldots + ab^{n-2} + b^{n-1})$.

$a^n + b^n$ is factorable by $a + b$ only when n is odd; thus,

$a^3 + b^3 = (a + b)(a^2 - ab + b^2)$,

$a^5 + b^5 = (a + b)(a^4 - a^3b + a^2b^2 - ab^3 + b^4)$; etc.

The following transformation is sometimes useful:

$$ax^2 + bx + c = a\left[\left(x + \frac{b}{2a}\right)^2 - \left(\frac{\sqrt{b^2 - 4ac}}{2a}\right)^2\right].$$

Fractions. If m is not zero, $\dfrac{ma + mb + mc}{mx + my} = \dfrac{a + b + c}{x + y}$; that is, both numerator and denominator of a fraction may be multiplied or divided by any quantity different from zero, without altering the value of the fraction.

To add two fractions, reduce each to a common denominator, and add the numerators: $\frac{a}{b}+\frac{x}{y}=\frac{ay}{by}+\frac{bx}{by}=\frac{ay+bx}{by}$.

To multiply two fractions: $\frac{a}{b}\times\frac{x}{y}=\frac{ax}{by}$; $\frac{a}{b}\times x=\frac{a}{b}\times\frac{x}{1}=\frac{ax}{b}$.

To divide one fraction by another, invert the divisor and multiply:

$$\frac{a}{b}\div\frac{x}{y}=\frac{a}{b}\times\frac{y}{x}=\frac{ay}{bx};\quad \frac{a}{b}\div x=\frac{a}{b}\times\frac{1}{x}=\frac{a}{bx}.$$

Ratio and Proportion. The notation $a:b::c:d$, which is now passing out of use, is read: "a is to b as c is to d," and means simply $(a/b)=(c/d)$, or $ad=bc$. a and d are called the "extremes," b and c the "means," and d the "fourth proportional" to a, b, and c. The "mean proportional" between two numbers is the square root of their product; also called the "geometric mean" of the numbers (p. 115). If $a/b=c/d$, then $(a+b)/b=(c+d)/d$, and $(a-b)/b=(c-d)/d$; whence also, $(a+b)/(a-b)=(c+d)/(c-d)$. If $a/x=b/y=c/z=\ .\ .\ .=r$, then

$$(a+b+c+\ .\ .\ .)/(x+y+z+\ .\ .\ .)=r.$$

Variation. The notation $x \propto y$ is read: "x varies directly as y," or "x is directly proportional to y," and means $x=ky$, where k is some constant. To determine the constant k, it is sufficient to know any pair of values, as x_1 and y_1, which belong together; then $x_1=ky_1$, and hence $x/x_1=y/y_1$, or $x=(x_1/y_1)y$. The expression "x varies inversely as y," or "x is inversely proportional to y," means that x is proportional to $1/y$, or $x=k/y$.

Exponents. $a^{m+n}=a^ma^n$. $a^{m-n}=a^m/a^n$. $a^0=1$ (if $a\neq 0$). $a^{-m}=1/a^m$. $(a^m)^n=a^{mn}$. $a^{1/n}=\sqrt[n]{a}$. Thus: $a^{1/2}=\sqrt{a}$, and $a^{1/3}=\sqrt[3]{a}$. $a^{m/n}=\sqrt[n]{a^m}$. Thus: $a^{2/3}=\sqrt[3]{a^2}$ and $a^{3/2}=\sqrt{a^3}$. $(\sqrt[n]{a})^n=a$. $(ab)^n=a^nb^n$. $(a/b)^n=a^n/b^n$. $(-a)^n=a^n$ if n is even. $(-a)^n=-a^n$ if n is odd. If n is positive and increases indefinitely, a^n becomes infinite if $a>1$, and approaches 0 if $a<1$ (a being always positive). Graphs, p. 174; series, p. 160.

Radicals. Except in the simple cases of square root and cube root, radical signs should always be replaced by fractional exponents: $\sqrt[n]{a}=a^{1/n}$. $(\sqrt[n]{a})^n=(a^{1/n})^n=a$. If n is odd, $\sqrt[n]{-a}=-\sqrt[n]{a}$; but if n is even, $\sqrt[n]{-a}$ is imaginary. Every positive number a has two square roots, one positive and the other negative; but the notation $\sqrt{a}$ always means the positive root; thus, $\sqrt{9}=3$; $-\sqrt{9}=-3$. If the denominator of a fraction is of the form $\sqrt{a}\pm\sqrt{b}$, it is possible to "rationalize the denominator" by multiplying both numerator and denominator by $\sqrt{a}\mp\sqrt{b}$. Thus:

$$\frac{\sqrt{a}+\sqrt{b}}{\sqrt{a}-\sqrt{b}}=\frac{(\sqrt{a}+\sqrt{b})(\sqrt{a}+\sqrt{b})}{(\sqrt{a}-\sqrt{b})(\sqrt{a}+\sqrt{b})}=\frac{a+b+2\sqrt{ab}}{a-b}$$

Logarithms. (For the use of logarithms in numerical computation, see p. 91.) The logarithm of a (positive) number N is the exponent of that power to which the base (10 or e) must be raised to produce N. Thus, $x=\log_{10}N$ means that $10^x=N$, and $x=\log_e N$ means that $e^x=N$. Logarithms to base 10 are called **common, denary**, or **Briggsian** logarithms. For table of 4-place common logarithms see pp. 40–43.

Logarithms to base e are called **hyperbolic, natural,** or **Napierian** logarithms. Here $e = 1 + 1 + 1/2! + 1/3! + 1/4! + \ldots = 2.718281828459\ldots$ For table of 4-place hyperbolic logarithms see pp. 58, 59.

If the subscript 10 or e is omitted, the base must be inferred from the context, the base 10 being used in numerical computation, and the base e in theoretical work. In either system,

$\log (ab) = \log a + \log b$	$\log (a^n) = n \log a$	$\log 0 = -\infty$
$\log (a/b) = \log a - \log b$	$\log (\sqrt[n]{a}) = (1/n) \log a$	$\log 1 = 0$
$\log (1/n) = -\log n$	$\log (\text{base}) = 1$	$\log \infty = \infty$

The two systems are related as follows:

$\log_{10} e = M = 0.4342944819\ldots$; $\log_e 10 = 1/M = 2.3025850930\ldots$
$\log_{10} x = 0.4343 \log_e x$; $\log_e x = 2.3026 \log_{10} x$.

For tables of multiples of M and $1/M$, see p. 62. For graphs of the logarithmic and exponential functions, see p. 174; series, p. 160.

The Binomial Theorem. (For table of binomial coefficients, see p. 39 and p. 116.)

Let $(n)_1 = n$, $(n)_2 = \dfrac{n(n-1)}{1 \times 2}$, $(n)_3 = \dfrac{n(n-1)(n-2)}{1 \times 2 \times 3}$,

$$(n)_4 = \frac{n(n-1)(n-2)(n-3)}{1 \times 2 \times 3 \times 4}, \ldots$$

Then, for any value of n, provided $|x| < 1$,

$$(1+x)^n = 1 + (n)_1 x + (n)_2 x^2 + (n)_3 x^3 + (n)_4 x^4 + \ldots$$

(If n is a positive integer, the series breaks off with the term in x^n, and is valid without restrictions on x, see p. 112.)

The most useful **special cases** are the following:

$$\sqrt{1+x} = (1+x)^{1/2} = 1 + \frac{1}{2}x - \frac{1}{8}x^2 + \frac{1}{16}x^3 - \frac{5}{128}x^4 + \ldots \quad (|x| < 1)$$

$$\sqrt[3]{1+x} = (1+x)^{1/3} = 1 + \frac{1}{3}x - \frac{1}{9}x^2 + \frac{5}{81}x^3 - \frac{10}{243}x^4 + \ldots \quad (|x| < 1)$$

$$\frac{1}{1+x} = (1+x)^{-1} = 1 - x + x^2 - x^3 + x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{1+x}} = (1+x)^{-1/2} = 1 - \frac{1}{2}x + \frac{3}{8}x^2 - \frac{5}{16}x^3 + \frac{35}{128}x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt[3]{1+x}} = (1+x)^{-1/3} = 1 - \frac{1}{3}x + \frac{2}{9}x^2 - \frac{14}{81}x^3 + \frac{35}{243}x^4 - \ldots \quad (|x| < 1)$$

$$\sqrt{(1+x)^3} = (1+x)^{3/2} = 1 + \frac{3}{2}x + \frac{3}{8}x^2 - \frac{1}{16}x^3 + \frac{3}{128}x^4 - \ldots \quad (|x| < 1)$$

$$\frac{1}{\sqrt{(1+x)^3}} = (1+x)^{-3/2} = 1 - \frac{3}{2}x + \frac{15}{8}x^2 - \frac{35}{16}x^3 + \frac{315}{128}x^4 - \ldots \quad (|x| < 1)$$

with corresponding formulæ for $\sqrt{1-x}$, etc., obtained by reversing the signs of the odd powers of x. Also, provided $|b| < |a|$:

$$(a+b)^n = a^n\left(1 + \frac{b}{a}\right)^n = a^n + (n)_1 a^{n-1}b + (n)_2 a^{n-2}b^2 + (n)_3 a^{n-3}b^3 + \ldots$$

where $(n)_1$, $(n)_2$, etc., have the values given above.

Arithmetical Progression. In an arithmetical progression, a; $a + d$; $a + 2d$; $a + 3d$; . . ., each term is obtained from the preceding term by adding a constant, called the constant difference, d. If n is the number of terms, the last term is $l = a + (n-1)d$; the "average" term is $\frac{1}{2}(a + l)$;

and the sum of the n terms is n times the average term, or $S = \frac{1}{2}n(a + l)$. The **arithmetical mean** between a and b is $(a + b)/2$.

Geometrical Progression. In a geometrical progression, a; ar; ar^2; ar^3; . . ., each term is obtained from the preceding term by multiplying by a constant, called the constant ratio, r. The nth term is ar^{n-1}. The sum of the first n terms is $S = a(r^n - 1)/(r - 1) = a(1 - r^n)/(1 - r)$. If r is a positive or negative fraction, that is, if $-1 < r < +1$, then r^n will approach zero as n increases, and the sum of n terms will approach $a/(1 - r)$ as a limit. The **geometric mean** between a and b is $\sqrt{ab}$; also called the **mean proportional** between a and b (p. 113; construction, p. 102).

The **harmonic mean** between a and b is $2ab/(a + b)$.

Summation of Certain Series by Second and Third Differences. Let $a_1, a_2, a_3, \ldots a_n$ be any series of n numbers, as in the first column of the adjoining scheme. By subtracting each number from the next following, form the column of "first differences," and by repeating this process, form the columns of second, third, etc., differences. If the kth differences are all equal, so that subsequent differences are all zero, the original series is called an arithmetical series of the kth order. In this special case the series can be summed as follows: Denote the numbers which stand at the head of the successive columns of differences by $D', D'', D''', \ldots$ Then the nth term of the series is a_n, and the sum of the first n terms is S_n, where

Numbers	1st diff.	2nd diff.	3rd diff.
−64	37	.	
−27	19	−18	
−8	7	−12	6
−1	1	−6	6
0	1	0	6
1	7	6	6
8	.	.	.
.			

$$a_n = a_1 + (n-1)D' + \frac{(n-1)(n-2)}{1 \times 2}D'' + \frac{(n-1)(n-2)(n-3)}{1 \times 2 \times 3}D''' + \ldots$$

$$S_n = na_1 + \frac{n(n-1)}{1 \times 2}D' + \frac{n(n-1)(n-2)}{1 \times 2 \times 3}D'' + \frac{n(n-1)(n-2)(n-3)}{1 \times 2 \times 3 \times 4}D''' + \ldots$$

If the series is, for example, of the third order, each of these formulæ will stop with the term involving D'''; and only a few terms of the series are required for the computation of the D's. (Differentials, p. 159.)

Sum of the Squares or Cubes of the First n Natural Numbers.

$$1 + 2 + 3 + \ldots + (n - 1) + n = \tfrac{1}{2}n(n + 1).$$
$$1^2 + 2^2 + 3^2 + \ldots + (n - 1)^2 + n^2 = \tfrac{1}{6}n(n + 1)(2n + 1).$$
$$1^3 + 2^3 + 3^3 + \ldots + (n - 1)^3 + n^3 = [\tfrac{1}{2}n(n + 1)]^2.$$

Formula for Interpolation by Second Differences. In any ordinary table giving a quantity y as a function of a variable x, let it be required to find the value of y corresponding to a value of x which is not given directly in the table, but which lies between two tabulated values, as x_1 and x_2. If $x = x_1 + md$, where $d = x_2 - x_1$ = the constant interval between two successive x's, and m is some proper fraction, then the corresponding value of y will be given by the formula

$$y = y_1 + mD' + \frac{m(m-1)}{1 \times 2}D'' + \frac{m(m-1)(m-2)}{1 \times 2 \times 3}D''' + \ldots$$

where $D', D'', D''', \ldots$ are the first, second, third, . . . differences in the series of y's which begins with y_1 (see above), provided the function is of such a nature that the differences of higher orders become negligibly small.

The coefficients of D', D'', D''', . . . in the formula are the binomial coefficients for fractional values of m (see following table). The several terms of the formula (with careful attention to sign) are the successive corrections which must be added to y_1; the sum of these corrections should be rounded out to the nearest unit of the last significant place before adding. If $D'' < 4$, the term involving D'', and later terms, can be neglected; the formula then reduces to $y = y_1 + mD'$, which is the familiar formula for ordinary, or "linear," interpolation. If $D''' < 8$ (or $D''''' < 12$, or $D'''''' < 16$), the term involving D''' (or D'''', or D''''') can be neglected.

Binomial Coefficients for Fractional Values of m

m	$(m)_2$	$(m)_3$	$(m)_4$	$(m)_5$
0.0	− 0.0000	0.0000	− 0.0000	0.0000
0.1	− 0.0450	0.0285	− 0.0207	0.0161
0.2	− 0.0800	0.0480	− 0.0336	0.0255
0.3	− 0.1050	0.0595	− 0.0402	0.0297
0.4	− 0.1200	0.0640	− 0.0416	0.0300
0.5	− 0.1250	0.0625	− 0.0391	0.0273
0.6	− 0.1200	0.0560	− 0.0336	0.0228
0.7	− 0.1050	0.0455	− 0.0262	0.0173
0.8	− 0.0800	0.0320	− 0.0176	0.0113
0.9	− 0.0450	0.0165	− 0.0087	0.0054

Here $(m)_2 = \frac{m(m-1)}{1 \times 2}$, $(m)_3 = \frac{m(m-1)(m-2)}{1 \times 2 \times 3}$, $(m)_4 = \frac{m(m-1)(m-2)(m-3)}{1 \times 2 \times 3 \times 4}$, etc. Compare p. 39.

Permutations. The number of possible permutations or arrangements of n different elements is $1 \times 2 \times 3 \times \ldots \times n = n!$ (read: "n factorial").

If among the n elements there are p equal ones of one sort, q equal ones of another sort, r equal ones of a third sort, etc., then the number of possible permutations is $(n!)/(p! \times q! \times r! \times \ldots)$, where $p + q + r + \ldots = n$.

Combinations. The number of possible combinations or groups of n elements taken r at a time (without repetition of any element within any one group), is $[n(n-1)(n-2)(n-3) \ldots (n-r+1)]/(r!) = (n)_r$. (See table of binomial coefficients, p. 39.) If repetitions are allowed, so that a group, for example, may contain as many as r equal elements, then the number of combinations of n elements taken r at a time is $(m)_r$, where $m = n + r - 1$. NOTE: $(n)_1 + (n)_2 + \ldots + (n)_n = 2^n - 1$.

SOLUTION OF EQUATIONS IN ONE UNKNOWN QUANTITY

Roots of an Equation. An equation containing a single variable x will in general be true for some values of x and false for other values. Any value of x for which the equation is true is called a **root** of the equation. To "solve" an equation means to find all its roots. Any root of an equation, when substituted therein for x, will "satisfy" the equation. An equation which is true for all values of x, like $(x+1)^2 = x^2 + 2x + 1$, is called an **identity** [often written $(x+1)^2 \equiv x^2 + 2x + 1$].

Types of Equations.

(*a*) Algebraic Equations:
of the first degree (linear), *e.g.*, $2x + 6 = 0$ (root: $x = -3$);
of the second degree (quadratic), *e.g.*, $x^2 - 2x - 3 = 0$ (roots: $-1, 3$);
of the third degree (cubic), *e.g.*, $x^3 - 6x^2 + 5x + 12 = 0$ (roots: $-1, 3, 4$).

(*b*) Transcendental Equations:
exponential equations, *e.g.*, $2^x = 32$ (root: $x = 5$); $2^x = -32$ (no root); trigonometric equations, *e.g.*, $10 \sin x - \sin 3x = 4$ (roots: 30°, 150°).

Legitimate Operations on Equations. An equation which is true for a particular value of x will remain true for that value of x after any one of the following operations is performed:

Adding any quantity to both sides; subtracting any quantity from both sides; transposing any term from one side to the other, provided its sign be changed; multiplying or dividing both sides by any quantity which is not zero; changing the signs of all the terms; raising both sides to any positive integral power; extracting any odd root of both sides; extracting any even root of both sides, provided the $\pm$ sign is used; taking the logarithms of both sides (both sides being positive); taking the sin, cos, tan, etc., of both sides.

Notice, however, that the new equation obtained by some of these operations may possess "additional roots" which did not belong to the original equation. This occurs especially when both sides are squared; thus, $x = -2$ has only one root, namely, -2; but $x^2 = 4$, obtained by squaring, has not only the root -2 but also another root, $+2$.

Equations of the First Degree (Linear Equations). Solution: Collect all the terms involving x on one side of the equation, thus: $ax = b$, where a and b are known numbers. Then divide through by the coefficient of x, obtaining $x = b/a$ as the root.

Equations of the Second Degree (Quadratic Equations). Solution: Throw the equation into the standard form $ax^2 + bx + c = 0$. Then the two roots are:

$$x_1 = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \qquad x_2 = \frac{-b - \sqrt{b^2 - 4ac}}{2a}$$

The roots are real-and-distinct, coincident, or imaginary, according as $b^2 - 4ac$ is positive, zero, or negative. The sum of the roots is $x_1 + x_2 = -b/a$; the product of the roots is $x_1x_2 = c/a$.

Graphical Solution. Write the equation in the form $x^2 = px + q$, and plot the parabola $y_1 = x^2$, and the straight line $y_2 = px + q$. The abscissæ of the points of intersection will be the roots of the equation. If the line does not cut the parabola, the roots are imaginary.

Equations of the Third Degree with Term in x^2 Absent. Solution: After dividing through by the coefficient of x^3, any equation of this type can be written $x^3 = Ax + B$. Let $p = A/3$ and $q = B/2$. The general solution is as follows:

Case 1. $q^2 - p^3$ positive. One root is real, namely

$$x_1 = \sqrt[3]{q + \sqrt{q^2 - p^3}} + \sqrt[3]{q - \sqrt{q^2 - p^3}};$$

the other two roots are imaginary.

Case 2. $q^2 - p^3 =$ zero. Three roots real, but two of them equal.

$$x_1 = 2\sqrt[3]{q}, \quad x_2 = -\sqrt[3]{q}, \quad x_3 = -\sqrt[3]{q}.$$

Case 3. $q^2 - p^3$ negative. All three roots real and distinct. Determine an angle u between 0 and 180°, such that $\cos u = q/(p\sqrt{p})$. Then

$$x_1 = 2\sqrt{p}\cos(u/3), \quad x_2 = 2\sqrt{p}\cos(u/3 + 120°), \quad x_3 = 2\sqrt{p}\cos(u/3 + 240°).$$

Graphical Solution. Plot the curve $y_1 = x^3$, and the straight line $y_2 = Ax + B$. The abscissæ of the points of intersection will be the roots of the equation.

Equations of the Third Degree (General Case). Solution: The general cubic equation, after dividing through by the coefficient of the highest power, may be written $x^3 + ax^2 + bx + c = 0$. To get rid of the term in x^2, let $x = x_1 - a/3$. The equation then becomes $x_1^3 = Ax_1 + B$, where $A = 3(a/3)^2 - b$, and $B = -2(a/3)^3 + b(a/3) - c$. Solve this equation for x_1, by the method above, and then find x itself from $x = x_1 - (a/3)$.

Graphical Solution. Without getting rid of the term in x^2, write the equation in the form $x^3 = -a[x + (b/2a)]^2 + [a(b/2a)^2 - c]$, and solve by the graphical method.

General Properties of Algebraic Equations. An algebraic equation of the nth degree in x is an equation of the type

$$a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \ldots + a_{n-1}x + a_n = 0$$

where the a's are any given numbers (a_0 not zero), the expression on the left being called a **polynomial** of the nth degree in x. Such an equation will, in general, have n roots; but some of these n roots may be equal, and some may be imaginary. **Imaginary roots** always occur in pairs.

If the equation is written in the form: (a polynomial in x) $= 0$, then (1) if a is a root of the equation, $x - a$ is a factor of the polynomial; (2) if the polynomial can be factored in the form $(x - p)(x - q)(x - r) \ldots = 0$, each of the quantities $p, q, r, \ldots$ is a root of the equation; (3) if x is very large (either positive or negative), the higher powers of x are the most important; (4) if x is very small, the higher powers may be neglected.

Short Method of Substitution in a Polynomial. To find the value of $4x^4 - 14x^3 + 23x - 26$ when $x = 3$, for example, first arrange the terms in order of descending powers of x, and write the detached coefficients, with their signs, in a row, taking care to supply a zero coefficient for any missing term, including the constant term. Then, beginning at the left, bring down the first coefficient; multiply this by 3, and add to the second coefficient; multiply this result by 3 again, and add to the third coefficient; and so on. The final result, -11, is the value of the polynomial when $x = 3$.

$$\begin{array}{rrrrrl} 4 & -14 & 0 & 23 & -26 & (3 \\ & 12 & -6 & -18 & 15 & \\ \hline 4 & -2 & -6 & 5 & -11 & \end{array}$$

Short Method of Dividing a Polynomial by x − a. The device just explained gives not only the value of the polynomial when $x = 3$, but also the result of dividing the polynomial by $x - 3$. Thus, in the case illustrated, the quotient is $4x^3 - 2x^2 - 6x + 5$ and the remainder is -11. That is, $4x^4 - 14x^3 + 0x^2 + 23x - 26 = (x - 3)(4x^3 - 2x^2 - 6x + 5) - 11$.

Exponential Equations. To solve an equation of the form $a^x = b$, take the logarithms of both sides: $x \log a = \log b$, whence $x = (\log b)/(\log a)$. For example, if $3^x = 0.4$, $x = \log 0.4/\log 3 = (0.6021 - 1)/0.4771 = -0.3979/0.4771 = -0.8340$. Notice that the complete logarithm must be taken, not merely the mantissa.

Trigonometric Equations. (1) To solve $a \cos x + b \sin x = c$, where a and b are positive: Find the acute angle u for which $\tan u = b/a$, and the angle v (between 0 and 180°) for which $\cos v = c/\sqrt{a^2 + b^2}$. Then $x_1 = u + v$ and $x_2 = u - v$ are roots of the equation.

(2) To solve $a \cos x - b \sin x = c$, where a and b are positive: Find u and v as above. Then $x_1 = -(u + v)$ and $x_2 = -(u - v)$ are roots of the equation.

General Method of Solution by Trial and Error. This method is applicable to a numerical equation of any form, and can be carried out to any desired degree of approximation. It is especially useful when a first approximation to a root is already known. Write the equation in the form

$f(x) = 0$, where $f(x)$ means any function of x, and plot the curve $y = f(x)$ for a sufficient number of values of x to obtain a general idea of the shape of the curve. Then pick out the regions in which the curve appears to cross the axis of x, and plot the curve more accurately in each of these regions. Thus, by successive approximations, plotting the important parts of the curve on a larger and larger scale, determine as accurately as necessary the points where the curve crosses the axis—that is, the values of x which make $f(x)$ equal to zero.

Thus, suppose that $f(x) = 3.0$ when $x = 2.6$ and -5.0 when $x = 2.7$ (see Fig. 1). Then the curve must cross the axis somewhere between $x = 2.6$ and $x = 2.7$; and since it will not vary greatly from a straight line between those points, it is seen that it must

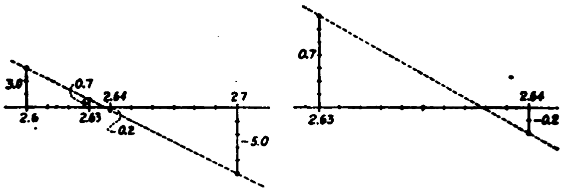

FIG. 1.

cross near 2.64. Suppose the value of $f(x)$ when computed for $x = 2.64$, is -0.2, and when computed for $x = 2.63$ is $+0.7$; then the root lies between $x = 2.63$ and 2.64. Plotting this section on the larger scale, it is seen that the next guess should be about 2.638; and so on.

Instead of writing the original equation with all the terms on the left-hand side, it is often better to divide the expression into two parts, say $f_1(x)$ and $f_2(x)$, writing the equation in the form $f_1(x) = f_2(x)$. If then the two curves $y_1 = f_1(x)$ and $y_2 = f_2(x)$ be plotted separately, on the same diagram, the value of x corresponding to their point of intersection will be the desired root.

SOLUTION OF SIMULTANEOUS EQUATIONS

The Meaning of a System of Simultaneous Equations. To solve a system of n simultaneous equations in n unknowns, means to find all the sets of values of the unknowns (if any) which, when substituted in the given equations, will satisfy all the equations at the same time. If a system of equations has no solution, the equations are "inconsistent;" if it has an infinite number of solutions, the equations are "not all independent."

Simultaneous Equations of the First Degree in Two Unknowns.

$$\begin{array}{ll|c|c|}
 & & \multicolumn{2}{c}{\text{Factors}} \\
(1) & a_1x + b_1y = c_1 & b_2 & -a_2 \\
(2) & a_2x + b_2y = c_2 & -b_1 & a_1 \\
\hline
\end{array}$$

$$(a_1b_2 - a_2b_1)x = b_2c_1 - b_1c_2 \qquad \therefore x = (b_2c_1 - b_1c_2)/(a_1b_2 - a_2b_1)$$
$$(a_1b_2 - a_2b_1)y = a_1c_2 - a_2c_1 \qquad \therefore y = (a_1c_2 - a_2c_1)/(a_1b_2 - a_2b_1)$$

Here (1) is multiplied by b_2, (2) by $-b_1$, and the products added so as to eliminate y; again, (1) is multiplied by $-a_2$, (2) by a_1, and the products added so as to eliminate x. (The process is most conveniently performed as follows: Write the multipliers, as b_2 and $-b_1$, at the right of the equations; multiply the first term of each equation by its proper multiplier and add; then multiply the second term of each equation by its proper multiplier, and add; and so on. This is simpler than the common practice of multiplying out each equation separately before adding.) If $a_1b_2 - a_2b_1 = 0$, the equations have no solution when $c_1 \neq c_2$, and an infinite number of solutions when

$c_1 = c_2$. The following **special solution** is possible when the sum and difference of the two unknowns are given:

$$\begin{array}{lll} & \text{Let } x + y = m & (1) \\ & \text{and } x - y = n & (2) \\ \hline (1) + (2): & 2x = m + n & \therefore x = \tfrac{1}{2}(m+n) \\ (1) - (2): & 2y = m - n & \therefore y = \tfrac{1}{2}(m-n) \end{array}$$

Simultaneous Equations of the Second Degree in Two Unknowns.

(a) When the product of the unknowns, and their sum or difference, are given:

$$\begin{array}{lll} & x + y = 5 & (1) \\ & xy = 4 & (2) \\ \hline \text{Squaring (1),} & x^2 + 2xy + y^2 = 25 & \\ \text{From (2),} & -4xy = -16 & \\ \hline \text{Adding,} & x^2 - 2xy + y^2 = 9 & \\ \hline \text{Hence,} & x - y = 3 \text{ or } -3 & \\ \text{But} & x + y = 5 \text{ or } 5 & \\ \hline \text{Therefore} & x = 4,\ y = 1 \text{ or } x = 1,\ y = 4 & \end{array}$$

$$\begin{array}{ll} x - y = 3 & (1) \\ xy = 4 & (2) \\ \hline x^2 - 2xy + y^2 = 9 & \\ 4xy = 16 & \\ \hline x^2 + 2xy + y^2 = 25 & \\ \hline x + y = 5 \text{ or } -5 & \\ x - y = 3 \text{ or } 3 & \\ \hline x = 4,\ y = 1 \text{ or } x = -1,\ y = -4 & \end{array}$$

(b) When the product and the sum of the squares are given:

$$\begin{array}{lll} & xy = 5 & (1) \\ & x^2 + y^2 = 26 & (2) \\ \hline \text{From (1),} & 2xy = 10 & (3) \\ (2)+(3): & x^2 + 2xy + y^2 = 36 & (4) \\ (2)-(3): & x^2 - 2xy + y^2 = 16 & (5) \end{array}$$

$$\begin{array}{l} \sqrt{(4)}: x + y = 6 \text{ or } 6 \text{ or } -6 \text{ or } -6 \\ \sqrt{(5)}: x - y = 4 \text{ or } -4 \text{ or } 4 \text{ or } -4 \\ \hline \therefore x = 5 \text{ or } 1 \text{ or } -1 \text{ or } -5 \\ \therefore y = 1 \text{ or } 5 \text{ or } -5 \text{ or } -1 \end{array}$$

(c) When the sum or difference, and the sum of the squares, are given:

$$\begin{array}{lll} & x + y = 5 & (1) \\ & x^2 + y^2 = 17 & (2) \\ (1)^2: & x^2 + 2xy + y^2 = 25 & \\ (2): & x^2 + y^2 = 17 & \\ \hline (1)^2 - (2): & 2xy = 8 & \\ & xy = 4 & \end{array}$$

Then proceed as in case (*a*), above.

$$\begin{array}{lll} & x - y = 3 & (1) \\ & x^2 + y^2 = 17 & (2) \\ (1)^2: & x^2 - 2xy + y^2 = 9 & \\ (2): & x^2 + y^2 = 17 & \\ \hline (1)^2 - (2): & -2xy = -8 & \\ & xy = 4 & \end{array}$$

Then proceed as in case (*a*), above.

(d) When one equation is of the first degree and the other of the second, as $ax + by = c$, and $Ax^2 + Bxy + Cy^2 + Dx + Ey + F = 0$: Solve the first equation for y in terms of x, and substitute in the second. This will give a quadratic equation in x. Solve this quadratic for the two values of x, and for each of these values of x find the corresponding value of y by substituting in the equation of the first degree.

Simultaneous Equations of the First Degree in n Unknowns. For example:

		Factors		
(*a*)	$2x - y + 3z + 5w = 29$	3	1	2
(*b*)	$5x + 2y - 2z + 3w = 15$	−5		
(*c*)	$3x - 4y + 7z - w = 12$		5	
(*d*)	$4x + 3y - 5z + 2w = 3$			−5

(*e*)	$-19x - 13y + 19z = 12$	−2	−31
(*f*)	$17x - 21y + 38z = 89$	1	
(*g*)	$-16x - 17y + 31z = 43$		19

(*h*)	$55x + 5y = 65$	16
(*i*)	$285x + 80y = 445$	−1

$$
\begin{array}{llr}
(j) \quad 595x = 595; & & \therefore x = 1; \\
5y = 65 - 55x = 65 - 55 = 10; & & \therefore y = 2; \\
19z = 12 + 19x + 13y = 12 + 19 + 26 = 57; & & \therefore z = 3; \\
2w = 3 - 4x - 3y + 5z = 3 - 4 - 6 + 15 = 8; & & \therefore w = 4.
\end{array}
$$

Here w is eliminated from (a) and (b), obtaining (e); from (a) and (c), obtaining (f); and from (a) and (d), obtaining (g). Then z is eliminated from (e) and (f), obtaining (h), and from (e) and (g), obtaining (i). Then y is eliminated from (h) and (i), obtaining (j), which contains only the single variable x. Hence $x = 1$. Now substituting this value of x in either (h) or (i), y is found; substituting these values of x and y in either (e), (f), or (g), z is found; and so on. (Solution by determinants, see p. 123.)

Approximate Solution of a Set of Simultaneous Equations of the First Degree When the Number of Equations is Greater Than the Number of Unknowns. (Method of Least Squares.)

Case 1. Single Unknown Quantity. Given n equations in one unknown x; for example, n equally careful, independent measurements of some physical quantity:

$$x = x_1, \; x = x_2, \; . \; . \; . \; x = x_n.$$

As the "best" value of x, take the arithmetic mean, x_0, of the several determinations, namely, $x_0 = (x_1 + x_2 + \; . \; . \; . \; + x_n)/n$. The quantities $v_1 = x_0 - x_1$, $v_2 = x_0 - x_2$, . . . $v_n = x_0 - x_n$ are called the **residuals** of the observed values with respect to x_0, and their absolute values (that is, their numerical values without regard to sign) are denoted by $|v_1|$, $|v_2|$, . . . $|v_n|$. [It can be shown that the sum of the squares of the residuals with respect to x_0 is smaller than the sum of the squares of the residuals with respect to any other value x'_0; hence the name of the method: "least squares."]

The quantities r and r_0, defined exactly by Bessel's formulæ:

$$r = \frac{0.6745}{\sqrt{n-1}}\sqrt{v_1^2 + v_2^2 + \; . \; . \; . \; + v_n^2},$$

$$r_0 = \frac{0.6745}{\sqrt{n(n-1)}}\sqrt{v_1^2 + v_2^2 + \; . \; . \; . \; + v_n^2},$$

or given approximately by the simpler formulæ of Peters:

$$r = \frac{0.8453}{\sqrt{n(n-1)}}\left(|v_1| + |v_2| + \; . \; . \; . \; + |v_n|\right),$$

$$r_0 = \frac{0.8453}{n\sqrt{n-1}}\left(|v_1| + |v_2| + \; . \; . \; . \; + |v_n|\right),$$

are called the **probable error of a single observation** (r), and the **probable error of the mean** (r_0), for the given series of observations. Note that $r_0 = r/\sqrt{n}$. For tables of the coefficients, see p. 63. This quantity r (or r_0) is best regarded as merely a conventional means of recording the relative precision of different sets of observations. If r is small, it may be inferred that most errors of the "accidental" class have been eliminated; but it should be especially noted that the smallness of r gives no information in regard to "constant" or "systematic" errors.

A statement like "x is equal to 2.36 with a probable error of 0.02," is written: $x = 2.36 \pm 0.02$, and is usually understood to mean that the true value of x, as far as can be told, is just as likely to lie inside as outside the interval from 2.34 to 2.38.

To test the **distribution of residuals**, arrange the residuals in order of magnitude, without regard to sign, and count the number, y, of residuals which are numerically less than some assigned value a; divide y by n, the total number of observations, and divide a by r, the probable error of a single observation. Do this for various values of a, and compare the results with the table on p. 63, which gives the standard distribution of residuals, as found from experience from a large number of different series of observations. In particular, the number of residuals numerically less than r should be about equal to the number numerically greater than r (if n is large). If any large discrepancy appears, the series of observations should be regarded as unsatisfactory.

NOTE. The "mean square error" sometimes met with is equal to the probable error divided by 0.6745.

Case 2. Several Unknown Quantities. Assume that there have been obtained by measurement or observation n different equations of the first degree involving, say, three unknown quantities, x, y, z. There are then n simultaneous equations in three unknowns, and if $n > 3$ there will be, in general, no set of values of x, y, z which will satisfy all these n equations exactly. In such a case, the "best" set of values, x_0, y_0, z_0, may be found by the method of least squares as follows. (The process usually involves a large amount of labor; the use of a computing machine is advisable.)

Given Equations

$$\begin{aligned} a_1x + b_1y + c_1z &= p_1 \\ a_2x + b_2y + c_2z &= p_2 \\ \cdot \quad \cdot \quad \cdot \quad &\cdot \\ a_nx + b_ny + c_nz &= p_n \end{aligned}$$

First, arrange the n given equations in the form indicated, being careful not to modify any of them by multiplication or division. (Any of the coefficients may of course be zero.)

Next, form the three "normal equations" as follows: (1) Multiply each of the given equations by the coefficient of x in that equation, and add; the result will be the first normal equation. (2) Multiply each of the given equations by the coefficient of y in that equation, and add; the result will be the second normal equation. (3) Similarly for the third. {Notation: $[aa] = a_1^2 + a_2^2 + \ . \ . \ . + a_n^2$; $[ab] = a_1b_1 + a_2b_2 + \ . \ . \ . + a_nb_n$; $[ap] = a_1p_1 + a_2p_2 + \ . \ . \ . + a_np_n$; etc.}

Normal Equations

$$\begin{aligned} [aa]x_0 + [ab]y_0 + [ac]z_0 &= [ap] \\ [ba]x_0 + [bb]y_0 + [bc]z_0 &= [bp] \\ [ca]x_0 + [cb]y_0 + [cc]z_0 &= [cp] \end{aligned}$$

Finally, solve the three normal equations for the three unknowns in the usual way.

The quantities $v_1 = a_1x_0 + b_1y_0 + c_1z_0 - p_1$, etc., are called the **residuals** with respect to x_0, y_0, z_0. [It can be shown that the sum of the squares of the residuals with respect to x_0, y_0, z_0 is smaller than the corresponding quantity with respect to any other set of values, x'_0, y'_0, z'_0; this relation is taken as the criterion for the "best" set of values of x, y, z.]

The **probable error of a single observation** is

$$r = \frac{0.6745}{\sqrt{n-m}}\sqrt{v_1^2 + v_2^2 + \ . \ . \ . + v_n^2}, \text{ or approximately,}$$

$$r = \frac{0.8453}{\sqrt{n(n-m)}}(|v_1| + |v_2| + \ . \ . \ . + |v_n|),$$

where m = the number of unknown quantities (here $m = 3$).

DETERMINANTS

Determinants are used chiefly in formulating theoretical results; they are seldom of use in numerical computation.

Evaluation of Determinants:

Of the second order:

$$\begin{vmatrix} a_1 b_1 \\ a_2 b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

Of the third order:

$$\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = a_1 \begin{vmatrix} b_2 c_2 \\ b_3 c_3 \end{vmatrix} - a_2 \begin{vmatrix} b_1 c_1 \\ b_3 c_3 \end{vmatrix} + a_3 \begin{vmatrix} b_1 c_1 \\ b_2 c_2 \end{vmatrix}$$

$$= a_1(b_2 c_3 - b_3 c_2) - a_2(b_1 c_3 - b_3 c_1) + a_3(b_1 c_2 - b_2 c_1)$$

Of the fourth order:

$$\begin{vmatrix} a_1 b_1 c_1 d_1 \\ a_2 b_2 c_2 d_2 \\ a_3 b_3 c_3 d_3 \\ a_4 b_4 c_4 d_4 \end{vmatrix} = a_1 \begin{vmatrix} b_2 c_2 d_2 \\ b_3 c_3 d_3 \\ b_4 c_4 d_4 \end{vmatrix} - a_2 \begin{vmatrix} b_1 c_1 d_1 \\ b_3 c_3 d_3 \\ b_4 c_4 d_4 \end{vmatrix} + a_3 \begin{vmatrix} b_1 c_1 d_1 \\ b_2 c_2 d_2 \\ b_4 c_4 d_4 \end{vmatrix} - a_4 \begin{vmatrix} b_1 c_1 d_1 \\ b_2 c_2 d_2 \\ b_3 c_3 d_3 \end{vmatrix}$$

etc. In general, to evaluate a determinant of the nth order, take the elements of the first column with signs alternately plus and minus, and form the sum of the products obtained by multiplying each of these elements by its corresponding **minor**. The minor corresponding to any element a_1 is the determinant (of next lower order) obtained by striking out from the given determinant the row and column containing a_1.

Properties of Determinants.

1. The columns may be changed to rows and the rows to columns:

$$\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = \begin{vmatrix} a_1 a_2 a_3 \\ b_1 b_2 b_3 \\ c_1 c_2 c_3 \end{vmatrix}$$

2. Interchanging two columns changes the sign of the result.
3. If two columns are equal, the determinant is zero.
4. If the elements of one column are m times the elements of another column, the determinant is zero.
5. To multiply a determinant by any number m, multiply all the elements of any one column by m.
6. $\begin{vmatrix} a_1 + p_1 + q_1, & b_1 & c_1 \\ a_2 + p_2 + q_2, & b_2 & c_2 \\ a_3 + p_3 + q_3, & b_3 & c_3 \end{vmatrix} = \begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} + \begin{vmatrix} p_1 b_1 c_1 \\ p_2 b_2 c_2 \\ p_3 b_3 c_3 \end{vmatrix} + \begin{vmatrix} q_1 b_1 c_1 \\ q_2 b_2 c_2 \\ q_3 b_3 c_3 \end{vmatrix}$
7. $\begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} = \begin{vmatrix} a_1 + mb_1, & b_1 & c_1 \\ a_2 + mb_2, & b_2 & c_2 \\ a_3 + mb_3, & b_3 & c_3 \end{vmatrix}$

Solution of Simultaneous Equations by Determinants.

If
$$\begin{aligned} a_1 x + b_1 y + c_1 z &= \mathbf{p}_1 \\ a_2 x + b_2 y + c_2 z &= \mathbf{p}_2 \\ a_3 x + b_3 y + c_3 z &= \mathbf{p}_3 \end{aligned} \qquad \text{where } D = \begin{vmatrix} a_1 b_1 c_1 \\ a_2 b_2 c_2 \\ a_3 b_3 c_3 \end{vmatrix} \neq 0,$$

then
$$\begin{aligned} x &= D_1/D, \\ y &= D_2/D, \\ z &= D_3/D, \end{aligned} \quad \text{where } D_1 = \begin{vmatrix} \mathbf{p}_1 b_1 c_1 \\ \mathbf{p}_2 b_2 c_2 \\ \mathbf{p}_3 b_3 c_3 \end{vmatrix},\ D_2 = \begin{vmatrix} a_1 \mathbf{p}_1 c_1 \\ a_2 \mathbf{p}_2 c_2 \\ a_3 \mathbf{p}_3 c_3 \end{vmatrix},\ D_3 = \begin{vmatrix} a_1 b_1 \mathbf{p}_1 \\ a_2 b_2 \mathbf{p}_2 \\ a_3 b_3 \mathbf{p}_3 \end{vmatrix}$$

Similarly for a larger (or smaller) number of equations.

THE ALGEBRA OF IMAGINARY OR COMPLEX QUANTITIES

In the algebra of imaginary or complex quantities, the objects on which the operations of the algebra are performed are not numbers in any ordinary sense of the word, but are best thought of as **points in a plane** (or as **vectors** drawn from a fixed origin to these points). The "**complex plane**" is determined by three fundamental points, O, U, i, arranged as in Fig. 2 and called the **zero point**, the **unit point**, and the **imaginary unit point**, respectively. All points on the line through O and U are called **real points**—positive if on the right of O, negative if on the left. All the remaining points in the plane are called **imaginary points**—those on the line through O and i being called the **pure imaginary points**.

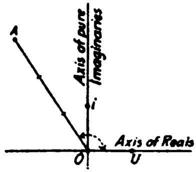

FIG. 2.

The position of any point A in the plane may be determined by the *distance* from the origin O, measured in terms of OU as the unit length, and the *angle* φ which OA makes with the positive direction of the axis of reals. The distance r is sometimes called the modulus or absolute value of the point; the angle φ is sometimes called the amplitude or argument of the point. The notation $A = (3, \angle 120°)$ means the point whose *distance*, r, is 3 times OU, and whose *angle*, φ, is 120°. The development of the algebra depends wholly on the definitions of three fundamental operations denoted by $A + B$, $A \times B$, and e^A, as follows.

Addition and Subtraction. The **sum**, $A + B$, of two points A and B is defined as the point reached by starting from A and performing a journey equal in length and direction to the journey from O to B. That is, the vector from O to $A + B$ is the vector sum of the vectors OA and OB. In case A and B are not in line with O, the point $A + B$ is the fourth vertex of a parallelogram of which OA and OB are the sides (Fig. 3). Conversely, if any two points A and B are given, there is a definite point X such that $A = B + X$; this point X is called the **remainder**, A minus B, and is denoted by $A - B$. The point $O - B$ is denoted for brevity by $-B$. With these definitions of $A + B$ and $A - B$, all the ordinary laws of addition and subtraction that hold in the algebra of real numbers hold also in the algebra of complex quantities. In particular, the zero point O has all the formal properties of the number zero, and is denoted by 0.

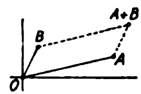

FIG. 3.

[Note: If A and B are "real" points, $A + B$ and $A - B$ will also be real.

Repeated Addition. Multiples and Submultiples. The point $A + A + A + \ldots + A$ to n terms is called the **nth multiple of A** and is denoted by nA. The points U, $2U$, $3U$, . . . are denoted, for brevity, by 1, 2, 3, ... Conversely, if any point A, and any positive integer n are given, there is a definite point X such that $nX = A$; this point X is called the **nth submultiple of A**, and is denoted by A/n. The points $U/2$, $U/3$, . . . are denoted, for brevity, by ½, ⅓, ...

Multiplication and Division. The **product**, $A \times B$, or $A \cdot B$, or AB, of two points A and B is defined as the point whose angle is the sum of the angles of the given points, and whose distance is the product of the distances. (See Fig. 4.) Thus, if $A = (5, \angle 120°)$ and $B = (2, \angle 270°)$, then $AB = (10, \angle 30°)$. Conversely, if any two points A and B are given, provided B is not zero, there is a definite point X such that

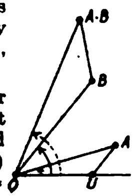

FIG. 4.

$A = BX$. This point X is called the **quotient,** A divided by B, and is denoted by A/B (where $B \neq 0$). Thus, the point A/B is a point whose angle is the angle of A minus the angle of B, and whose distance is the distance of A divided by the distance of B. The point U/B ($B \neq 0$) is called the **reciprocal** of the point B, and is denoted by $1/B$. (See Fig. 5.) With these definitions of AB and A/B the elementary laws of multiplication and division that hold in the algebra of real numbers hold also in the algebra of complex quantities. In particular, the point U has all the formal properties of the number unity, and is denoted by 1.

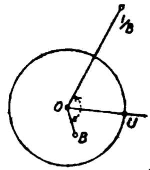

FIG. 5.

[Note: If A and B are real, AB and A/B will also be real.]

Repeated Multiplication. Powers and Roots. The point $A \times A \times A \times \ldots \times A$ to n factors is called the nth power of A and is denoted by A^n (Fig. 6). Conversely, if any point A (not 0) and any positive integer n are given, there will be n distinct points X such that $X^n = A$; each of these points is called an **nth root of A,** some one of them, usually the one with the smallest positive angle, being denoted by $\sqrt[n]{A}$ or $A^{1/n}$. Thus, the point $\sqrt[n]{A}$ is a point whose distance is the nth root of the distance of A, and whose angle is $1/n$th of the angle of A. All the nth roots of A will lie on the circumference of a circle about O as center, and will divide that circumference into n equal parts (Fig. 7). Every point A (not 0) has two square roots, three cube roots, etc. Hence the theorem "If $A^n = B^n$ then $A = B$" does not hold in this algebra, and the ordinary rules for radical signs must be applied with caution. For example, if A and B are positive reals, $\sqrt{-A} \cdot \sqrt{-B} = -\sqrt{AB}$ and not $\sqrt{(-A)(-B)}$, which would give $+\sqrt{AB}$.

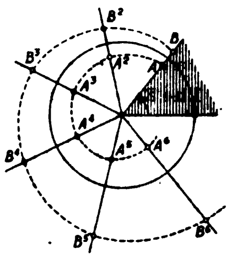

FIG. 6.

[Note: If A is real and positive, $\sqrt[n]{A}$ will be real and positive; if A is real and negative, $\sqrt[n]{A}$ will be real if n is odd and imaginary if n is even.]

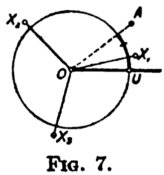

FIG. 7.

Properties of i. The point i is the point whose distance is 1 and whose angle is 90 deg. It follows from the definition above that **multiplying any point A by i has the effect of rotating the point through an angle of** $+ 90°$ without changing its distance from O. In particular,

$i^2 = -1$, $i^3 = -i$, $i^4 = 1$, $i^5 = i$, etc.; $i = \sqrt{-1}$, $-i = -\sqrt{-1}$; where "1" denotes not the *number* one, but the *point* U.

Similarly, multiplying any point A by -1 has the effect of rotating the point through 180 deg.

First Standard Form for a Complex Quantity (Fig. 8). Any point A can be expressed in the form $x + iy$, where x and y are real points. For example, the three cube roots of 1 are 1, $-\frac{1}{2} + \frac{1}{2}i\sqrt{3}$, and $-\frac{1}{2} - \frac{1}{2}i\sqrt{3}$.

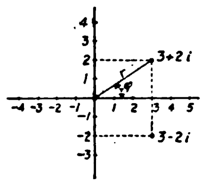

FIG. 8.

In general, $(x_1 + iy_1) + (x_2 + iy_2) = (x_1 + x_2) + i(y_1 + y_2)$;

$$(x_1 + iy_1)(x_2 + iy_2) = (x_1x_2 - y_1y_2) + i(x_2y_1 + x_1y_2);$$

$$\frac{x_1 + iy_1}{x_2 + iy_2} = \frac{x_1x_2 + y_1y_2}{x_2^2 + y_2^2} + i\,\frac{x_2y_1 - x_1y_2}{x_2^2 + y_2^2}.$$

If two complex quantities are equal, their real parts must be equal, and the coefficients of their pure imaginary parts must also be equal. That is, if $x_1 + iy_1 = x_2 + iy_2$, then $x_1 = x_2$ and $y_1 = y_2$. Thus a single equation between complex quantities is equivalent to two equations between real quantities.

Conjugate Imaginaries. Two points $A = x + iy$ and $B = x - iy$ are called conjugate imaginaries. Two such points are symmetrically situated with regard to the axis of reals. The sum and product of two conjugate imaginaries will be real.

Second Standard Form for a Complex Quantity. Since $x = r \cos \varphi$ and $y = r \sin \varphi$, any point $A = x + iy$ can be expressed $A = r (\cos \varphi + i \sin \varphi)$, where r is real and positive (namely, the distance of A), and φ is real (namely the angle of A). For example, the three cube roots of 1 are 1, $\cos 120° + i \sin 120°$, and $\cos 240° + i \sin 240°$. In general,

$[r_1 (\cos \varphi_1 + i \sin \varphi_1)] [r_2(\cos \varphi_2 + i \sin \varphi_2)] = r_1r_2[(\cos (\varphi_1 + \varphi_2) + i \sin (\varphi_1 + \varphi_2)]$;

$[r(\cos \varphi + i \sin \varphi)]^n = r^n[\cos(n\varphi) + i \sin (n\varphi)]$ (**De Moivre's Theorem**).

The Exponential Function, e^A, or $\exp A$, of any point $A = x + iy$ is defined as the point whose distance is e^x and whose angle (measured in radians) is y. That is, $e^{x+iy} = e^x(\cos y + i \sin y)$. Here e^x means the ordinary exponential function of the real quantity x, where $e = 2.718$.

From this definition, the usual formal laws of exponents can be deduced: $e^Ae^B = e^{A+B}$, $(e^A)^n = e^{nA}$, $e^{-A} = 1/e^A$; $e^1 = e$, $e^0 = 1$.

The function e^A is a periodic function with a pure imaginary period $2\pi i$; that is, $e^{A \pm k2\pi i} = e^A$, where k is any positive integer.

If A is made to move along a line parallel to the axis of reals [or axis of pure imaginaries], the corresponding point e^A will move along a straight line through O [or along a circle about O as center].

Properties of $e^{i\varphi}$. The point $e^{i\varphi}$ is a point whose distance is 1 and whose angle is φ. It follows from the definitions above that **multiplying any point A by $e^{i\varphi}$ has the effect of rotating the point through an angle** φ, without changing its distance from O. In particular, $e^{i\pi} = -1$, $e^{-i\pi} = -1$; $e^{i\pi/2} = i$; $e^{-i\pi/2} = -i$; $e^{2\pi i} = 1$.

Third Standard Form for a Complex Quantity. Any point A can be expressed in the form $A = re^{i\varphi}$, where r is the distance and φ the angle of the point. For example, the three cube roots of 1 are 1, $e^{\frac{2}{3}\pi i}$, $e^{\frac{4}{3}\pi i}$. In general,

$$(r_1e^{i\varphi_1})(r_2e^{i\varphi_2}) = (r_1r_2)e^{i(\varphi_1 + \varphi_2)}; \quad (re^{i\varphi})^n = (r^n)e^{in\varphi}.$$

If $x + iy = re^{i\varphi}$, then $r = \sqrt{x^2 + y^2}$, $\sin \varphi = \dfrac{y}{r}$, $\cos \varphi = \dfrac{x}{r}$, $\tan \varphi = \dfrac{y}{x}$.

If two complex quantities are equal, their distances will be equal, and their angles will differ at most by some multiple of 2π. Thus, if $r_1e^{i\varphi_1} = r_2e^{i\varphi_2}$ then $r_1 = r_2$ and $\varphi_1 = \varphi_2$ or $\varphi_2 \pm k2\pi$. Here again a single equation between complex quantities is equivalent to two equations between real quantities.

Definition of A^B. Let $A = re^{i\varphi}$; then $A^B = \exp[(\log_e r + i\varphi)B]$.

For example, $i^i = e^{-\pi/2}$ where $i = \sqrt{-1}$.

If a is a positive real, $a^{x+iy} = a^x [\cos(y \log_e a) + i \sin(y \log_e a)]$.

Trigonometric and Hyperbolic Functions of a Complex Variable. If A is any point, then, by definition,

$$\sin A = \frac{e^{iA} - e^{-iA}}{2i}, \quad \cos A = \frac{e^{iA} + e^{-iA}}{2}, \quad \tan A = \frac{\sin A}{\cos A} \quad (\cos A \neq 0);$$

$$\sinh A = \frac{e^{A} - e^{-A}}{2}, \quad \cosh A = \frac{e^{A} + e^{-A}}{2}, \quad \tanh A = \frac{\sinh A}{\cosh A}.$$

Hence the formulæ that hold for these functions in the real case (p. 131; p. 135; p. 161) hold also for the complex case. Further:

$$\begin{aligned}
\sin(x+iy) &= \sin x \cosh y + i \cos x \sinh y, & \sin iy &= i \sinh y;\\
\cos(x+iy) &= \cos x \cosh y - i \sin x \sinh y, & \cos iy &= \cosh y;\\
\sinh(x+iy) &= \sinh x \cos y + i \cosh x \sin y, & \sinh iy &= i \sin y;\\
\cosh(x+iy) &= \cosh x \cos y + i \sinh x \sin y, & \cosh iy &= \cos y;
\end{aligned}$$

where $\sin x$, $\sinh x$, etc., are the ordinary trigonometric and hyperbolic functions of the real variables x and y. The functions $\sin A$ and $\cos A$ are periodic with a real period 2π. The functions $\sinh A$ and $\cosh A$ are periodic with a pure imaginary period $2\pi i$.

Logarithmic and Other Inverse Functions of a Complex Variable. If any point A is given, there will be an infinite number of points X such that $e^X = A$; any one of these points may be called a logarithm of A, and be denoted by $\log A$. All the values of the logarithm of A may be obtained from any one value by adding multiples of $2\pi i$.

If $x + iy = re^{i\varphi}$, then $\log_e(x + iy) = \log_e r + i\varphi \pm k \cdot 2\pi i$.

If any point A is given, there will be an infinite number of points X such that $\sin X = A$; any one of these may be denoted by $\sin^{-1} A$. The functions $\cos^{-1} A$, $\sinh^{-1} A$, etc., are defined in a similar way.

The elementary laws of operation which hold for these functions in the algebra of reals hold also, in a general way, in the algebra of complex quantities; but caution must be used, on account of the ambiguity in the symbols $\log A$, $\sin^{-1} A$, etc., which denote many-valued functions.

Differentiation of Functions of a Complex Variable. If $w = f(z)$, the derivative of w with respect to z is defined as

$$dw/dz = \lim \{[f(z + \Delta z) - f(z)]/\Delta z\} \text{ when } \Delta z \text{ approaches } 0.$$

It can be shown that $\lim \{[\exp \Delta z - 1]/\Delta z\} = 1$; hence $d(e^z) = e^z dz$, $d(\sin z) = \cos z\, dz$, etc., so that the formulæ for differentiation here are the same as in the case of a real variable (p. 157).

NOTE. For the algebra of vector analysis, which differs in important respects from the algebra of complex quantities, see p. 185.

TRIGONOMETRY

FORMAL TRIGONOMETRY

Angles, or Rotations. An **angle** is generated by the rotation of a ray, as Ox, about a fixed point O in the plane. Every angle has an **initial line** (OA) from which the rotation started (Fig. 1), and a **terminal line** (OB) where it stopped; and the counterclockwise direction of rotation is taken as positive. Since the rotating ray may revolve as often as desired, angles of any magnitude, positive or negative, may be obtained. Two angles are **congruent** if they may be superposed so that their initial lines coincide and their terminal lines coincide. That is, two congruent angles are either equal or differ by some multiple of 360 deg. Two angles are **complementary** if their sum is 90 deg.; **supplementary** if their sum is 180 deg. (The acute angles of a right-angled triangle are complementary.) If the initial line is placed so that it runs horizontally to the right, as in Fig. 2, then the angle is said to be an angle in the 1st, 2nd, 3rd, or 4th **quadrant** according as the terminal line lies across the region marked I, II, III, or IV. The angles 0 deg., 90 deg., 180 deg., 270 deg. are called the quadrantal angles.

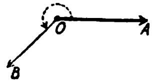

FIG. 1.

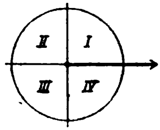

FIG. 2.

Units of Angular Measurement.

(1) SEXAGESIMAL MEASURE. (360 degrees = 1 revolution.) 1 degree = 1° = $1/90$ of a right angle. The degree is usually divided into 60 equal parts called minutes ($'$), and each minute into 60 equal parts called seconds ($''$); while the second is subdivided decimally. But for many purposes it is more convenient to divide the degree itself into decimal parts, thus avoiding the use of minutes and seconds. (See tables, pp. 46–51.)

(2) CENTESIMAL MEASURE, used chiefly in France. (400 grades = 1 revolution.) 1 grade = $1/100$ of a right angle. The grade is always divided decimally, the following terms being sometimes used: 1 "centesimal minute" = $1/100$ of a grade; 1 "centesimal second" = $1/100$ of a centesimal minute. In reading Continental books it is important to notice carefully which system is employed.

(3) RADIAN, OR CIRCULAR, MEASURE. (π radians = 180 degrees.) 1 radian = the angle subtended by an arc whose length is equal to the length of the radius. The radian is constantly used in higher mathematics and in mechanics, and is always divided decimally. Table, pp. 44–45.

1 radian $= 57^\circ.30- = 57^\circ.2957795131 = 57^\circ\ 17'\ 44''.806247 = 180^\circ/\pi$.

$1^\circ = 0.01745\ldots$ radian $= 0.01745\,32925$ radian.

$1' = 0.00029\,08882$ radian. $1'' = 0.00000\,48481$ radian.

(For 10-place conversion tables, see the Smithsonian Tables of Hyperbolic Functions, Washington, D. C.)

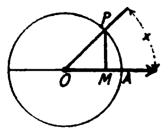

FIG. 3.

Definitions of the Trigonometric Functions. Let x be any angle whose initial line is OA and terminal line OP (see Fig. 3). Drop a perpendicular from P on OA or OA produced. In the right triangle OMP, the three sides are MP = "side opposite" O (positive if running upward); OM = "side adjacent" to O (positive if running to the right); OP = "hypothenuse" or "radius" (may always be taken as positive); and the six ratios between these sides are the principal trigonometric functions of the angle x; thus:

$$\begin{aligned}
\text{sine of } x &= \sin x = \text{opp/hyp} = MP/OP;\\
\text{cosine of } x &= \cos x = \text{adj/hyp} = OM/OP;\\
\text{tangent of } x &= \tan x = \text{opp/adj} = MP/OM;\\
\text{cotangent of } x &= \cot x = \text{adj/opp} = OM/MP;\\
\text{secant of } x &= \sec x = \text{hyp/adj} = OP/OM;\\
\text{cosecant of } x &= \csc x = \text{hyp/opp} = OP/MP.
\end{aligned}$$

The last three are best remembered as the reciprocals of the first three:

$$\cot x = 1/\tan x;\ \sec x = 1/\cos x;\ \csc x = 1/\sin x.$$

Other functions in use are the versed sine, the coversed sine, and the exterior secant:

$$\text{vers } x = 1 - \cos x;\ \text{covers } x = 1 - \sin x;\ \text{exsec } x = \sec x - 1.$$

For graphs, see p. 174; series, p. 161.

Signs of the Trigonometric Functions

If x is in quadrant	I	II	III	IV
$\sin x$ and $\csc x$ are	+	+	−	−
$\cos x$ and $\sec x$ are	+	−	−	+
$\tan x$ and $\cot x$ are	+	−	+	−

vers x and covers x are always positive.

Variations in the Functions as x Varies from 0 deg. to 360 deg. are shown in the accompanying table. The variations in the sine and cosine are

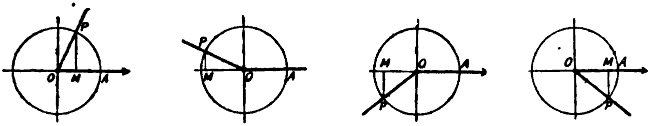

FIG. 4.

best remembered by noting the changes in the lines MP and OM (Fig. 4) in the "unit circle" (that is, a circle with radius $= OP = 1$), as P moves around the circumference.

x	0° to 90°	90° to 180°	180° to 270°	270° to 360°	Values at 30°	45°	60°
sin x	$+0$ to $+1$	$+1$ to $+0$	-0 to -1	-1 to -0	$\frac{1}{2}$	$\frac{1}{2}\sqrt{2}$	$\frac{1}{2}\sqrt{3}$
csc x	$+\infty$ to $+1$	$+1$ to $+\infty$	$-\infty$ to -1	-1 to $-\infty$	2	$\sqrt{2}$	$\frac{2}{3}\sqrt{3}$
cos x	$+1$ to $+0$	-0 to -1	-1 to -0	$+0$ to $+1$	$\frac{1}{2}\sqrt{3}$	$\frac{1}{2}\sqrt{2}$	$\frac{1}{2}$
sec x	$+1$ to $+\infty$	$-\infty$ to -1	-1 to $-\infty$	$+\infty$ to $+1$	$\frac{2}{3}\sqrt{3}$	$\sqrt{2}$	2
tan x	$+0$ to $+\infty$	$-\infty$ to -0	$+0$ to $+\infty$	$-\infty$ to -0	$\frac{1}{3}\sqrt{3}$	1	$\sqrt{3}$
cot x	$+\infty$ to $+0$	-0 to $-\infty$	$+\infty$ to $+0$	-0 to $-\infty$	$\sqrt{3}$	1	$\frac{1}{3}\sqrt{3}$
vers x	$+0$ to $+1$	$+1$ to $+2$	$+2$ to $+1$	$+1$ to $+0$			
covers x	$+1$ to $+0$	$+0$ to $+1$	$+1$ to $+2$	$+2$ to $+1$			

$\sqrt{2} = 1.4142$; $\frac{1}{2}\sqrt{2} = 0.7071$; $\sqrt{3} = 1.7321$; $\frac{1}{2}\sqrt{3} = 0.8660$; $\frac{1}{3}\sqrt{3} = 0.5774$; $\frac{2}{3}\sqrt{3} = 1.1547$

Trigonometrical Tables. The tables on pp. 46–56 give the values of the principal trigonometric functions and of their logarithms, correct to four places of decimals, the angle advancing either by tenths of a degree (p. 46) or by 10 min. (p. 52). These tables will be found adequate for most computations in which an accuracy of 1 part in 1000 is sufficient. If much computing is to be done, it is advisable to use a separate volume of tables, containing more facilities for interpolation, and printed in larger type, such as the four-place tables of E. V. Huntington (Harvard Coöperative Society, Cambridge, Mass.), with convenient marginal tabs; the five-place tables published by Macmillan or many others; the six-place tables of Bremiker; the standard seven-place tables of Schrön, Vega, or Bruhns (angles advancing by 10 sec.); or the great eight-place of Bauschinger and Peters (angles advancing at intervals of 1 sec. from 0 deg. to 90 deg.). The larger tables give only the logarithms of the functions, not the natural values.

To Find Any Function of a Given Angle. (Reduction to the first quadrant.) It is often required to find the functions of any angle x from a table that includes only angles between 0 deg. and 90 deg. If x is not already between 0 deg. and 360 deg., first "reduce to the first revolution" by simply adding or subtracting the proper multiple of 360 deg.; [for any function of (x) = the same function of $(x \pm n \times 360°)$]. Next **reduce to the first quadrant** as follows:

If x is between	90° and 180°	180° and 270°	270° and 360°
Subtract	90° from x	180° from x	270° from x
Then sin x	$=+\cos(x-90°)$	$=-\sin(x-180°)$	$=-\cos(x-270°)$
csc x	$=+\sec(x-90°)$	$=-\csc(x-180°)$	$=-\sec(x-270°)$
cos x	$=-\sin(x-90°)$	$=-\cos(x-180°)$	$=+\sin(x-270°)$
sec x	$=-\csc(x-90°)$	$=-\sec(x-180°)$	$=+\csc(x-270°)$
tan x	$=-\cot(x-90°)$	$=+\tan(x-180°)$	$=-\cot(x-270°)$
cot x	$=-\tan(x-90°)$	$=+\cot(x-180°)$	$=-\tan(x-270°)$
vers x	$=1+\sin(x-90°)$	$=1+\cos(x-180°)$	$=1-\sin(x-270°)$
covers x	$=1-\cos(x-90°)$	$=1+\sin(x-180°)$	$=1+\cos(x-270°)$

The "reduced angle" ($x - 90°$, or $x - 180°$, or $x - 270°$) will in each case be an angle between 0° and 90°, whose functions can then be found in the table.

[NOTE. The formulæ for sine and cosine are best remembered by aid of the unit circle.]

To Find the Angle When One of Its Functions is Given. In general, there will be two angles between 0 deg. and 360 deg. corresponding to any given function. The following tabulated rules show how to find these angles.

Given	First find from the tables an *acute* angle x_0 such that	Then the required angles x_1 and x_2 will be
$\sin x = +a$	$\sin x_0 = a$	x_0 and $180° - x_0$
$\cos x = +a$	$\cos x_0 = a$	x_0 and $[360° - x_0]$
$\tan x = +a$	$\tan x_0 = a$	x_0 and $[180° + x_0]$
$\cot x = +a$	$\cot x_0 = a$	x_0 and $[180° + x_0]$
$\sin x = -a$	$\sin x_0 = a$	$[180° + x_0]$ and $[360° - x_0]$
$\cos x = -a$	$\cos x_0 = a$	$180° - x_0$ and $[180° + x_0]$
$\tan x = -a$	$\tan x_0 = a$	$180° - x_0$ and $[360° - x_0]$
$\cot x = -a$	$\cot x_0 = a$	$180° - x_0$ and $[360° - x_0]$

The angles enclosed in brackets lie outside the range from 0 deg. to 180 deg., and hence cannot occur as angles in a triangle.

For solution of trigonometric equations, see p. 118.

Relations Between the Functions of a Single Angle. (See Fig. 5.)

$\sin^2 x + \cos^2 x = 1$; $\tan x = \dfrac{\sin x}{\cos x}$; $\cot x = \dfrac{1}{\tan x} = \dfrac{\cos x}{\sin x}$;

$1 + \tan^2 x = \sec^2 x = \dfrac{1}{\cos^2 x}$; $1 + \cot^2 x = \csc^2 x = \dfrac{1}{\sin^2 x}$;

$$\sin x = \sqrt{1 - \cos^2 x} = \frac{\tan x}{\sqrt{1 + \tan^2 x}} = \frac{1}{\sqrt{1 + \cot^2 x}};$$

$$\cos x = \sqrt{1 - \sin^2 x} = \frac{1}{\sqrt{1 + \tan^2 x}} = \frac{\cot x}{\sqrt{1 + \cot^2 x}}.$$

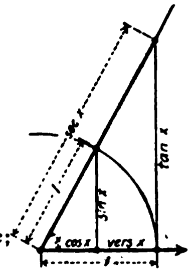

FIG. 5.

Functions of Negative Angles. $\sin(-x) = -\sin x$; $\cos(-x) = \cos x$; $\tan(-x) = -\tan x$.

Functions of the Sum and Difference of Two Angles.

$\sin(x + y) = \sin x \cos y + \cos x \sin y$;
$\cos(x + y) = \cos x \cos y - \sin x \sin y$;
$\tan(x + y) = [\tan x + \tan y]/[1 - \tan x \tan y]$;
$\cot(x + y) = [\cot x \cot y - 1]/[\cot x + \cot y]$;

$\sin(x - y) = \sin x \cos y - \cos x \sin y$;
$\cos(x - y) = \cos x \cos y + \sin x \sin y$;
$\tan(x - y) = [\tan x - \tan y]/[1 + \tan x \tan y]$;
$\cot(x - y) = [\cot x \cot y + 1]/[\cot y - \cot x]$;

$\sin x + \sin y = 2 \sin \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$;
$\sin x - \sin y = 2 \cos \tfrac{1}{2}(x + y) \sin \tfrac{1}{2}(x - y)$;
$\cos x + \cos y = 2 \cos \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$;
$\cos x - \cos y = -2 \sin \tfrac{1}{2}(x + y) \sin \tfrac{1}{2}(x - y)$;

$\tan x + \tan y = \dfrac{\sin(x + y)}{\cos x \cos y}$; $\cot x + \cot y = \dfrac{\sin(x + y)}{\sin x \sin y}$;

$\tan x - \tan y = \dfrac{\sin(x - y)}{\cos x \cos y}$; $\cot x - \cot y = \dfrac{\sin(y - x)}{\sin x \sin y}$;

$\sin^2 x - \sin^2 y = \cos^2 y - \cos^2 x = \sin(x + y) \sin(x - y)$;
$\cos^2 x - \sin^2 y = \cos^2 y - \sin^2 x = \cos(x + y) \cos(x - y)$;
$\sin(45° + x) = \cos(45° - x)$; $\tan(45° + x) = \cot(45° - x)$;
$\sin(45° - x) = \cos(45° + x)$; $\tan(45° - x) = \cot(45° + x)$.

In the following transformations, a and b are supposed to be positive, $c = \sqrt{a^2 + b^2}$, A = the positive acute angle for which $\tan A = a/b$, and B = the positive acute angle for which $\tan B = b/a$:

$a \cos x + b \sin x = c \sin(A + x) = c \cos(B - x)$;
$a \cos x - b \sin x = c \sin(A - x) = c \cos(B + x)$.

Functions of Multiple Angles and Half Angles.

$\sin 2x = 2 \sin x \cos x$; $\sin x = 2 \sin \tfrac{1}{2}x \cos \tfrac{1}{2}x$;
$\cos 2x = \cos^2 x - \sin^2 x = 1 - 2 \sin^2 x = 2 \cos^2 x - 1$;

$\tan 2x = \dfrac{2 \tan x}{1 - \tan^2 x}$; $\cot 2x = \dfrac{\cot^2 x - 1}{2 \cot x}$;

$\sin 3x = 3 \sin x - 4 \sin^3 x$; $\tan 3x = \dfrac{3 \tan x - \tan^3 x}{1 - 3 \tan^2 x}$;

$\cos 3x = 4 \cos^3 x - 3 \cos x$;

$$\sin (nx) = n \sin x \cos^{n-1} x - (n)_3 \sin^3 x \cos^{n-3} x + (n)_5 \sin^5 x \cos^{n-5} x - \ldots;$$
$$\cos (nx) = \cos^n x - (n)_2 \sin^2 x \cos^{n-2} x + (n)_4 \sin^4 x \cos^{n-4} x - \ldots,$$
where $(n)_2$, $(n)_3$, . . . are the binomial coefficients (see p. 39).

$$\sin \tfrac{1}{2} x = \pm \sqrt{\tfrac{1}{2}(1 - \cos x)};\; 1 - \cos x = 2 \sin^2 \tfrac{1}{2}x;$$
$$\cos \tfrac{1}{2}x = \pm \sqrt{\tfrac{1}{2}(1 + \cos x)};\; 1 + \cos x = 2 \cos^2 \tfrac{1}{2}x;$$
$$\tan \tfrac{1}{2}x = \pm \sqrt{\frac{1 - \cos x}{1 + \cos x}} = \frac{\sin x}{1 + \cos x} = \frac{1 - \cos x}{\sin x};$$
$$\tan \left(\frac{x}{2} + 45^\circ\right) = \pm \sqrt{\frac{1 + \sin x}{1 - \sin x}}.$$

Here the + or − sign is to be used according to the sign of the left-hand side of the equation.

Relations Between Three Angles Whose Sum is 180°.

$$\sin A + \sin B + \sin C = 4 \cos \tfrac{1}{2}A \cos \tfrac{1}{2}B \cos \tfrac{1}{2}C;$$
$$\cos A + \cos B + \cos C = 4 \sin \tfrac{1}{2}A \sin \tfrac{1}{2}B \sin \tfrac{1}{2}C + 1;$$
$$\sin A + \sin B - \sin C = 4 \sin \tfrac{1}{2}A \sin \tfrac{1}{2}B \cos \tfrac{1}{2}C;$$
$$\cos A + \cos B - \cos C = 4 \cos \tfrac{1}{2}A \cos \tfrac{1}{2}B \sin \tfrac{1}{2}C - 1;$$
$$\sin^2 A + \sin^2 B + \sin^2 C = 2 \cos A \cos B \cos C + 2;$$
$$\sin^2 A + \sin^2 B - \sin^2 C = 2 \sin A \sin B \cos C;$$
$$\tan A + \tan B + \tan C = \tan A \tan B \tan C;$$
$$\cot \tfrac{1}{2}A + \cot \tfrac{1}{2}B + \cot \tfrac{1}{2}C = \cot \tfrac{1}{2}A \cot \tfrac{1}{2}B \cot \tfrac{1}{2}C;$$
$$\cot A \cot B + \cot A \cot C + \cot B \cot C = 1;$$
$$\sin 2A + \sin 2B + \sin 2C = 4 \sin A \sin B \sin C;$$
$$\sin 2A + \sin 2B - \sin 2C = 4 \cos A \cos B \sin C.$$

Inverse Trigonometric Functions. The notation $\sin^{-1}x$ (read: anti-sine of x, or inverse sine of x; sometimes written arc sin x) means the principal angle whose sine is x. Similarly for $\cos^{-1}x$, $\tan^{-1}x$, etc. (The principal angle means an angle between −90° and +90° in case of $\sin^{-1}$ and $\tan^{-1}$, and between 0° and 180° in the case of $\cos^{-1}$.) For graphs, see p. 174.

SOLUTION OF PLANE TRIANGLES

The "parts" of a plane triangle are its three sides, a, b, c, and its three angles A, B, C (A being opposite a, B opposite b, C opposite c, and $A + B + C = 180°$). A triangle is, in general, determined by any three parts (not all angles). To "solve" a triangle means to find the unknown parts from the known. The fundamental formulæ are:

Law of sines: $\dfrac{a}{b} = \dfrac{\sin A}{\sin B}$. Law of cosines: $c^2 = a^2 + b^2 - 2ab \cos C$.

Right Triangles. Use the definitions of the trigonometric functions, selecting for each unknown part a relation which connects that unknown with known quantities; then solve the resulting equations. Thus, in Fig. 6, if $C = 90°$, then $A + B = 90°$, $c^2 = a^2 + b^2$,

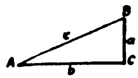

Fig. 6.

$$\sin A = a/c,\ \cos A = b/c,\ \tan A = a/b,\ \cot A = b/a.$$

If A is very small, use $\tan \tfrac{1}{2}A = \sqrt{(c - b)/(c + b)}$.

Oblique Triangles. There are four cases. It is highly desirable in all these cases to draw a sketch of the triangle approximately to scale before commencing the computation, so that any large numerical error may be readily detected.

Case 1. Given Two Angles (provided their sum is < 180 deg.), and One

SIDE (say a, Fig. 7). The third angle is known, since $A + B + C = 180°$. To find the remaining sides, use $b = \dfrac{a \sin B}{\sin A}$, $c = \dfrac{a \sin C}{\sin A}$. Or, drop a perpendicular from either B or C on the opposite side, and solve by right triangles.

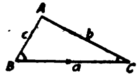

FIG. 7.

Check: $c \cos B + b \cos C = a$.

Case 2. GIVEN TWO SIDES (say a and b), AND THE INCLUDED ANGLE (C); and suppose $a > b$. Fig. 8.

First Method: Find c from $c^2 = a^2 + b^2 - 2ab \cos C$ [or $c^2 = (a - b)^2 + 2ab \text{ vers } C$]; then find the smaller angle, B, from $\sin B = (b/c) \sin C$; and finally, find A from $A = 180° - (B + C)$. Check: $a \cos B + b \cos A = c$.

Second Method: Find $\tfrac{1}{2}(A - B)$ from the law of tangents:

$$\tan \tfrac{1}{2}(A - B) = [(a - b)/(a + b)] \cot \tfrac{1}{2}C,$$

and $\tfrac{1}{2}(A + B)$ from $\tfrac{1}{2}(A + B) = 90° - C/2$; hence $A = \tfrac{1}{2}(A + B) + \tfrac{1}{2}(A - B)$ and $B = \tfrac{1}{2}(A + B) - \tfrac{1}{2}(A - B)$. Then find c from $c = a \sin C/\sin A$ or $c = b \sin C/\sin B$. Check: $a \cos B + b \cos A = c$.

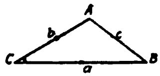

FIG. 8.

Third Method: Drop a perpendicular from A to the opposite side, and solve by right triangles.

Case 3. GIVEN THE THREE SIDES (provided the largest is less than the sum of the other two), Fig. 9.

First Method: Find the largest angle A (which may be acute or obtuse) from $\cos A = (b^2 + c^2 - a^2)/2bc$ {or $\text{vers } A = [a^2 - (b - c)^2]/2bc$} and then find B and C (which will always be acute) from $\sin B = b \sin A/a$ and $\sin C = c \sin A/a$. Check: $A + B + C = 180°$.

Second Method: Find A, B, and C from $\tan \tfrac{1}{2}A = r/(s - a)$, $\tan \tfrac{1}{2}B = r/(s - b)$, $\tan \tfrac{1}{2}C = r/(s - c)$, where $s = \tfrac{1}{2}(a + b + c)$, and $r = \sqrt{(s - a)(s - b)(s - c)/s}$. Check: $A + B + C = 180°$.

Third Method: If only one angle, say A, is required, use

$$\sin \tfrac{1}{2}A = \sqrt{(s - b)(s - c)/bc} \quad \text{or}$$

$$\cos \tfrac{1}{2}A = \sqrt{s(s - a)/bc},$$

according as $\tfrac{1}{2}A$ is nearer 0° or nearer 90°.

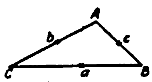

FIG. 9.

Case 4. GIVEN TWO SIDES (say b and c) AND THE ANGLE OPPOSITE ONE OF THEM (B). This is the "ambiguous case" in which there may be two solutions, or one, or none (see Fig. 10).

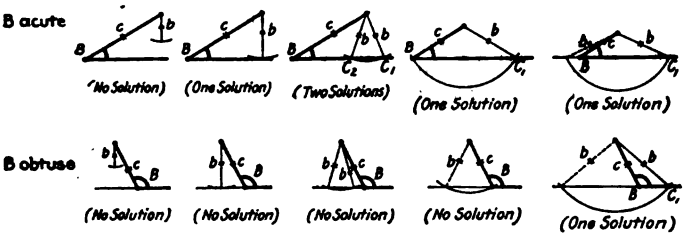

FIG. 10.

First, try to find C from $\sin C = c \sin B/b$. If $\sin C > 1$, there is no solution. If $\sin C = 1$, $C = 90°$ and the triangle is a right triangle. If $\sin C < 1$, this determines two angles C, namely, an acute angle C_1, and an obtuse angle $C_2 = 180° - C_1$. Then C_1 will yield a solution when and only when

$C_1 + B < 180°$ (see Case 1); and similarly C_2 will yield a solution when and only when $C_2 + B < 180°$ (see Case 1).

Other Properties of Triangles. (See also p. 99 and p. 105.)

Area $= \frac{1}{2}ab \sin C = \sqrt{s(s-a)(s-b)(s-c)} = rs$, where $s = \frac{1}{2}(a+b+c)$, and $r =$ radius of inscribed circle $= \sqrt{(s-a)(s-b)(s-c)/s}$.

Radius of circumscribed circle $= R$, where

$$2R = a/\sin A = b/\sin B = c/\sin C;\ r = 4R \sin\frac{A}{2}\sin\frac{B}{2}\sin\frac{C}{2} = \frac{abc}{4Rs}.$$

The length of the bisector of the angle C is

$$z = \frac{2\sqrt{abs(s-c)}}{a+b} = \frac{\sqrt{ab[(a+b)^2 - c^2]}}{a+b}.$$

The median from C to the middle point of c is $m = \frac{1}{2}\sqrt{2(a^2+b^2) - c^2}$.

SOLUTION OF SPHERICAL TRIANGLES

For the occasional solution of a spherical triangle the following formulæ will be sufficient. For a detailed discussion, see any text-book on spherical trigonometry.

Let a, b, c be the sides of the spherical triangle, that is, portions of arcs of great circles of the sphere; and let A, B, C be the angles of the triangle, that is, the angles made by tangents drawn to the sides at their points of intersection on the sphere. The sum of the angles will always be greater than two right angles, and may be nearly six right angles. The angle $E = A + B + C - 180°$ is called the **spherical excess** of the triangle. (See also p. 100.)

$$\frac{\sin a}{\sin A} = \frac{\sin b}{\sin B};\quad \frac{\sin b}{\sin B} = \frac{\sin c}{\sin C};\quad \frac{\sin c}{\sin C} = \frac{\sin a}{\sin A}.$$

$$\cos a = \cos b \cos c + \sin b \sin c \cos A,$$

with similar formulæ for $\cos b$ and $\cos c$.

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a,$$

with similar formulæ for $\cos B$ and $\cos C$.

In the special case of a right spherical triangle, in which $C = 90°$,

$$\cos c = \cos a \cos b = \cot A \cot B;\ \cos a = \frac{\cos A}{\sin B};\ \cos b = \frac{\cos B}{\sin A};$$

$$\sin A = \frac{\sin a}{\sin c};\ \cos A = \frac{\tan b}{\tan c};\ \tan A = \frac{\tan a}{\sin b}.$$

$$\frac{\text{The area of a spherical triangle}}{\text{area of a great circle}} = \frac{\text{spherical excess}}{180°}.$$

HYPERBOLIC FUNCTIONS

The **hyperbolic sine, hyperbolic cosine,** etc., of any number x, are functions of x which are closely related to the exponential e^x, and which have formal properties very similar to those of the trigonometric functions, sine, cosine, etc. Their definitions and fundamental properties are as follows (see also p. 127; graphs, p. 175; table, p. 60; series, p. 161):

$\sinh x = \frac{1}{2}(e^x - e^{-x})$; $\cosh x = \frac{1}{2}(e^x + e^{-x})$; $\tanh x = \sinh x/\cosh x$;

$\operatorname{csch} x = 1/\sinh x$; $\operatorname{sech} x = 1/\cosh x$; $\coth x = 1/\tanh x$;

$\cosh^2 x - \sinh^2 x = 1$; $1 - \tanh^2 x = \operatorname{sech}^2 x$; $1 - \coth^2 x = -\operatorname{csch}^2 x$;
$\sinh(-x) = -\sinh x$; $\cosh(-x) = \cosh x$; $\tanh(-x) = -\tanh x$;

$\sinh(x \pm y) = \sinh x \cosh y \pm \cosh x \sinh y$;
$\cosh(x \pm y) = \cosh x \cosh y \pm \sinh x \sinh y$;
$\tanh(x \pm y) = (\tanh x \pm \tanh y)/(1 \pm \tanh x \tanh y)$;

$\sinh 2x = 2 \sinh x \cosh x$; $\cosh 2x = \cosh^2 x + \sinh^2 x$;
$\tanh 2x = (2 \tanh x)/(1 + \tanh^2 x)$;
$\sinh \frac{1}{2}x = \sqrt{\frac{1}{2}(\cosh x - 1)}$; $\cosh \frac{1}{2}x = \sqrt{\frac{1}{2}(\cosh x + 1)}$;
$\tanh \frac{1}{2}x = (\cosh x - 1)/(\sinh x) = (\sinh x)/(\cosh x + 1)$.

The **inverse hyperbolic sine** of y, denoted by $\sinh^{-1} y$, is the number whose hyperbolic sine is y; that is, the notation $x = \sinh^{-1} y$ means $\sinh x = y$. Similarly for $\cosh^{-1} y$, $\tanh^{-1} y$, etc. These functions are closely related to the logarithmic function, and are especially valuable in the integral calculus. For graphs, see p. 175.

$\sinh^{-1}(y/a) = \log_e(y + \sqrt{y^2 + a^2}) - \log_e a$;
$\cosh^{-1}(y/a) = \log_e(y + \sqrt{y^2 - a^2}) - \log_e a$;

$$\tanh^{-1}\frac{y}{a} = \frac{1}{2}\log_e \frac{a + y}{a - y};\quad \coth^{-1}\frac{y}{a} = \frac{1}{2}\log_e \frac{y + a}{y - a}.$$

The **anti-gudermannian** of an angle u, denoted by $\operatorname{gd}^{-1} u$, is a number defined by $\operatorname{gd}^{-1} u = \log_e \tan(\frac{1}{4}\pi + \frac{1}{2}u) = \int \sec u\, du$. When u is small, $\operatorname{gd}^{-1} u = u + \frac{1}{6}u^3 + \frac{1}{24}u^5 + \frac{61}{5040}u^7 + \ldots$.

ANALYTICAL GEOMETRY

THE POINT AND THE STRAIGHT LINE

Rectangular Co-ordinates (Fig. 1). Let $P_1 = (x_1, y_1)$, $P_2 = (x_2, y_2)$. Then, distance $P_1P_2 = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$; slope of $P_1P_2 = m = \tan u = (y_2 - y_1)/(x_2 - x_1)$; co-ordinates of mid-point are $x = \frac{1}{2}(x_1 + x_2)$, $y = \frac{1}{2}(y_1 + y_2)$; co-ordinates of point $(1/n)$th of the way from P_1 to P_2 are $x = x_1 + (1/n)(x_2 - x_1)$, $y = y_1 + (1/n)(y_2 - y_1)$.

Let m_1, m_2 be the slopes of two lines; then, if the lines are parallel, $m_1 = m_2$; if the lines are perpendicular to each other, $m_1 = -1/m_2$.

Equations of a Straight Line.

1. Intercept Form (Fig. 2): $\dfrac{x}{a} + \dfrac{y}{b} = 1$. ($a$, b = intercepts of the line on the axes.)

2. Slope Form (Fig. 3): $y = mx + b$. ($m = \tan u$ = slope; b = intercept on the y-axis; see also Fig. 2, p. 174.)

3. Normal Form (Fig. 4): $x \cos v + y \sin v = p$. (p = perpendicular from origin to line; v = angle p makes with the x-axis.)

4. Parallel-intercept Form (Fig. 5): $\dfrac{y - b}{c - b} = \dfrac{x}{k}$. ($b$, c = intercepts on two parallels at distance k apart.)

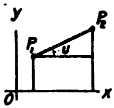

FIG. 1.

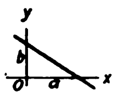

FIG. 2.

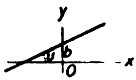

FIG. 3.

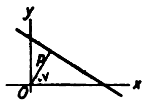

FIG. 4.

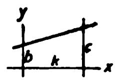

FIG. 5.

5. General Form: $Ax + By + C = 0$. [Here $a = -C/A$, $b = -C/B$, $m = -A/B$, $\cos v = A/R$, $\sin v = B/R$, $p = -C/R$, where $R = \pm\sqrt{A^2 + B^2}$ (sign to be so chosen that p is positive).]

6. Line Through (x_1, y_1) with Slope m: $y - y_1 = m(x - x_1)$.

7. Line Through (x_1, y_1) and (x_2, y_2): $y - y_1 = \dfrac{y_2 - y_1}{x_2 - x_1}(x - x_1)$.

8. Line Parallel to x-axis: $x = a$; to y-axis: $y = b$.

Angles and Distances.

If u = angle between two lines whose slopes are m_1, m_2, then

$$\tan u = \frac{m_2 - m_1}{1 + m_2 m_1}.$$

If parallel, $m_1 = m_2$.
If perpendicular, $m_1 m_2 = -1$.

If u = angle between the lines $Ax + By + C = 0$ and $A'x + B'y + C' = 0$, then

$$\cos u = \frac{AA' + BB'}{\pm\sqrt{(A^2 + B^2)(A'^2 + B'^2)}}.$$

If parallel, $A/A' = B/B'$.
If perpendicular, $AA' + BB' = 0$.

The equations of the bisectors of the angles between the two lines just mentioned are

$$\frac{Ax + By + C}{\sqrt{A^2 + B^2}} \mp \frac{A'x + B'y + C'}{\sqrt{A'^2 + B'^2}} = 0.$$

The equation of a line through (x_1, y_1) and meeting a given line $y = mx + b$ at an angle u, is

$$y - y_1 = \frac{m + \tan u}{1 - m \tan u}(x - x_1).$$

The distance from (x_0, y_0) to the line $Ax + By + C = 0$ is

$$D = \left|\frac{Ax_0 + By_0 + C}{\sqrt{A^2 + B^2}}\right|$$

where the vertical bars mean "the absolute value of."

The distance from (x_0, y_0) to a line which passes through (x_1, y_1) and makes an angle u with the x-axis, is

$$D = (x_0 - x_1)\sin u - (y_0 - y_1)\cos u.$$

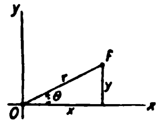

FIG. 6.

Polar Co-ordinates (Fig. 6). Let (x, y) be the rectangular and (r, θ) the polar co-ordinates of a given point P. Then $x = r\cos\theta$; $y = r\sin\theta$; $x^2 + y^2 = r^2$.

Transformation of Co-ordinates. If origin is moved to point (x_0, y_0), the new axes being parallel to the old, $x = x_0 + x'$, $y = y_0 + y'$.

If axes are turned through the angle u, without change of origin,

$$x = x'\cos u - y'\sin u, \quad y = x'\sin u + y'\cos u.$$

THE CIRCLE

(See also pp. 99, 103–105, 106)

Equation of Circle with center (a,b) and radius r:

$$(x - a)^2 + (y - b)^2 = r^2.$$

If center is at the origin, the equation becomes $x^2 + y^2 = r^2$. If circle goes through the origin and center is on the x-axis at point $(r, 0)$, equation becomes $x^2 + y^2 = 2rx$. The **general equation** of a circle is

$x^2 + y^2 + Dx + Ey + F = 0$; it has center at $(-D/2, -E/2)$, and radius $= \sqrt{(D/2)^2 + (E/2)^2 - F}$ (which may be real, null, or imaginary).

The **equation of the radical axis** of two circles, $x^2 + y^2 + Dx + Ey + F = 0$ and $x^2 + y^2 + D'x + E'y + F' = 0$, is $(D - D')x + (E - E')y + (F - F') = 0$. The tangents drawn to two circles from any point of their radical axis are of equal length. If the circles intersect, the radical axis passes through their points of intersection (see p. 100).

The **equation of the tangent** to $x^2 + y^2 = r^2$ at (x_1, y_1) is $x_1x + y_1y = r^2$. The tangent to $x^2 + y^2 + Dx + Ey + F = 0$ at (x_1, y_1) is $x_1x + y_1y + \frac{1}{2}D(x + x_1) + \frac{1}{2}E(y + y_1) + F = 0$. The line $y = mx + b$ will be tangent to the circle $x^2 + y^2 = r^2$ if $b = a\sqrt{1 + m^2}$.

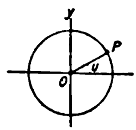

FIG. 7.

Equations of Circle in Parametric Form. It is sometimes convenient to express the co-ordinates x and y of the moving point P (Fig. 7) in terms of an auxiliary variable, called a **parameter**. Thus, if the parameter be taken as the angle u which the radius OP makes with the x-axis, then the equations of the circle in parametric form will be $x = a\cos u$; $y = a\sin u$. For every value of the parameter u, there corresponds a point (x, y) on the circle. The ordinary equation $x^2 + y^2 = a^2$ can be obtained from the parametric equations by eliminating u.

THE PARABOLA

The **parabola** (see also p. 107) is the locus of a point which moves so that its distance from a fixed line (called the **directrix**) is always equal to its distance from a fixed point F (called the **focus**). See Fig. 8. The point half-way from focus to directrix is the **vertex**, O, The line through the focus, perpendicular to the directrix, is the **principal axis**. The breadth of the curve at the focus is called the **latus rectum**, or **parameter**, $= 2p$, where p is the distance from focus to directrix. (Compare also Fig. 3, p. 174.)

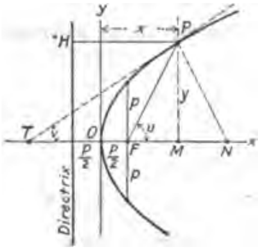

Fig. 8.

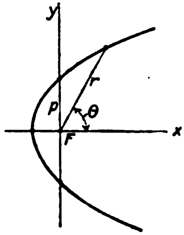

Fig. 9.

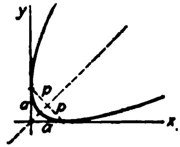

Fig. 10.

Any section of a right circular cone made by a plane parallel to a tangent plane of the cone will be a parabola.

Equation of Parabola, origin at vertex (Fig. 8): $y^2 = 2px$.

Polar Equation of Parabola, referred to F as origin and Fx as axis (Fig. 9): $r = p/(1 - \cos\theta)$.

Equation Referred to the Tangents at the ends of the latus rectum as axes (Fig. 10): $x^{1/2} + y^{1/2} = a^{1/2}$, where $a = p\sqrt{2}$.

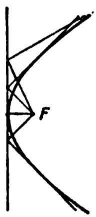

Fig. 11.

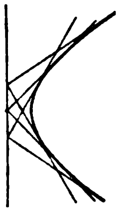

Fig. 12.

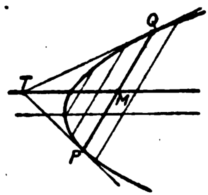

Fig. 13.

Equation of Tangent to $y^2 = 2px$ at (x_1, y_1): $y_1 y = p(x + x_1)$. The line $y = mx + b$ will be tangent to $y^2 = 2px$ if $b = p/(2m)$.

The **tangent** PT at any point P bisects the angle between PF and PH (Fig. 8). A ray of light from F, reflected at P, will move off parallel to the principal axis. The **subtangent**, TM, is bisected at O. The **subnormal**, MN, is constant, and equal to p. The locus of the foot of the perpendicular from the focus on a moving tangent is the tangent at the vertex (Fig. 11). The locus of the point of intersection of perpendicular tangents is the directrix (Fig. 12). The locus of the mid-points of a set of parallel chords whose slope is m is a straight line parallel to the principal axis at a distance p/m

and is called a **diameter** (Fig. 13). If M is the mid-point of a chord PQ, and if T is the point of intersection of the tangents at P and Q, then TM is parallel to the principal axis, and is bisected by the curve (Fig. 13).

To Construct a Tangent to a Given Parabola. (1) At a given point of contact, P (Fig. 14): Find T so that $OT = OM$, or $FT = FP$. Then TP is the tangent at P. Or, make $MN = p = 2(OF)$; then PN is the normal at P.

(2) From a given external point, Q (Fig. 15): With Q as center and radius QF draw circle cutting the directrix in H; draw HP parallel to principal axis; then P is required point of contact. As check, note that QP is the perpendicular bisector of FH.

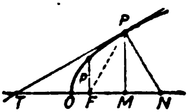

FIG. 14.

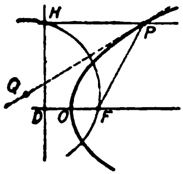

FIG. 15.

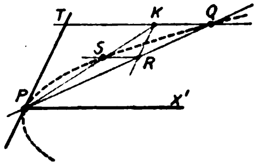

FIG. 16.

To Construct a Parabola. 1. GIVEN ANY TWO POINTS, P AND Q, THE TANGENT PT AT ONE OF THEM, AND THE DIRECTION OF THE PRINCIPAL AXIS OX. In Fig. 16, let K be a variable point on a line through Q parallel to OX. Draw KR parallel to PT (meeting PQ in R), and draw RS parallel to OX (meeting PK in S); then S is a point of the curve. NOTE. A line through P parallel to the principal axis bisects all chords parallel to the tangent PT.

2. GIVEN THE VERTEX O AND FOCUS F. (a) In Fig. 17 draw Oy perpendicular to OF, and slide the vertex of a right angle along Oy so that one side always passes through F; then the other side will always be a tangent to the parabola.

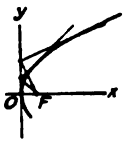

FIG. 17.

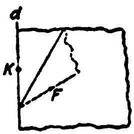

FIG. 18.

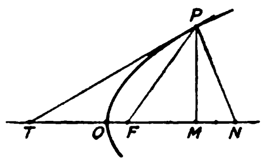

FIG. 19.

(b) Take a piece of paper (Fig. 18) with a straight edge, d, and mark a point F near the edge. Let K be a variable point of the edge, and fold the paper so that K coincides with F. The crease will be a tangent to the parabola which has focus F and directrix d.

(c) In Fig. 19, let M be a variable point of the principal axis, and lay off $MN = 2(OF) = p$. With F as center and radius FN draw a circle, cutting the perpendicular at M in P. Then P is a point of the curve, and PT and PN are the tangent and normal at P.

3. GIVEN TWO TANGENTS AND THEIR POINTS OF CONTACT, P AND Q (Fig. 20). Divide TP and QT into any number of equal parts (here 4). Then the lines 11, 22, 33, . . . will be tangents to the parabola. This method is especially advantageous in drawing rather flat arcs.

The Radius of Curvature of $y^2 = 2px$ at a point $P = (x,y)$ is $R = (p + 2x)^{3/2}/\sqrt{p}$, or $R = p/\sin^3 v$, where v = the angle which the tangent at P makes with PF (Fig. 21). At the vertex, $R = p$. To construct the radius of curvature at any point P, lay off $PR = 2(PF)$ parallel to the principal axis, and draw RC perpendicular to the axis, meeting the normal, PN, in C. Then C is the center of curvature for the point P, and a circle about C with radius CP will coincide closely with the parabola in the neighborhood of P.

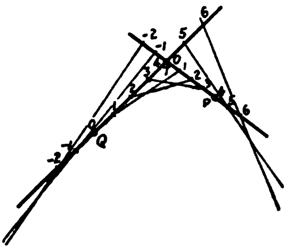

FIG. 20.

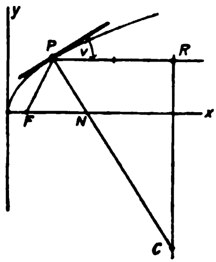

FIG. 21.

THE ELLIPSE

The **ellipse** (see also p. 107) has two **foci**, F and F' (Fig. 22), and two **directrices**, DH and $D'H'$. If P is any point of the curve, $PF + PF'$ is constant, $= 2a$; and PF/PH (or PF'/PH') is also constant, $= e$, where e is the **eccentricity** ($e < 1$). Either of these properties may be taken as the definition of the curve. The relations between e and the semi-axes a and b are as shown in Fig. 23. Thus, $b^2 = a^2(1 - e^2)$, $ae = \sqrt{a^2 - b^2}$, $e^2 = 1 - (b/a)^2$. The **semi-latus rectum** $= p = a(1 - e^2) = b^2/a$. Note that b is always less than a, except in the special case of the circle, in which $b = a$ and $e = 0$.

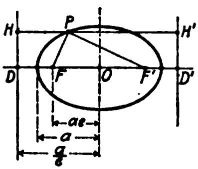

FIG. 22.

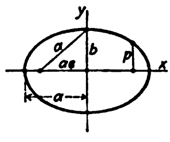

FIG. 23.

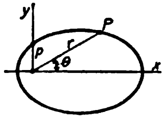

FIG. 24.

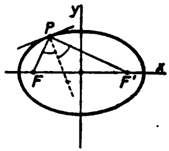

FIG. 25.

Any section of a right circular cone made by a plane which cuts all the elements of one nappe of the cone will be an ellipse; if the plane is perpendicular to the axis of the cone, the ellipse becomes a circle.

Equation of Ellipse, center as origin:

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \quad \text{or} \quad y = \pm \frac{b}{a}\sqrt{a^2 - x^2}.$$

If $P = (x, y)$ is any point of the curve, $PF = a + ex$, $PF' = a - ex$.

Equations of the Ellipse in Parametric Form: $x = a \cos u$, $y = b \sin u$, where u is the eccentric angle of the point $P = (x,y)$. See Fig. 28.

Polar Equation, focus as origin, axes as in Fig. 24: $r = p/(1 - e \cos \theta)$.

Equation of the Tangent at (x_1,y_1): $b^2x_1x + a^2y_1y = a^2b^2$.

The line $y = mx + k$ will be a tangent if $k = \pm\sqrt{a^2m^2 + b^2}$. The normal at any point P bisects the angle between PF and PF' (Fig. 25). The locus of the foot of the perpendicular from the focus on a moving tangent is the circle on the major axis as diameter (Fig. 26). The locus of the point of intersection of perpendicular tangents is a circle with radius $\sqrt{a^2 + b^2}$ (Fig. 27).

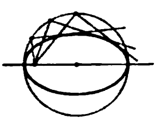

Fig. 26.

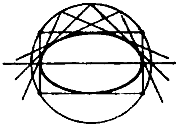

Fig. 27.

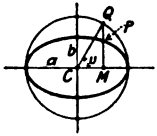

Fig. 28.

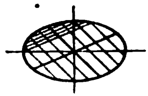

Fig. 29.

Ellipse as a Flattened Circle. Eccentric Angle. If the ordinates in a circle are diminished in a constant ratio, the resulting points will lie on an ellipse (Fig. 28). If Q traces the circle with uniform velocity, the corresponding point P will trace the ellipse, with varying velocity. The angle u in the figure is called the eccentric angle of the point P.

Conjugate Diameters are lines through the center, each of which bisects all the chords parallel to the other (Fig. 29). If m_1 and m_2 are the slopes, then $m_1m_2 = -b^2/a^2$. One pair of conjugate diameters are the diagonals of the rectangle circumscribing the ellipse. The eccentric angles of the ends of two conjugate diameters differ by 90 deg. Thus (Fig. 30), if CQ and CQ' are perpendicular radii in the circle, CP and CP' will be conjugate semi-diameters in the ellipse. A parallelogram formed by tangents drawn parallel to a pair of conjugate diameters has a constant area, $= 4ab$ (Fig. 31). Also, if a',b' are conjugate semi-diameters, and w the angle between them, then $a'^2 + b'^2 = a^2 + b^2$ and $a'b' = ab/\sin w$.

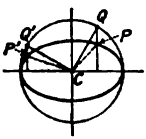

Fig. 30.

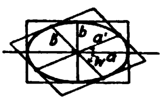

Fig. 31.

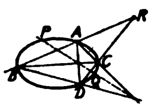

Fig. 32.

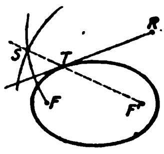

Fig. 33.

To Construct a Tangent to a Given Ellipse. (1) At a Given Point of Contact, P. Bisect the angle between the focal radii PF and PF' (Fig. 25).

(2) From a Given External Point, R. (*a*) Through R draw any two lines cutting the ellipse, one in A and B, the other in C and D (Fig. 32). Through the point of intersection of AD and BC and the point of intersection of AC and BD, draw a line cutting the ellipse in P and Q. Then P and Q are the required points of contact. (*b*) With R as a center and radius RF, draw an arc; with F' as center and radius $2a$ draw an arc, intersecting the first in S; and let SF' meet the curve in T. Then T is the point of contact (Fig. 33).

To Construct an Ellipse, Given a and b. (1) In Fig. 34, with O as center, draw circles with radii a and b (and also a third circle with radius $a + b$). Let a variable ray through O cut these circles in J, K (and S); through J and K draw parallels to the axes, meeting in P. Then P is a point of the ellipse (and SP is the normal at P).

(2) In Fig. 35, let P divide a line AB so that $PA = a$ and $PB = b$. Then if A and B slide on the axes, P will describe an ellipse.

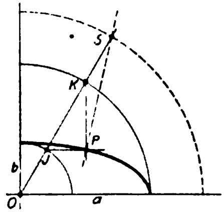

FIG. 34.

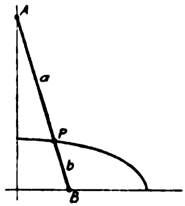

FIG. 35.

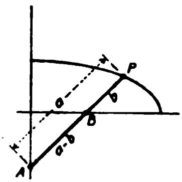

FIG. 36.

(3) In Fig. 36, let PBA be a straight line such that $PA = a$ and $PB = b$. Then if A and B slide on the axes, P will trace an ellipse. (Use a strip of paper, with the points P, B, and A marked on it.)

(4) Find the foci, F and F', by striking an arc of radius a with center at B (Fig. 37). Drive pins at F, F', and B, and adjust a loop of thread around them. Then remove the pin at B, and replace it by a pencil point; by moving the pencil so as to keep the string taut, the complete ellipse can be drawn at one sweep. Or, use a mechanical ellipsograph.

(5) and (6). Apply methods (1) and (2) of the following paragraph to the special case in which OP and OQ are perpendicular semi-axes.

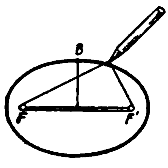

FIG. 37.

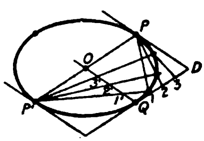

FIG. 38.

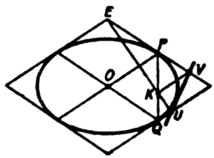

FIG. 39.

To Construct an Ellipse, Given a Pair of Conjugate Semi-diameters, OP and OQ. (1) Complete the parallelogram, as in Fig. 38. Divide QD and QO into n equal parts, 1, 2, 3, . . . and 1′, 2′, 3′, . . . Connect P with 1, 2, 3, . . . and P' with 1′, 2′, 3′ . . .. The points of intersection of corresponding lines will be points of the ellipse.

(2) Take any point K on PQ (Fig. 39). Draw EKU, and draw KV parallel to OP. Then UV will be a tangent. By varying K along PQ as many tangents may be drawn as desired, thus "enveloping" the ellipse.

(3) Through P (Fig. 40), draw a perpendicular PT to OQ, and lay off $PR = PS = OQ$. Then if the line RPT is made to slide with one end on OR and the other on OQ, P will trace the ellipse. Further, the bisectors of the angle ROS show the directions of the principal axes, and $OR + OS = 2a$ and

$OR - OS = 2b$. Also, if a line through P perpendicular to RS (and therefore tangent to the ellipse at P) meets the minor axis in M, a circle with M as center and MR or MS as radius will cut the major axis in the two foci.

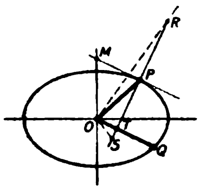

FIG. 40.

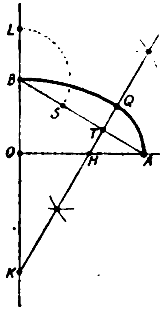

FIG. 41.

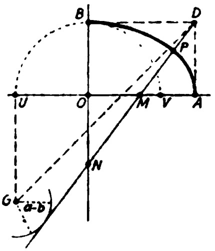

FIG. 42.

To Construct an Ellipse Approximately by Circular Arcs. [Methods (1) and (2) employ two radii, (3) and (4) employ three radii.] (1) In Fig. 41, lay off $OL = OA$ and $BS = BL = a - b$. Bisect SA in T, and draw THK perpendicular to BA. Then H is one center, with radius HA, and K is the other center, with radius KB. The junction point Q of the two arcs will fall a little outside the true ellipse.

(2) In Fig. 42, lay off $OU = OV = OB = b$. Draw UG perpendicular to the axis and DG at 45°. With G as center draw an auxiliary arc with radius

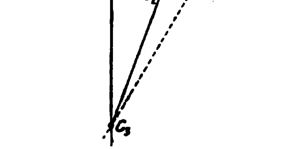

FIG. 43.

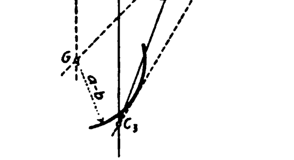

FIG. 44.

$= AV = a - b$, and through D draw DMN just touching this arc. Then M is one center (with radius MA) and N is the other center (with radius NB). The junction point P of the two arcs will be a true point of the ellipse. [E. V. Huntington.]

(3) Through D (Fig. 43) draw DC_1C_3 perpendicular to AB. Call $C_1A = r_1$ and $C_3B = r_3$. Lay off $BE = BO$ ($= b$), and on ED as diameter draw a semicircle cutting the minor axis in W; then $BW = \sqrt{ab} = r_2$. Lay off $AZ =$

BW. From C_1 with radius $C_1Z(=r_2-r_1)$, and from C_3 with radius C_3W $(=r_3-r_2)$, draw arcs intersecting in C_2. Draw C_3C_2 extended and C_2C_1 extended. Then draw in the three arcs, with centers at C_1, C_2, C_3 and radii r_1, r_2, r_3. NOTE. Since r_1 and r_3 are the radii of curvature of the ellipse at A and B, this construction gives a curve which is a little too sharp at A and a little too flat at B. A more accurate construction is the following:

(4) In Fig. 44, lay off $BE = BH = BO = b$. Through the mid-point X of BE draw XG perpendicular to the axis, and through D draw DG at an angle of 45 deg. From G as center draw an auxiliary arc with radius $= DH$ $(= a - b)$, and through D draw DC_1C_3 just touching this arc. Take C_1A as r_1 and C_3B as r_3. On DE as diameter draw a semi-circle cutting the minor axis in W, and take $BW(=\sqrt{ab})$ as r_2. Lay off $AZ = BW$. From C_1 with radius $C_1Z(=r_2-r_1)$, and from C_3 with radius $C_3W(=r_3-r_2)$, draw arcs intersecting in C_2. Then C_1, C_2, C_3 are the required centers. [E. V. Huntington.]

Radius of Curvature of Ellipse at Any Point $P = (x, y)$ is $R = a^2b^2(x^2/a^4 + y^2/b^4)^{3/2} = p/\sin^3 v$, where v is the angle which the tangent at P makes with PF or PF'. At end of major axis, $R = b^2/a = MA$; at end of minor axis, $R = a^2/b = NB$ (see Fig. 45). To construct the radius of curvature at any other point P (Fig. 46), draw the normal at P (by bisecting the angle between PF and PF') and let it meet the major axis in N. At N draw a perpendicular to PN meeting PF in H. At H draw a perpendicular to PH meeting PN in C. Then C is the center of curvature for the point P, and a circle about C with radius CP will coincide closely with the ellipse in the neighborhood of P. [Note. If the circle of curvature meets the ellipse in Q, then the tangent at P and the line PQ are equally inclined to the axis.]

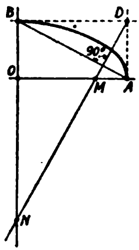

FIG. 45.

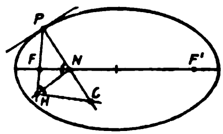

FIG. 46.

THE HYPERBOLA

The **hyperbola** (see also p. 107) has two **foci**, F and F', at distances $\pm ae$ from the center, and two **directrices**, DH and $D'H'$, at distances $\pm a/e$ from

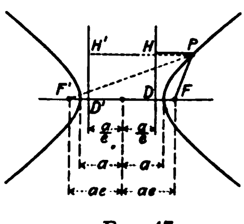

FIG. 47.

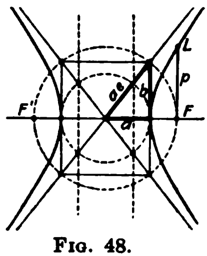

FIG. 48.

the center (Fig. 47). If P is any point of the curve, $|PF - PF'|$ is constant, $= 2a$; and PF/PH (or PF'/PH') is also constant, $= e$ (called the **eccentricity**), where $e > 1$. Either of these properties may be taken as the definition of the curve. The curve has two branches which approach more and more nearly two straight lines called the **asymptotes.** Each asymptote makes with the principal axis an angle whose tangent is b/a. The relations between e, a, and b are shown in Fig. 48: $b^2 = a^2(e^2 - 1)$, $ae = \sqrt{a^2 + b^2}$, $e^2 = 1 + (b/a)^2$. The semi-latus rectum, or ordinate at the focus, is $p = a(e^2 - 1) = b^2/a$.

Any section of a right circular cone made by a plane which cuts both nappes of the cone will be a hyperbola. (Compare also Fig. 3, p. 174.)

Equation of the Hyperbola, center as origin:

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1, \text{ or } y = \pm \frac{b}{a}\sqrt{x^2 - a^2}.$$

If $P = (x,y)$ is on the right-hand branch, $PF = ex - a$, $PF' = ex + a$. If P is on the left-hand branch, $PF = -ex + a$, $PF' = -ex - a$.

Equations of Hyperbola in Parametric Form. (1) $x = a \cosh u$, $y = b \sinh u$. (For tables of hyperbolic functions, see pp. 60 and 61.) Here u may be interpreted as A/a^2, where A is the area shaded in Fig. 49.

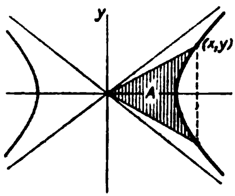

FIG. 49.

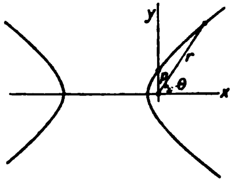

FIG. 50.

(2) $x = a \sec v$, $y = b \tan v$, where v is an auxiliary angle of no special geometric interest.

Polar Equation, referred to focus as origin, axes as in Fig. 50:

$$r = p/(1 - e \cos \theta).$$

Equation of the Tangent at (x_1,y_1): $b^2x_1x - a^2y_1y = a^2b^2$.

The line $y = mx + k$ will be a tangent if $k = \pm\sqrt{a^2m^2 - b^2}$. The tangent at any point P (Fig. 51) bisects the angle between PF and PF'. The locus of the foot of the perpendicular from the focus on a moving tangent is the circle on the principal axis as diameter (Fig. 52). The locus of the point of intersection of perpendicular tangents is a circle with radius $\sqrt{a^2 - b^2}$, which will be imaginary if $b > a$ (Fig. 53).

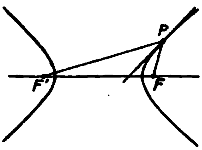

FIG. 51.

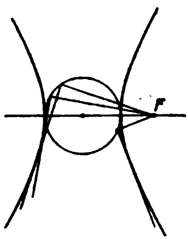

FIG. 52.

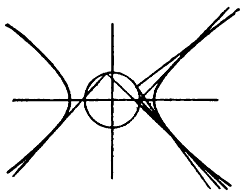

FIG. 53.

Properties of the Asymptotes. (Fig. 54.) If P is any point of the curve, the product of the perpendicular distances from P to the two asymptotes is constant, $= a^2b^2/(a^2 + b^2)$. Also, the product of the oblique distances (the distance to each asymptote being measured parallel to the other) is constant, and equal to $\frac{1}{4}(a^2 + b^2)$. If a line cuts the hyperbola and its asymptotes, the parts of the line intercepted between the curve and the asymptotes are equal. The part of a tangent intercepted between the asymptotes is bisected by the point of contact. The triangle bounded by the asymptotes and a variable tangent is of constant area, $= ab$. If a line through Q perpendicular to the principal axis meets the asymptotes in R and S (see Fig. 54), then $\overline{QR} \times \overline{QS} = b^2$. If a line through Q parallel to the principal axis meets the asymptotes in U and V, then $\overline{QU} \times \overline{QV} = a^2$.

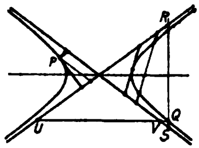

FIG. 54.

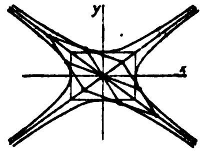

FIG. 55.

Conjugate Hyperbolas are two hyperbolas having the same asymptotes with semi-axes interchanged (Fig. 55). The equation of the hyperbola conjugate to $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$, is $\frac{x^2}{a^2} - \frac{y^2}{b^2} = -1$.

Conjugate Diameters are lines through the center, each of which bisects all the chords parallel to the other—a chord which does not meet the given hyperbola being understood to be terminated by the conjugate hyperbola (Fig. 55). If m_1 and m_2 are the slopes, then $m_1m_2 = b^2/a^2$. Each asymptote, regarded as a diameter, is its own conjugate. If a parallelogram is formed by tangents drawn parallel to a pair of conjugate diameters, its vertices will lie on the asymptotes, and its area will be constant $= 4ab$. If a', b' are conjugate semi-diameters, and w the angle between them, then $a'^2 - b'^2 = a^2 - b^2$, and $a'b' = ab/\sin w$.

Equilateral Hyperbola ($a = b$). Equation referred to principal axes (Fig. 56): $x^2 - y^2 = a^2$. NOTE. $p = a$. Equation referred to asymptotes as axes (Fig. 57): $xy = a^2/2$. (See also Fig. 3, p. 174.)

Asymptotes are perpendicular. Eccentricity $= \sqrt{2}$. Any diameter is equal in length to its conjugate diameter.

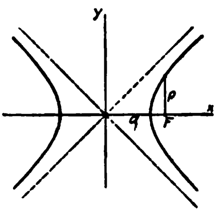

FIG. 56.

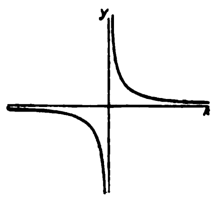

FIG. 57.

To Construct a Tangent at any given point P of a hyperbola. In Fig. 58, draw PA and PB parallel to the asymptotes, and take $OS = 2(OA)$ and $OT = 2(OB)$. Then ST is the tangent at P.

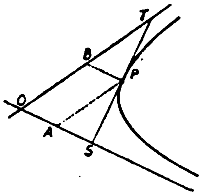

FIG. 58.

To Construct a Hyperbola, given the asymptotes and any point P. (1) In Fig. 59 let TPT' be a variable line through P, and lay off $T'P' = TP$; then P' is a point of the curve.

(2) In Fig. 60, draw PA and PB parallel to the asymptotes. Lay off $OA' = n(OA)$ and $OB' = (1/n)(OB)$, where n is any number; and through A' and B' draw parallels to the axes; these will meet in a point P' of the curve.

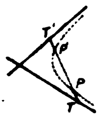

FIG. 59.

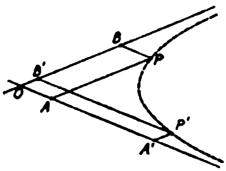

FIG. 60.

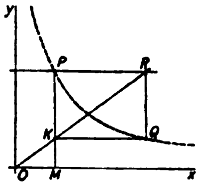

FIG. 61.

(3) (Fig. 61.) Take any point K in the ordinate PM, and draw OK meeting the line through P parallel to the x-axis in R. Draw a parallel to the x-axis through K and a parallel to the y-axis through R, meeting in Q. Then Q is a point of the curve.

THE CATENARY

The catenary is the curve in which a flexible chain or cord of uniform density will hang when supported by the two ends. Let w = weight of the chain per unit length; T = the tension at any point P; and T_h, T_v = the horizontal and vertical components of T. The horizontal component T_h is the same at all points of the curve.

The length $a = T_h/w$ is called the **parameter** of the catenary, or the distance from the lowest point O to the **directrix** DQ (Fig. 62). When a is very large, the curve is very flat. For methods of finding a in any given case, see problems 1–6 below.

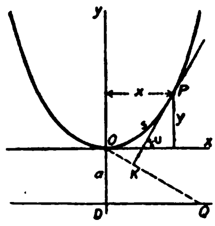

FIG. 62.

The rectangular **equation**, referred to the lowest point as origin, is $y = a\ [\cosh\ (x/a) - 1]$. (For table of hyperbolic functions, see p. 60.) In case of very flat arcs (a large), $y = \dfrac{x^2}{2a} + \ldots$; $s = x + \frac{1}{6}\dfrac{x^3}{a^2} + \ldots$, approximately, so that in such a case the catenary closely resembles a parabola.

If the perpendicular from O to the tangent at P meets the directrix in Q, then $DQ = \text{arc}\, OP = s$ and $OQ = y + a$. The **radius of curvature** at P is $R = (y + a)^2/a$, which is equal in length to the portion of the normal intercepted between P and the directrix.

Problems on the Catenary (Fig. 62). When any two of the four quantities x, y, s, T/w are known, the remaining two, and also the parameter a, can be found, as follows:

(1) GIVEN x AND y. Compute y/x, and find from Table 1 the value of the auxiliary variable z. Then compute $a = x/z$, $s = a \sinh z$, and $T = wa \cosh z$. Or, having z, find s/x and wx/T by using Tables 3 and 2 inversely, and hence (since x is known) compute s and T/w without the use of a.

TABLE 1. GIVING z WHEN y/x IS KNOWN. THEN $a = x/z$.

y/x	0	1	2	3	4	5	6	7	8	9

(4) GIVEN y AND s. Then $\dfrac{T}{w} = \dfrac{s^2}{2y} + \dfrac{y}{2}$, $x = \left(\dfrac{s^2}{y} - y\right)\tanh^{-1}\left(\dfrac{y}{s}\right)$, $a = \dfrac{s^2}{2y} - \dfrac{y}{2}$. Or, if y/s is small, $x = s\left[1 - \dfrac{2}{3}\left(\dfrac{y}{s}\right)^2 - \dfrac{2}{15}\left(\dfrac{y}{s}\right)^4 - \cdots\right]$.

(5) GIVEN y AND T/w. Then $a = \dfrac{T}{w} - y$, $x = \left(\dfrac{T}{w} - y\right)\cosh^{-1}\dfrac{T/w}{(T/w) - y}$, $s = \sqrt{2y(T/w) - y^2}$. Or, if $y/(T/w)$ is small,

$$x = \sqrt{\frac{2yT}{w}}\left[1 - \frac{7}{12}\frac{wy}{T} - \cdots\right], \quad \frac{s - x}{s} = \frac{1}{3}\frac{wy}{T}, \text{ approximately,}$$

$$s = \sqrt{\frac{2yT}{w}}\left[1 - \frac{1}{4}\frac{wy}{T} - \frac{1}{32}\left(\frac{wy}{T}\right)^2 - \frac{1}{128}\left(\frac{wy}{T}\right)^3 - \cdots\right].$$

(6) GIVEN s AND T/w. Then $x = \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2}\tanh^{-1}\left(\dfrac{ws}{T}\right)$,

$y = \dfrac{T}{w} - \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2}$, $a = \dfrac{T}{w}\sqrt{1 - \left(\dfrac{ws}{T}\right)^2}$. Or, if ws/T is small,

$$x = s\left[1 - \frac{1}{6}\left(\frac{ws}{T}\right)^2 - \frac{11}{120}\left(\frac{ws}{T}\right)^4 - \cdots\right], \quad y = s\left[\frac{1}{2}\left(\frac{ws}{T}\right) + \frac{1}{8}\left(\frac{ws}{T}\right)^3 + \cdots\right]$$

$$s = \frac{T}{w}\left[1 - \frac{1}{2}\left(\frac{ws}{T}\right)^2 - \frac{1}{8}\left(\frac{ws}{T}\right)^4 - \cdots\right].$$

Given the Length 2L of a Chain Supported at Two Points A and B not in the Same Level, to find a. (See Fig. 63; b and c are supposed known.) Let $(\sqrt{L^2 - b^2})/c = s/x$; enter Table 3 with this value of s/x, and find the corresponding value of the auxiliary variable z. Then $a = c/z$, Note. The co-ordinates of the mid-point M of AB (see Fig. 63) are $x_0 = a \tanh^{-1}(b/L)$, $y_0 = (L/\tanh z) - a$, so that the position of the lowest point is determined.

Correction for Sag in Chaining Uphill (Fig. 64). Let l = length of tape (corrected for stretch and temperature), w = weight per unit length of tape, A = angle between the chord AB and the horizontal.

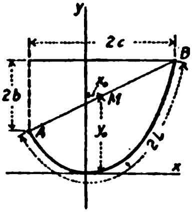

Fig. 63.

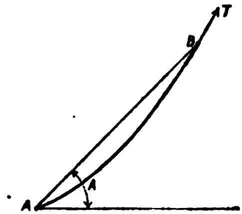

Fig. 64.

If the tension P at the upper end is known, compute wl/P and find k from Table 4. If the tension Q at the lower end is known, compute wl/Q and find k from Table 5. In either case, chord $AB = l - kl$.

Note. $k = 1 - \{[1 - \sqrt{1 - 2m \sin u + m^2}]/[m \sin A]\}$, where $m = wl/P$ and u is given by

$$[1 - \sqrt{1 - 2m \sin u + m^2}] \sec u = [\sinh^{-1}(\tan u) - \sinh^{-1}(\tan u - m \sec u)] \tan A.$$

Also, $Q = P - wl(1 - k) \sin A$, where k is the value in Table 4 corresponding to the given values of P and A.

Correction for Stretch in Chaining Uphill. Let L = unstretched length of tape at working temperature, w = weight per unit length of tape, A = angle between chord AB and the horizontal, F = area of cross-section, E = Young's modulus of elasticity (for steel, E = 29,000,000 lb. per sq. in.), l = stretched length (along curve).

If the tension P at the upper end is known, compute wL/P and find m from Table 6. Then $l = L + (LP/FE)(1 - m)$.

If the tension Q at the lower end is known, compute wL/Q and find n from Table 7. Then $l = L + (LQ/FE)(1 + n)$.

OTHER USEFUL CURVES

The Cycloid is traced by a point on the circumference of a circle which rolls without slipping along a straight line. **Equations** of cycloid, in parametric form (axes as in Fig. 65): $x = a\,(\text{rad}\,u - \sin u)$, $y = a(1 - \cos u)$, where a is

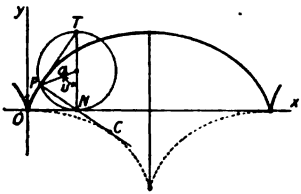

FIG. 65.

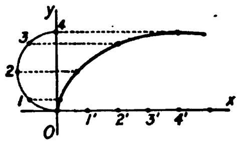

FIG. 66.

the radius of the rolling circle, and rad u is the radian measure of the angle u through which it has rolled. The tangent and normal at any point pass through the highest and lowest points of the corresponding position of the generating circle. The **radius of curvature** at any point P is $PC = 4a \sin(u/2) = 2\sqrt{2ay}$ = twice the length of the normal, PN. The **evolute**, or locus of centers of curvature, is an equal cycloid. **To construct** a cycloid (Fig. 66), divide the semi-circumference of the generating circle into n equal parts (here 4) and lay off these arcs along the base (from O to $4'$). Describe arcs with centers at $1'$, $2'$, . . . and radii equal to the chords $O1$, $O2$, . . ., and sketch the cycloid as a curve tangent to all of these arcs. Or, on horizontal lines through 1, 2, . . . lay off distances equal to $O1'$, $O2'$, etc.; the points thus reached will lie on the cycloid.

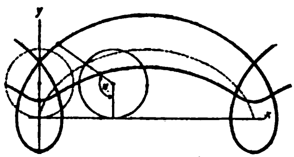

FIG. 67.

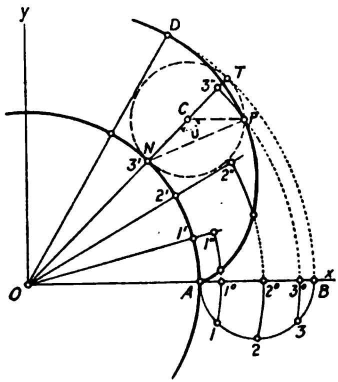
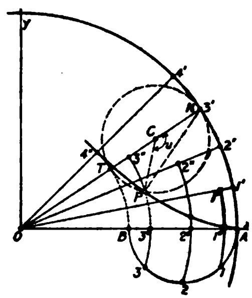
The area of one arch $= 3\pi a^2$, length of arc of one arch $= 8a$. Area bounded by the ordinate of the point P corresponding to any value of u is $a^2\,(\tfrac{3}{2}\,\text{rad}\,u - 2 \sin u + \tfrac{1}{4} \sin 2u) = \tfrac{3}{2}\,ax - \tfrac{1}{2}\,y\sqrt{(2a - y)y}$. Length of arc $OP = 4a\,(1 - \cos \tfrac{1}{2} u) = 4a - 2\sqrt{2a(2a - y)}$.

The Trochoid is a more general curve, traced by any point on a radius of the rolling circle, at distance b from the center (Fig. 67). It is a prolate trochoid if $b < a$, and a curtate or looped trochoid if $b > a$. The equations in either case are $x = a \text{ rad } u - b \sin u, \quad y = a - b \cos u$.

The Epicycloid (or **Hypocycloid**) is a curve generated by a point on the circumference of a circle of radius a which rolls without slipping on the outside (or inside) of a fixed circle of radius c. For the **equations**, put $b = a$ in the equations of the epi- (or hypo-) trochoid, below. The normal at any point P passes through the point of contact N of the corresponding position of the rolling circle. To construct the curve (Figs. 68 and 69),



Epicycloid.
FIG. 68.



Hypocycloid.
FIG. 69.

divide the semi-circumference of the rolling circle into n equal parts, by points 1, 2, 3 . . ., and lay off these arcs ($A1$, $A2$, $A3$) along the circumference of the base circle, as $A1'$, $A2'$, $A3'$, ... Describe circles with centers at $1'$, $2'$, $3'$, . . . and radii equal to the chords $A1$, $A2$, $A3$, . . .; then the required curve will be tangent to all these circles. Or, with O as center, draw arcs through 1, 2, 3, . . ., meeting the radius OA in 1^0, 2^0, 3^0, . . ., and the radii $O1'$, $O2'$, $O3'$, . . . in $1''$, $2''$, $3''$, . . .; then from $1''$, $2''$, $3''$, . . . lay off arcs equal to 1^01, 2^02, 3^03, . . . respectively; the points thus reached will be points of the curve.

The area $OAP = \dfrac{a(c \pm a)(c \pm 2a)}{2c}(\text{rad } u - \sin u)$, where the upper sign applies to the epicycloid, the lower to the hypocycloid, and rad u = the radian measure of the angle u shown in Figs. 68 and 69. Arc $AP = (4\,a/c)(c \pm a)(1 - \cos \tfrac{1}{2}u)$; arc $AD = (4a/c)(c \pm a)$. [In Fig. 69, $D = 4''$.]

Radius of curvature at any point P is $R = \dfrac{4a(c \pm a)}{c \pm 2a} \sin \tfrac{1}{2}u$; at A, $R = 0$; at D, $R = \dfrac{4a(c \pm a)}{c \pm 2a}$.

Special Cases. If $a = \tfrac{1}{2}c$, the hypocycloid becomes a straight line, diameter of the fixed circle (Fig. 70). In this case the hypotrochoid traced by any

point rigidly connected with the rolling circle (not necessarily on the circumference) will be an ellipse. If $a = \frac{1}{4}c$, the curve generated will be the four-cusped hypocycloid, or **astroid,** (Fig. 71), whose equation is $x^{2/3} + y^{2/3} = c^{2/3}$. If $a = c$, the epicycloid is the **cardioid,** whose equation in polar coordinates (axes as in Fig. 72) is $r = 2c(1 + \cos\theta)$. Length of cardioid $= 16c$.

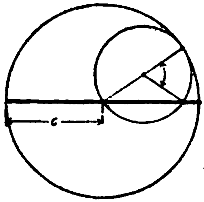


FIG. 70.

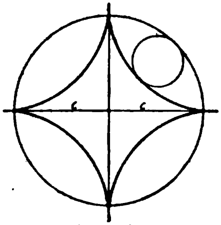
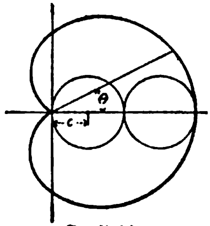


Astroid.
FIG. 71.

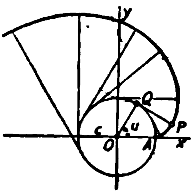


Cardioid.
FIG. 72.

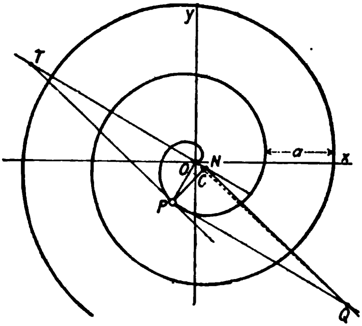
The Epitrochoid (or Hypotrochoid) is a curve traced by any point rigidly attached to a circle of radius a, at distance b from the center, when this circle rolls without slipping on the outside (or inside) of a fixed circle of radius c. The equations are $x = (c \pm a)\cos\left(\frac{a}{c}u\right) \mp b\cos\left[\left(1 \pm \frac{a}{c}\right)u\right]$,

$y = (c \pm a)\sin\left(\frac{a}{c}u\right) - b\sin\left[\left(1 \pm \frac{a}{c}\right)u\right]$, where u = the angle which the moving radius makes with the line of centers; take the upper sign for the epi- and the lower for the hypo-trochoid. The curve is called prolate or curtate according as $b < a$ or $b > a$. When $b = a$, the special case of the epi- or hypocycloid arises.

The Involute of a Circle is the curve traced by the end of a taut string which is unwound from the circumference of a fixed circle, of radius c. If QP



Involute of Circle.
FIG. 73.



Spiral of Archimedes.
FIG. 74.

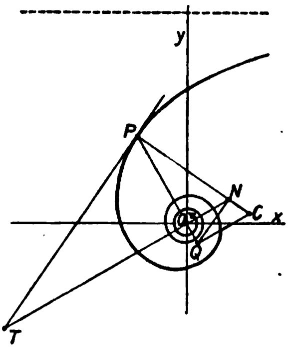
is the free portion of the string at any instant (Fig. 73), QP will be tangent to the circle at Q, and the length of QP = length of arc QA; hence the construction of the curve. The equations of the curve in parametric form (axes as in figure) are $x = c(\cos u + \text{rad } u \sin u)$, $y = c(\sin u - \text{rad } u \cos u)$, where rad u is the radian measure of the angle u which OQ makes with the x-axis. Length of arc $AP = \frac{1}{2}c(\text{rad } u)^2$; radius of curvature at P is QP.

The Spiral of Archimedes (Fig. 74) is traced by a point P which, starting from O, moves with uniform velocity along a ray OP, while the ray itself revolves with uniform angular velocity about O. Polar equation: $r = k \text{ rad } \theta$, or $r = a\,(\theta/360°)$. Here $a = 2\pi k =$ the distance, measured along a radius, from each coil to the next.

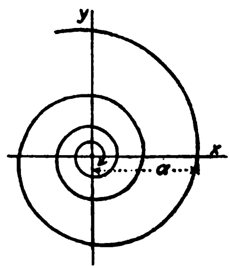
In order to construct the curve, draw radii $O1, O2, O3, \ldots$ making angles $\frac{1}{n}(360°)$, $\frac{2}{n}(360°)$, $\frac{3}{n}(360°)$, . . . with Ox, and along these radii lay off distances equal to $\frac{1}{n}a$, $\frac{2}{n}a$, $\frac{3}{n}a$, . . .; the points thus reached will lie on the spiral. The figure shows one-half of the curve, corresponding to positive values of θ.

Construction for tangent and normal: Let PT and PN be the tangent and normal at any point P, the line TON being perpendicular to OP. Then $OT = r^2/k$, and $ON = k$, where $k = a/(2\pi)$. Hence the construction.

The radius of curvature at P is $R = (k^2 + r^2)^{3/2}/(2k^2 + r^2)$. To construct the center of curvature, C, draw NQ perpendicular to PN and PQ perpendicular to OP; then OQ will meet PN in C. Length of arc $OP = \frac{1}{2}k\,[\text{rad } \theta \sqrt{1 + (\text{rad } \theta)^2} + \sinh^{-1}(\text{rad } \theta)]$. After many windings, arc $OP = \frac{1}{2}r^2/k$, approximately.



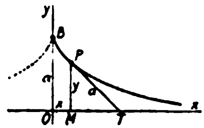
Hyperbolic Spiral.
FIG. 75.



Logarithmic Spiral.
FIG. 76.

The Hyperbolic Spiral is the curve whose polar equation is $r = a/\text{rad } \theta$. To construct the curve, take a series of points along Ox (Fig. 75); through each of these points, with center at O, draw an arc extending into the upper half of the plane; and along each of these arcs lay off a length $= a$. The points thus reached will lie on the curve. A line parallel to the x-axis, at distance a, is an asymptote of the curve. The curve winds around and around the point O without ever reaching it (asymptotic point). The figure shows one-half of the curve, corresponding to positive values of θ. If PT and PN are the tangent and normal at any point P, the line TON being perpendicular to OP, then $OT = a$, and $ON = r^2/a$. Hence a construction for the tangent and normal. Radius of curvature at P is $R = r/\sin^3 v$, where v = angle between OP and the tangent at P. Construction: At N draw a perpendicular to PN, meeting PO in Q; at Q draw a perpendicular to PQ, meeting PN in C; then C is the center of curvature for the point P.

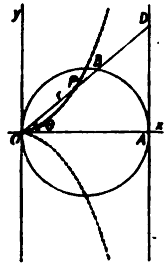
The Logarithmic Spiral (Fig. 76), is a curve which cuts the radii from O at a constant angle v, whose cotangent is m. Polar equation: $r = ae^{m \text{ rad } \theta}$. Here a is the value of r when $\theta = 0$. For large negative values of θ, the curve winds around O as an asymptotic point. If PT and PN are the tangent and normal at P, the line TON being perpendicular to OP (not shown in fig.), then $ON = rm$, and $PN = r\sqrt{1 + m^2} = r/\sin v$. Radius of curvature at P is PN. The evolute of the spiral is an equal spiral whose axis makes an angle $\frac{1}{2}\pi - (\log_e m)/m$ with the axis of the given spiral. Area swept out by the radius r from $r = 0$ (where $\theta = -\infty$) to $r = r$, is $A = r^2/(4m)$ = half the triangle OPT. Length of arc from O to $P = s = r/\cos v = PT$.



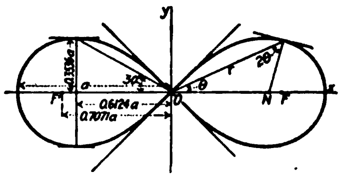
Tractrix.
FIG. 77.

The Tractrix, or Schiele's Anti-friction Curve (Fig. 77), is a curve such that the portion PT of the tangent between the point of contact and the x-axis is constant $= a$. Its equation is $x = \pm a \left[\cosh^{-1}\frac{a}{y} - \sqrt{1 - \left(\frac{y}{a}\right)^2}\right]$, or, in parametric form, $x = \pm a\,[t - \tanh t]$, $y = a/\cosh t$. (For tables of hyperbolic functions, see p. 60.) The x-axis is an asymptote of the curve. Length of arc $BP = a \log_e (a/y)$. The evolute (locus of centers of curvature) is the catenary whose lowest point is at B, and whose directrix is Ox.

The Cissoid (Fig. 78) is the locus of a point P such that OP, laid off on a variable ray from O, is equal to BD, the portion of the ray lying between a fixed circle through O and a fixed tangent at the point A opposite O. If a is the radius of the circle, the polar equation is $r = 2a \sin^2 \theta / \cos \theta$. Rectangular equation, $y^2(2a - x) = x^3$.



Cissoid.
FIG. 78.

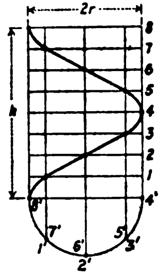


Lemniscate.
FIG. 79.

The Lemniscate (Fig. 79) is the locus of a point P the product of whose distances from two fixed points F, F' is constant, equal to $\frac{1}{2} a^2$. The distance $FF' = a\sqrt{2}$. Polar equation is $r = a\sqrt{\cos 2\theta}$. Angle between OP and the normal at P is 2θ. The two branches of the curve cross at right angles at O.

Maximum y occurs when $\theta = 30°$ and $r = a/\sqrt{2}$, and is equal to $\frac{1}{4} a\sqrt{2}$.
Area of one loop $= a^2/2$.

The Helix (Fig. 80) is the curve of a screw thread on a cylinder of radius r. The curve crosses the elements of the cylinder at a constant angle, v. The pitch, h, is the distance between two coils of the helix, measured along an element of the cylinder; hence $h = 2\pi r \tan v$. Length of one coil $= \sqrt{(2\pi r)^2 + h^2} = 2\pi r/\cos v$. To construct the projection of a helix on a plane containing the axis of the cylinder, draw a rectangle, breadth $2r$ and height h, to represent the plane, with a semicircle below it, as in the figure, to represent the base of the cylinder. Divide h into equal parts (here 8), numbered from 1 to 8; think of the circumference as also divided into 8 equal parts, represented on the semicircle by numbers from $1'$ to $4'$ and back again from $4'$ to $8'$. Then the point of intersection of a horizontal line through 1, 2, . . . with a vertical line through $1'$, $2'$, . . . will be a point of the required projection. If the cylinder is rolled out on a plane, the development of the helix will be a straight line, with slope equal to $\tan v$.



Helix.
FIG. 80.

DIFFERENTIAL AND INTEGRAL CALCULUS

DERIVATIVES AND DIFFERENTIALS

Derivaties and Differentials. A **function** of a single variable x may be denoted by $f(x), F(x)$, etc. The value of the function when x has the value x_0 is then denoted by $f(x_0), F(x_0)$, etc. The **derivative** of a function $y = f(x)$ may be denoted by $f'(x)$, or by dy/dx. The value of the derivative at a given point $x = x_0$ is the **rate of change** of the function at that point; or, if the function is represented by a curve in the usual way (Fig. 1), the value of the derivative at any point shows the **slope of the curve** (that is, the slope of the tangent to the curve) at that point (positive if the tangent points upward, and negative if it points downward, moving to the right).

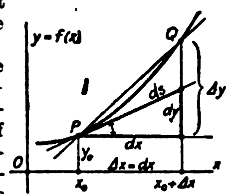


FIG. 1.

The **increment** Δy (read: "delta y"), in y is the change produced in y by increasing x from x_0 to $x_0 + \Delta x$; that is, $\Delta y = f(x_0 + \Delta x) - f(x_0)$. The **differential**, dy, of y is the value which Δy would have if the curve coincided with its tangent. (The differential, dx, of x is the same as Δx when x is the independent variable.) Note that the derivative depends only on the value of x_0, while Δy and dy depend not only on x_0 but also on the value of Δx. The ratio $\Delta y/\Delta x$ represents the slope of the secant, and dy/dx the slope of the tangent (see Fig. 1). If Δx is made to approach zero, the secant approaches the tangent as a limiting position, so that the derivative $= f'(x) =$

$$\frac{dy}{dx} = \lim_{\Delta x \doteq 0}\left[\frac{\Delta y}{\Delta x}\right] = \lim_{\Delta x \doteq 0}\left[\frac{f(x_0 + \Delta x) - f(x_0)}{\Delta x}\right].$$ Also, $dy = f'(x)\,dx$.

The symbol "lim" in connection with $\Delta x \doteq 0$ means "the limit, as Δx approaches 0, of . . ." [A constant c is said to be the **limit** of a variable u if, whenever any quantity m has been assigned, there is a stage in the variation-process beyond which $|c - u|$ is always less than m; or, briefly, c is the limit of u if the difference between c and u can be made to become and remain as small as we please.]

To find the derivative of a given function at a given point: (1) If the function is given only by a curve, measure graphically the slope of the tangent at the point in question; (2) if the function is given by a mathematical expression, use the following rules for differentiation. These rules give, directly, the differential, dy, in terms of dx; to find the derivative, dy/dx, divide through by dx.

Rules for Differentiation. (Here $u, v, w, \ldots$ represent any functions of a variable x, or may themselves be independent variables. a is a constant which does not change in value in the same discussion; $e = 2.71828$.)

1. $d(a + u) = du$. 2. $d(au) = adu$.
3. $d(u + v + w + \ldots) = du + dv + dw + \ldots$
4. $d(uv) = udv + vdu$.
5. $d(uvw\ldots) = (uvw\ldots)\left(\frac{du}{u} + \frac{dv}{v} + \frac{dw}{w} + \ldots\right)$
6. $d\frac{u}{v} = \frac{udv - vdu}{v^2}$.
7. $d(u^m) = mu^{m-1}du$.

Thus, $d(u^2) = 2udu$; $d(u^3) = 3u^2du$; etc.

8. $d\sqrt{u} = \dfrac{du}{2\sqrt{u}}$. 9. $d\left(\dfrac{1}{u}\right) = -\dfrac{du}{u^2}$.

10. $d(e^u) = e^u du$. 11. $d(a^u) = (\log_e a)a^u du$.

12. $d \log_e u = \dfrac{du}{u}$. 13. $d \log_{10} u = (\log_{10} e)\dfrac{du}{u} = (0.4343\ldots)\dfrac{du}{u}$.

14. $d \sin u = \cos u\, du$. 15. $d \csc u = -\cot u \csc u\, du$.

16. $d \cos u = -\sin u\, du$. 17. $d \sec u = \tan u \sec u\, du$.

18. $d \tan u = \sec^2 u\, du$. 19. $d \cot u = -\csc^2 u\, du$.

20. $d \sin^{-1} u = \dfrac{du}{\sqrt{1-u^2}}$. 21. $d \csc^{-1} u = -\dfrac{du}{u\sqrt{u^2-1}}$.

22. $d \cos^{-1} u = -\dfrac{du}{\sqrt{1-u^2}}$. 23. $d \sec^{-1} u = \dfrac{du}{u\sqrt{u^2-1}}$.

24. $d \tan^{-1} u = \dfrac{du}{1+u^2}$. 25. $d \cot^{-1} u = -\dfrac{du}{1+u^2}$.

26. $d \log_e \sin u = \cot u\, du$. 27. $d \log_e \tan u = \dfrac{2du}{\sin 2u}$.

28. $d \log_e \cos u = -\tan u\, du$. 29. $d \log_e \cot u = -\dfrac{2du}{\sin 2u}$.

30. $d \sinh u = \cosh u\, du$. 31. $d \operatorname{csch} u = -\operatorname{csch} u \coth u\, du$.

32. $d \cosh u = \sinh u\, du$. 33. $d \operatorname{sech} u = -\operatorname{sech} u \tanh u\, du$.

34. $d \tanh u = \operatorname{sech}^2 u\, du$. 35. $d \coth u = -\operatorname{csch}^2 u\, du$.

36. $d \sinh^{-1} u = \dfrac{du}{\sqrt{u^2+1}}$. 37. $d \operatorname{csch}^{-1} u = -\dfrac{du}{u\sqrt{u^2+1}}$.

38. $d \cosh^{-1} u = \dfrac{du}{\sqrt{u^2-1}}$. 39. $d \operatorname{sech}^{-1} u = -\dfrac{du}{u\sqrt{1-u^2}}$.

40. $d \tanh^{-1} u = \dfrac{du}{1-u^2}$. 41. $d \coth^{-1} u = \dfrac{du}{1-u^2}$.

42. $d(u^v) = (u^{v-1})(u \log_e u\, dv + v\, du)$.

Derivatives of Higher Orders. The derivative of the derivative is called the second derivative; the derivative of this, the third derivative; and so on. Notation: if $y = f(x)$,

$$f'(x) = D_x y = \frac{dy}{dx};\quad f''(x) = D_x^2 y = \frac{d^2y}{dx^2};\quad f'''(x) = D_x^3 y = \frac{d^3y}{dx^3};\quad \text{etc.}$$

NOTE. If the notation d^2y/dx^2 is used, this must not be treated as a fraction, like dy/dx but as an inseperable symbol, made up of a symbol of operation, d^2/dx^2, and an operand y

The geometric meaning of the second derivative is this: if the original function $y = f(x)$ is represented by a curve in the usual way, then at any point where $f''(x)$ is *positive*, the curve is *concave upward*, and at any point where $f''(x)$ is *negative*, the curve is *concave downward* (Fig. 2). When $f''(x) = 0$, the curve usually has a **point of inflection.**

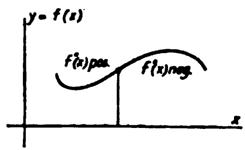

FIG. 2.

Differentials of Higher Orders. The differential of the differential is called the second differential; the differential of this, the third differential; etc. These quantities are of little importance except in the case where dx = a constant. In this case

$$dy = f'(x)dx; \quad d^2y = f''(x)\cdot(dx)^2; \quad d^3y = f'''(x)\cdot(dx)^3; \ . \ . \ .$$

The first, second, third, etc., differentials are close approximations to the first, second, third, etc., differences (p. 115), and are therefore sometimes useful in constructing tables. Thus, denoting the first, second, third, etc., differences by D', D'', D''', etc., and, assuming always that dx = a constant,

$$D' = dy + \tfrac{1}{2} d^2y + \tfrac{1}{6} d^3y + \tfrac{1}{24} d^4y + \ . \ . \ .; \quad d^3y = D''' - \tfrac{3}{2} D'''' + \ . \ . \ .$$
$$D'' = d^2y + d^3y + \tfrac{7}{12} d^4y + \ . \ . \ .; \quad d^2y = D'' - D''' + \tfrac{11}{12} D'''' + \ . \ . \ .$$
$$D''' = d^3y + \tfrac{3}{2} d^4y + \ . \ . \ .; \quad dy = D' - \tfrac{1}{2} D'' + \tfrac{1}{3} D''' - \tfrac{1}{4} D'''' + \ . \ . \ .$$

Functions of Two or More Variables may be denoted by $f(x, y, \ . \ . \ .)$, $F(x, y, \ . \ . \ .)$, etc. The derivative of such a function $u = f(x, y, \ . \ . \ .)$ formed on the assumption that x is the only variable (y, . . . being regarded for the moment as constants) is called the **partial derivative of u with respect to x**, and is denoted by $f_x(x,y)$, or D_xu, or $\dfrac{d_xu}{dx}$, or $\dfrac{\partial u}{\partial x}$. Similarly, the partial derivative of u with respect to y is $f_y(x,y)$, or D_yu, or $\dfrac{d_yu}{dy}$, or $\dfrac{\partial u}{\partial y}$.

NOTE. In the third notation, d_xu denotes the differential of u formed on the assumption that x is the only variable. If the fourth notation, $\partial u/\partial x$, is used, this must not be treated as a fraction like du/dx; the $\partial/\partial x$ is a symbol of operation, operating on u, and the "∂x" must not be separated.

Partial derivatives of the second order are denoted by f_{xx}, f_{xy}, f_{yy}, or by D_x^2u, $D_x(D_yu)$, D_y^2u, or by $\dfrac{\partial^2 u}{\partial x^2}$, $\dfrac{\partial^2 u}{\partial x \partial y}$, $\dfrac{\partial^2 u}{\partial y^2}$, the last symbols being "inseparable." Similarly for higher derivatives. Note that $f_{xy} = f_{yx}$.

If increments Δx, Δy, (or dx, dy) are assigned to the independent variables x, y, the increment, Δu, produced in $u = f(x,y)$ is

$$\Delta u = f(x + \Delta x, y + \Delta y) - f(x,y);$$

while the **differential**, du, that is, the value which Δu would have if the partial derivatives of u with respect to x and y were constant, is given by

$$du = (f_x)\cdot dx + (f_y)\cdot dy.$$

Here the coefficients of dx and dy are the values of the partial derivatives of u at the point in question.

If x and y are functions of a third variable t, then the equation

$$\frac{du}{dt} = (f_x)\,\frac{dx}{dt} + (f_y)\,\frac{dy}{dt}$$

expresses the rate of change of u with respect to t, in terms of the separate rates of change of x and y with respect to t.

For the graphical representation of $u = f(x,y)$, see p. 178.

Implicit Functions. If $f(x,y) = 0$, either of the variables x and y is said to be an implicit function of the other. To find dy/dx, either (1) solve for y in terms of x, and then find dy/dx directly; or (2) differentiate the equation through as it stands, remembering that both x and y are variables, and then divide by dx; or (3) use the formula $dy/dx = -(f_x/f_y)$, where f_x and f_y are the partial derivatives of $f(x,y)$ at the point in question.

MAXIMA AND MINIMA

A Function of One Variable, as $y = f(x)$, is said to have a **maximum** at a point $x = x_0$, if at that point the slope of the curve is zero and the concavity downward (see Fig. 3); a sufficient condition for a maximum is $f'(x_0) = 0$ and $f''(x_0)$ negative. Similarly, $f(x)$ has a **minimum** if the slope is zero and the concavity upward; a sufficient condition for a minimum is $f'(x_0) = 0$ and $f''(x_0)$ positive. If $f'(x_0) = 0$ and $f''(x_0) = 0$ and $f'''(x_0) \neq 0$, the point x_0 will be a **point of inflection.** If $f'(x_0) = 0$ and $f''(x_0) = 0$ and $f'''(x_0) = 0$, the point x_0 will be a maximum if $f''''(x_0) < 0$, and a minimum if $f''''(x_0) > 0$. It is usually sufficient, however, in any practical case, to find the values of x which make $f'(x) = 0$, and then decide, from a general knowledge of the curve, which of these values (if any) give maxima or minima, without investigating the higher derivatives.

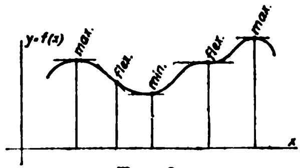

Fig. 3.

A Function of Two Variables, as $u = f(x,y)$, will have a **maximum** at a point (x_0,y_0) if at that point $f_x = 0$, $f_y = 0$, and $f_{xx} < 0$, $f_{yy} < 0$; and a **minimum** if at that point $f_x = 0$, $f_y = 0$, and $f_{xx} > 0$, $f_{yy} > 0$; provided, in each case, $(f_{xx})(f_{yy}) - (f_{xy})^2$ is positive. If $f_x = 0$ and $f_y = 0$, and f_{xx} and f_{yy} have opposite signs, the point (x_0,y_0) will be a "saddle point" of the surface representing the function (p. 178).

EXPANSION IN SERIES

The range of values of x for which each of the series is convergent is stated at the right of the series.

Arithmetical and Geometrical Series, and the **Binomial Theorem.** See p. 114.

Exponential and Logarithmic Series.

$$e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \cdots; \qquad -\infty < x < +\infty.$$

$$a^x = e^{mx} = 1 + \frac{m}{1!}x + \frac{m^2}{2!}x^2 + \frac{m^3}{3!}x^3 + \cdots; \quad a > 0, \quad -\infty < x < +\infty,$$

where $m = \log_e a = (2.3026)(\log_{10} a)$.

$$\log_e(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \frac{x^5}{5} - \cdots; \qquad -1 < x < +1.$$

$$\log_e(1 - x) = -x - \frac{x^2}{2} - \frac{x^3}{3} - \frac{x^4}{4} - \frac{x^5}{5} - \cdots; \qquad -1 < x < +1.$$

$$\log_e\left(\frac{1 + x}{1 - x}\right) = 2\left(x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \cdots\right); \qquad -1 < x < +1.$$

$$\log_e\left(\frac{x + 1}{x - 1}\right) = 2\left(\frac{1}{x} + \frac{1}{3x^3} + \frac{1}{5x^5} + \frac{1}{7x^7} + \cdots\right); \qquad x < -1 \text{ or } +1 < x.$$

$$\log_e x = 2\left[\frac{x - 1}{x + 1} + \frac{1}{3}\left(\frac{x - 1}{x + 1}\right)^3 + \frac{1}{5}\left(\frac{x - 1}{x + 1}\right)^5 + \cdots\right]; \qquad 0 < x < \infty.$$

$$\log_e(a + x) = \log_e a + 2\left[\frac{x}{2a + x} + \frac{1}{3}\left(\frac{x}{2a + x}\right)^3 + \frac{1}{5}\left(\frac{x}{2a + x}\right)^5 + \cdots\right]; \quad \begin{cases} 0 < a < +\infty \\ -a < x < +\infty \end{cases}$$

Series for the Trigonometric Functions. In the following formulæ, *all angles must be expressed in radians.* If D = the number of degrees in the angle, and x = its radian measure, then $x = 0.017453\,D$.

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \ldots; \qquad -\infty < x < +\infty.$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \frac{x^8}{8!} - \ldots; \qquad -\infty < x < +\infty.$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \ldots; \qquad -\pi/2 < x < +\pi/2.$$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \frac{x^7}{4725} - \ldots; \qquad -\pi < x < +\pi.$$

$$\sin^{-1} y = y + \frac{y^3}{6} + \frac{3y^5}{40} + \frac{5y^7}{112} + \ldots; \qquad -1 \leqq y \leqq +1.$$

$$\tan^{-1} y = y - \frac{y^3}{3} + \frac{y^5}{5} - \frac{y^7}{7} + \ldots; \qquad -1 \leqq y \leqq +1.$$

$\cos^{-1} y = \frac{1}{2}\pi - \sin^{-1} y; \qquad \cot^{-1} y = \frac{1}{2}\pi - \tan^{-1} y.$

Series for the Hyperbolic Functions (x a pure number).

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \ldots; \qquad -\infty < x < \infty.$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \ldots; \qquad -\infty < x < \infty.$$

$$\sinh^{-1} y = y - \frac{y^3}{6} + \frac{3y^5}{40} - \frac{5y^7}{112} + \ldots; \qquad -1 < y < +1.$$

$$\tanh^{-1} y = y + \frac{y^3}{3} + \frac{y^5}{5} + \frac{y^7}{7} + \ldots; \qquad -1 < y < +1.$$

General Formulæ of Maclaurin and Taylor. If $f(x)$ and all its derivatives are continuous in the neighborhood of the point $x = 0$ (or $x = a$), then, for any value of x in this neighborhood, the function $f(x)$ may be expressed as a power series arranged according to ascending powers of x (or of $x - a$), as follows:

$$(1)\ f(x) = f(0) + \frac{f'(0)}{1!}x + \frac{f''(0)}{2!}x^2 + \frac{f'''(0)}{3!}x^3 + \ldots$$
$$+ \frac{f^{(n-1)}(0)}{(n-1)!}x^{n-1} + (P_n)x^n. \quad \text{(Maclaurin.)}$$

$$(2)\ f(x) = f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \frac{f'''(a)}{3!}(x-a)^3 + \ldots$$
$$+ \frac{f^{(n-1)}(a)}{(n-1)!}(x-a)^{n-1} + (Q_n)(x-a)^n. \quad \text{(Taylor.)}$$

Here $(P_n)x^n$, or $(Q_n)(x-a)^n$, is called the **remainder term**; the values of the coefficients P_n and Q_n may be expressed as follows:

$P_n = \{f^{(n)}(sx)\}/n! = \{(1-t)^{n-1}\ f^{(n)}(tx)\}/(n-1)!$

$Q_n = \{f^{(n)}[a + s(x-a)]\}/n! = \{(1-t)^{n-1} f^{(n)}[a + t(x-a)]\}/(n-1)!$

where s and t are certain unknown numbers between 0 and 1; the s-form is due to Lagrange, the t-form to Cauchy.

The error due to neglecting the remainder term is less than $(\bar{P}_n)x^n$, or

$(\bar{Q}_n)(x-a)^n$, where $\bar{P}_n$, or $\bar{Q}_n$, is the largest value taken on by P_n, or Q_n, when s or t ranges from 0 to 1. If this error, which depends on both n and x, approaches 0 as n increases (for any given value of x), then the general-expression-with-remainder becomes (for that value of x) a convergent infinite series.

The sum of the first few terms of Maclaurin's series gives a good approximation to $f(x)$ for values of x near $x = 0$; Taylor's series gives a similar approximation for values near $x = a$.

Fourier's Series. Let $f(x)$ be a function which is finite in the interval from $x = -c$ to $x = +c$ and has only a finite number of discontinuities in that interval (see note below), and only a finite number of maxima and minima. Then, for any value of x between $-c$ and c,

$$f(x) = \tfrac{1}{2} a_0 + a_1 \cos\frac{\pi x}{c} + a_2 \cos\frac{2\pi x}{c} + a_3 \cos\frac{3\pi x}{c} + \ldots$$

$$+ b_1 \sin\frac{\pi x}{c} + b_2 \sin\frac{2\pi x}{c} + b_3 \sin\frac{3\pi x}{c} + \ldots$$

where the constant coefficients are determined as follows:

$$a_n = \frac{1}{c}\int_{-c}^{c} f(t)\cos\frac{n\pi t}{c}\,dt, \quad b_n = \frac{1}{c}\int_{-c}^{c} f(t)\sin\frac{n\pi t}{c}\,dt.$$

In case the curve $y = f(x)$ is symmetrical with respect to the origin, the a's are all zero, and the series is a sine series. In case the curve is symmetrical with respect to the y-axis, the b's are all zero, and a cosine series results. (In this case, the series will be valid not only for values of x between $-c$ and c, but also for $x = -c$ and $x = c$.) A Fourier's series can be integrated term by term; but the result of differentiating term by term will in general not be a convergent series.

NOTE. If $x = x_0$ is a point of discontinuity, $f(x_0)$ is to be defined as $\tfrac{1}{2}[f_1(x_0) + f_2(x_0)]$, where $f_1(x_0)$ is the limit of $f(x)$ when x approaches x_0 from below, and $f_2(x_0)$ is the limit of $f(x)$ when x approaches x_0 from above.

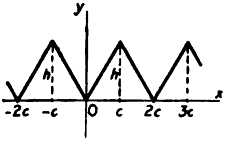

FIG. 4.

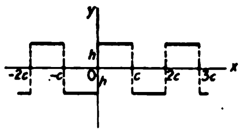

FIG. 5.

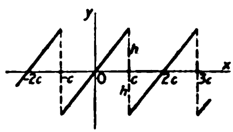

FIG. 6.

Examples of Fourier's Series.

1. If $y = f(x)$ is the curve in Fig. 4,

$$y = \frac{h}{2} - \frac{4h}{\pi^2}\left(\cos\frac{\pi x}{c} + \frac{1}{9}\cos\frac{3\pi x}{c} + \frac{1}{25}\cos\frac{5\pi x}{c} + \ldots\right)$$

2. If $y = f(x)$ is the curve in Fig. 5,

$$y = \frac{4h}{\pi}\left(\sin\frac{\pi x}{c} + \frac{1}{3}\sin\frac{3\pi x}{c} + \frac{1}{5}\sin\frac{5\pi x}{c} + \ldots\right)$$

3. If $y = f(x)$ is the curve in Fig. 6,

$$y = \frac{2h}{\pi}\left(\sin\frac{\pi x}{c} - \frac{1}{2}\sin\frac{2\pi x}{c} + \frac{1}{3}\sin\frac{3\pi x}{c} - \ldots\right)$$

INDETERMINATE FORMS

In the following paragraphs, $f(x)$, $g(x)$ denote functions which approach 0; $F(x)$, $G(x)$ functions which increase indefinitely; and $U(x)$ a function which approaches 1; when x approaches a definite quantity a. The problem in each case is to find the limit approached by certain combinations of these functions when x approaches a. The symbol $\doteq$ is to be read "approaches."

CASE 1. "$\frac{0}{0}$." To find the limit of $f(x)/g(x)$ when $f(x) \doteq 0$ and $g(x) \doteq 0$, use the theorem that $\lim \frac{f(x)}{g(x)} = \lim \frac{f'(x)}{g'(x)}$, where $f'(x)$ and $g'(x)$ are the derivatives of $f(x)$ and $g(x)$. This second limit may be easier to find than the first. If $f'(x) \doteq 0$ and $g'(x) \doteq 0$, apply the same theorem a second time: $\lim \frac{f'(x)}{g'(x)} = \lim \frac{f''(x)}{g''(x)}$; and so on.

CASE 2. "$\frac{\infty}{\infty}$." If $F(x) \doteq \infty$ and $G(x) \doteq \infty$, then $\lim \frac{F(x)}{G(x)} = \lim \frac{F'(x)}{G'(x)}$, precisely as in Case 1.

CASE 3. "$0 \cdot \infty$." To find the limit of $f(x) \cdot F(x)$ when $f(x) \doteq 0$ and $F(x) \doteq \infty$, write $\lim\ [f(x) \cdot F(x)] = \lim \frac{f(x)}{1/F(x)}$, or $= \lim \frac{F(x)}{1/f(x)}$; then proceed as in Case 1 or Case 2.

CASE 4. "0^0." If $f(x) \doteq 0$ and $g(x) \doteq 0$, find $\lim\ [f(x)]^{g(x)}$ as follows: let $y = [f(x)]^{g(x)}$, and take the logarithm of both sides thus:

$$\log_e y = g(x) \log_e f(x);$$

next, find $\lim\ [g(x) \log_e f(x)]$, $= m$, by Case 3; then $\lim y = e^m$.

CASE 5. "1^∞." If $U(x) \doteq 1$ and $F(x) \doteq \infty$, find $\lim\ [U(x)]^{F(x)}$ as follows: let $y = [U(x)]^{F(x)}$, and take the logarithm of both sides, as in Case 4.

CASE 6. "∞^0." If $F(x) \doteq \infty$ and $f(x) \doteq 0$, find $\lim\ [F(x)]^{f(x)}$ as follows: let $y = [F(x)]^{f(x)}$, and take the logarithm of both sides, as in Case 4.

CASE 7. "$\infty - \infty$." If $F(x) \doteq \infty$ and $G(x) \doteq \infty$, write $\lim\ [F(x) - G(x)]$

$$= \lim \frac{\frac{1}{G(x)} - \frac{1}{F(x)}}{\frac{1}{F(x) \cdot G(x)}};$$

then proceed as in Case 1. Sometimes it is shorter to expand the functions in series. It should be carefully noticed that expressions like $0/0$, ∞/∞, etc., do not represent mathematical quantities.

CURVATURE

The **radius of curvature** R of a plane curve at any point P (Fig. 7) is the distance, measured along the normal, on the concave side of the curve, to the **center of curvature,** C, this point being the limiting position of the point of intersection of the normals at P and a neighboring point Q, as Q is made to approach P along the curve. If the equation of the curve is $y = f(x)$,

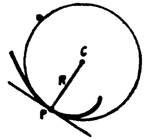

FIG. 7.

$$R = \frac{ds}{du} = \frac{[1 + (y')^2]^{3/2}}{y''}$$

where $ds = \sqrt{dx^2 + dy^2}$ = the differential of arc, $u = \tan^{-1}[f'(x)]$ = the angle which the tangent at P makes with the x-axis, and $y' = f'(x)$ and $y'' = f''(x)$ are the first and second derivatives of $f(x)$ at the point P. Note that $dx = ds \cos u$ and $dy = ds \sin u$. The **curvature**, K, at the point P, is $K = 1/R = du/ds$; that is, the curvature is the rate at which the angle u is changing with respect to the length of arc s. If the slope of the curve is small, $K = f''(x)$.

If the equation of the curve in polar co-ordinates is $r = f(\theta)$, where r = radius vector and θ = polar angle, then

$$R = \frac{[r^2 + (r')^2]^{3/2}}{r^2 - rr'' + 2(r')^2},$$

where $r' = f'(\theta)$ and $r'' = f''(\theta)$.

The **evolute** of a curve is the locus of its centers of curvature. If one curve is the evolute of another, the second is called the **involute** of the first.

INDEFINITE INTEGRALS

An integral of $f(x)dx$ is any function whose differential is $f(x)dx$, and is denoted by $\int f(x)dx$. All the integrals of $f(x)dx$ are included in the expression $\int f(x)dx + C$, where $\int f(x)dx$ is any particular integral, and C is an arbitrary constant. The process of finding (when possible) an integral of a given function consists in recognizing by inspection a function which, when differentiated, will produce the given function; or in transforming the given function into a form in which such recognition is easy. The most common integrable forms are collected in the following brief table; for a more extended list, see B. O. Peirce's "Table of Integrals" (Ginn & Co.).

General Formulæ

1. $\int a\,du = a\int du = au + C$ 2. $\int (u + v)dx = \int u\,dx + \int v\,dx$

3. $\int u\,dv = uv - \int v\,du$ 4. $\int f(x)dx = \int f[F(y)]F'(y)dy,\ x = F(y)$

5. $\int dy \int f(x,y)dx = \int dx \int f(x,y)dy.$

Fundamental Integrals

6. $\int x^n dx = \frac{x^{n+1}}{n+1} + C$; when $n \neq -1$

7. $\int \frac{dx}{x} = \log_e x + C = \log_e cx$ 8. $\int e^x dx = e^x + C$

9. $\int \sin x\,dx = -\cos x + C$ 10. $\int \cos x\,dx = \sin x + C$

11. $\int \frac{dx}{\sin^2 x} = -\cot x + C$ 12. $\int \frac{dx}{\cos^2 x} = \tan x + C$

13. $\int \frac{dx}{\sqrt{1 - x^2}} = \sin^{-1} x + C = -\cos^{-1} x + c$

14. $\int \frac{dx}{1 + x^2} = \tan^{-1} x + C = -\cot^{-1} x + c$

Rational Functions

15. $\int (a + bx)^n dx = \frac{(a + bx)^{n+1}}{(n + 1)b} + C$

16. $\int \frac{dx}{a+bx} = \frac{1}{b}\log_e (a+bx) + C = \frac{1}{b}\log_e c(a+bx)$

17. $\int \frac{1}{x^2}dx = -\frac{1}{x} + C$ 18. $\int \frac{dx}{(a+bx)^2} = -\frac{1}{b(a+bx)} + C$

19. $\int \frac{dx}{1-x^2} = \frac{1}{2}\log_e \frac{1+x}{1-x} + C = \tanh^{-1} x + C,$ when $x < 1$

20. $\int \frac{dx}{x^2-1} = \frac{1}{2}\log_e \frac{x-1}{x+1} + C = -\coth^{-1} x + C,$ when $x > 1$

21. $\int \frac{dx}{a+bx^2} = \frac{1}{\sqrt{ab}}\tan^{-1}\left(\sqrt{\frac{b}{a}}x\right) + C$

22. $\int \frac{dx}{a-bx^2} = \frac{1}{2\sqrt{ab}}\log_e \frac{\sqrt{ab}+bx}{\sqrt{ab}-bx} + C$

$= \frac{1}{\sqrt{ab}}\tanh^{-1}\left(\sqrt{\frac{b}{a}}x\right) + C$

when $a > 0,\quad b > 0$

23. $\int \frac{dx}{a+2bx+cx^2} = \frac{1}{\sqrt{ac-b^2}}\tan^{-1}\frac{b+cx}{\sqrt{ac-b^2}} + C$ when $ac - b^2 > 0$;

$= \frac{1}{2\sqrt{b^2-ac}}\log_e \frac{\sqrt{b^2-ac}-b-cx}{\sqrt{b^2-ac}+b+cx} + C$

$= -\frac{1}{\sqrt{b^2-ac}}\tanh^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$

when $b^2 - ac > 0$;

24. $\int \frac{dx}{a+2bx+cx^2} = -\frac{1}{b+cx} + C,$ when $b^2 = ac$

25. $\int \frac{(m+nx)dx}{a+2bx+cx^2} = \frac{n}{2c}\log_e (a+2bx+cx^2) + \frac{mc-nb}{c}\int \frac{dx}{a+2bx+cx^2}$

26. In $\int \frac{f(x)dx}{a+2bx+cx^2}$, if $f(x)$ is a polynominal of higher than the first degree, divide by the denominator before integrating.

27. $\int \frac{dx}{(a+2bx+cx^2)^p} = \frac{1}{2(ac-b^2)(p-1)} \times \frac{b+cx}{(a+2bx+cx^2)^{p-1}}$

$+ \frac{(2p-3)c}{2(ac-b^2)(p-1)}\int \frac{dx}{(a+2bx+cx^2)^{p-1}}$

28. $\int \frac{(m+nx)dx}{(a+2bx+cx^2)^p} = -\frac{n}{2c(p-1)} \times \frac{1}{(a+2bx+cx^2)^{p-1}}$

$+ \frac{mc-nb}{c}\int \frac{dx}{(a+2bx+cx^2)^p}$

29. $\int x^{m-1}(a+bx)^n dx = \frac{x^{m-1}(a+bx)^{n+1}}{(m+n)b}$

$- \frac{(m-1)a}{(m+n)b}\int x^{m-2}(a+bx)^n dx$

$= \frac{x^m(a+bx)^n}{m+n} + \frac{na}{m+n}\int x^{m-1}(a+bx)^{n-1} dx$

IRRATIONAL FUNCTIONS

30. $\int \sqrt{a+bx}\,dx = \frac{2}{3b}(\sqrt{a+bx})^3 + C$

31. $\int \frac{dx}{\sqrt{a+bx}} = \frac{2}{b}\sqrt{a+bx} + C$

32. $\int \frac{(m+nx)dx}{\sqrt{a+bx}} = \frac{2}{3b^2}(3mb - 2an + nbx)\sqrt{a+bx} + C$

33. $\int \frac{dx}{(m+nx)\sqrt{a+bx}}$; substitute $y = \sqrt{a+bx}$, and use 21 and 22

34. $\int \frac{f(x, \sqrt[n]{a+bx})}{F(x, \sqrt[n]{a+bx})}dx$; substitute $\sqrt[n]{a+bx} = y$

35. $\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\frac{x}{a} + C = -\cos^{-1}\frac{x}{a} + c$

36. $\int \frac{dx}{\sqrt{a^2+x^2}} = \log_e[x + \sqrt{a^2+x^2}] + C = \sinh^{-1}\frac{x}{a} + c$

37. $\int \frac{dx}{\sqrt{x^2-a^2}} = \log_e[x + \sqrt{x^2-a^2}] + C = \cosh^{-1}\frac{x}{a} + c$

38. $\int \frac{dx}{\sqrt{a+2bx+cx^2}} = \frac{1}{\sqrt{c}}\log_e[b + cx + \sqrt{c}\sqrt{a+2bx+cx^2}] + C,$ when $c > 0$;

$= \frac{1}{\sqrt{c}}\sinh^{-1}\frac{b+cx}{\sqrt{ac-b^2}} + C,$ when $ac - b^2 > 0$;

$= \frac{1}{\sqrt{c}}\cosh^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$ when $b^2 - ac > 0$;

$= \frac{-1}{\sqrt{-c}}\sin^{-1}\frac{b+cx}{\sqrt{b^2-ac}} + C,$ when $c < 0$

39. $\int \frac{(m+nx)dx}{\sqrt{a+2bx+cx^2}} = \frac{n}{c}\sqrt{a+2bx+cx^2}$

$+ \frac{mc-nb}{c}\int \frac{dx}{\sqrt{a+2bx+cx^2}}$

40. $\int \frac{x^m dx}{\sqrt{a+2bx+cx^2}} = \frac{x^{m-1}X}{mc} - \frac{(m-1)a}{mc}\int \frac{x^{m-2}dx}{X}$

$- \frac{(2m-1)b}{mc}\int \frac{x^{m-1}dx}{X},$ where $X = \sqrt{a+2bx+cx^2}$

41. $\int \sqrt{a^2+x^2}\,dx = \frac{x}{2}\sqrt{a^2+x^2} + \frac{a^2}{2}\log_e(x + \sqrt{a^2+x^2}) + C$

$= \frac{x}{2}\sqrt{a^2+x^2} + \frac{a^2}{2}\sinh^{-1}\frac{x}{a} + c$

42. $\int \sqrt{a^2-x^2}\,dx = \frac{x}{2}\sqrt{a^2-x^2} + \frac{a^2}{2}\sin^{-1}\frac{x}{a} + C$

43. $\int \sqrt{x^2 - a^2}\, dx = \frac{x}{2}\sqrt{x^2 - a^2} - \frac{a^2}{2}\log_e\left(x + \sqrt{x^2 - a^2}\right) + C$

$= \frac{x}{2}\sqrt{x^2 - a^2} - \frac{a^2}{2}\cosh^{-1}\frac{x}{a} + c$

44. $\int \sqrt{a + 2bx + cx^2}\, dx = \frac{b + cx}{2c}\sqrt{a + 2bx + cx^2}$

$+ \frac{ac - b^2}{2c}\int \frac{dx}{\sqrt{a + 2bx + cx^2}} + C$

Transcendental Functions

45. $\int a^x dx = \frac{a^x}{\log_e a} + C$

46. $\int x^n e^{ax}\, dx = \frac{x^n e^{ax}}{a}\left[1 - \frac{n}{ax} + \frac{n(n-1)}{a^2x^2} - \ldots \pm \frac{n!}{a^n x^n}\right] + C$

47. $\int \log_e x\, dx = x \log_e x - x + C$

48. $\int \frac{\log_e x}{x^2}\, dx = -\frac{\log_e x}{x} - \frac{1}{x} + C$

49. $\int \frac{(\log_e x)^n}{x}\, dx = \frac{1}{n+1}(\log_e x)^{n+1} + C$

50. $\int \sin^2 x\, dx = -\tfrac{1}{4}\sin 2x + \tfrac{1}{2}x + C = -\tfrac{1}{2}\sin x \cos x + \tfrac{1}{2}x + C$

51. $\int \cos^2 x\, dx = \tfrac{1}{4}\sin 2x + \tfrac{1}{2}x + C = \tfrac{1}{2}\sin x \cos x + \tfrac{1}{2}x + C$

52. $\int \sin mx\, dx = -\frac{\cos mx}{m} + C$ 53. $\int \cos mx\, dx = \frac{\sin mx}{m} + C$

54. $\int \sin mx \cos nx\, dx = -\frac{\cos(m+n)x}{2(m+n)} - \frac{\cos(m-n)x}{2(m-n)} + C$

55. $\int \sin mx \sin nx\, dx = \frac{\sin(m-n)x}{2(m-n)} - \frac{\sin(m+n)x}{2(m+n)} + C$

56. $\int \cos mx \cos nx\, dx = \frac{\sin(m-n)x}{2(m-n)} + \frac{\sin(m+n)x}{2(m+n)} + C$

57. $\int \tan x\, dx = -\log_e \cos x + C$ 58. $\int \cot x\, dx = \log_e \sin x + C$

59. $\int \frac{dx}{\sin x} = \log_e \tan\frac{x}{2} + C$ 60. $\int \frac{dx}{\cos x} = \log_e \tan\left(\frac{\pi}{4} + \frac{x}{2}\right) + C$

61. $\int \frac{dx}{1 + \cos x} = \tan\frac{x}{2} + C$ 62. $\int \frac{dx}{1 - \cos x} = -\cot\frac{x}{2} + C$

63. $\int \sin x \cos x\, dx = \tfrac{1}{2}\sin^2 x + C$ 64. $\int \frac{dx}{\sin x \cos x} = \log_e \tan x + C$

65.* $\int \sin^n x\, dx = -\frac{\cos x \sin^{n-1} x}{n} + \frac{n-1}{n}\int \sin^{n-2} x\, dx$

66.* $\int \cos^n x\, dx = \frac{\sin x \cos^{n-1} x}{n} + \frac{n-1}{n}\int \cos^{n-2} x\, dx$

* If n is an odd number, substitute $\cos x = z$ or $\sin x = z$.

67. $\int \tan^n x\,dx = \frac{\tan^{n-1} x}{n-1} - \int \tan^{n-2} x\,dx$

68. $\int \cot^n x\,dx = -\frac{\cot^{n-1} x}{n-1} - \int \cot^{n-2} x\,dx$

69. $\int \frac{dx}{\sin^n x} = -\frac{\cos x}{(n-1)\sin^{n-1} x} + \frac{n-2}{n-1}\int \frac{dx}{\sin^{n-2} x}$

70. $\int \frac{dx}{\cos^n x} = \frac{\sin x}{(n-1)\cos^{n-1} x} + \frac{n-2}{n-1}\int \frac{dx}{\cos^{n-2} x}$

71.* $\int \sin^p x \cos^q x\,dx = \frac{\sin^{p+1} x \cos^{q-1} x}{p+q} + \frac{q-1}{p+q}\int \sin^p x \cos^{q-2} x\,dx$

$= -\frac{\sin^{p-1} x \cos^{q+1} x}{p+q} + \frac{p-1}{p+q}\int \sin^{p-2} x \cos^q x\,dx$

72.* $\int \sin^{-p} x \cos^q x\,dx = -\frac{\sin^{-p+1} x \cos^{q+1} x}{p-1} + \frac{p-q-2}{p-1}\int \sin^{-p+2} x \cos^q x\,dx$

73.* $\int \sin^p x \cos^{-q} x\,dx = \frac{\sin^{p+1} x \cos^{-q+1} x}{q-1} + \frac{q-p-2}{q-1}\int \sin^p x \cos^{-q+2} x\,dx$

74. $\int \frac{dx}{a + b\cos x} = \frac{2}{\sqrt{a^2 - b^2}} \tan^{-1}\left(\sqrt{\frac{a-b}{a+b}} \tan \tfrac{1}{2}x\right) + C$, when $a^2 > b^2$

$$\left.\begin{aligned} &= \frac{1}{\sqrt{b^2 - a^2}} \log_e \frac{b + a\cos x + \sin x\sqrt{b^2 - a^2}}{a + b\cos x} + C, \\ &= \frac{2}{\sqrt{b^2 - a^2}} \tanh^{-1}\left(\sqrt{\frac{b-a}{b+a}} \tan \tfrac{1}{2}x\right) + C, \end{aligned}\right\}\ \text{when } a^2 < b^2$$

75. $\int \frac{\cos x\,dx}{a + b\cos x} = \frac{x}{b} - \frac{a}{b}\int \frac{dx}{a + b\cos x} + C$

76. $\int \frac{\sin x\,dx}{a + b\cos x} = -\frac{1}{b} \log_e (a + b\cos x) + C$

77. $\int \frac{A + B\cos x + C\sin x}{a + b\cos x + c\sin x}\,dx = A\int \frac{dy}{a + p\cos y}$

$+ (B\cos u + C\sin u)\int \frac{\cos y\,dy}{a + p\cos y} - (B\sin u - C\cos u)\int \frac{\sin y\,dy}{a + p\cos y},$

where $b = p\cos u$, $c = p\sin u$ and $x - u = y$.

78. $\int e^{ax} \sin bx\,dx = \frac{a\sin bx - b\cos bx}{a^2 + b^2} e^{ax} + C$

79. $\int e^{ax} \cos bx\,dx = \frac{a\cos bx + b\sin bx}{a^2 + b^2} e^{ax} + C$

80. $\int \sin^{-1} x\,dx = x\sin^{-1} x + \sqrt{1 - x^2} + C$

81. $\int \cos^{-1} x\,dx = x\cos^{-1} x - \sqrt{1 - x^2} + C$

82. $\int \tan^{-1} x\,dx = x\tan^{-1} x - \tfrac{1}{2}\log_e (1 + x^2) + C$

83. $\int \cot^{-1} x\,dx = x\cot^{-1} x + \tfrac{1}{2}\log_e (1 + x^2) + C$

* If p or q is an odd number, substitute $\cos x = z$ or $\sin x = z$

84. $\int \sinh x\,dx = \cosh x + C$
85. $\int \tanh x\,dx = \log_e \cosh x + C$
86. $\int \cosh x\,dx = \sinh x + C$
87. $\int \coth x\,dx = \log_e \sinh x + C$
88. $\int \operatorname{sech} x\,dx = 2\tan^{-1}(e^x) + C$
89. $\int \operatorname{csch} x\,dx = \log_e \tanh(x/2) + C$
90. $\int \sinh^2 x\,dx = \tfrac{1}{2}\sinh x \cosh x - \tfrac{1}{2}x + C$
91. $\int \cosh^2 x\,dx = \tfrac{1}{2}\sinh x \cosh x + \tfrac{1}{2}x + C$
92. $\int \operatorname{sech}^2 x\,dx = \tanh x + C$
93. $\int \operatorname{csch}^2 x\,dx = -\coth x + C$

DEFINITE INTEGRALS

The definite integral of $f(x)dx$ from $x = a$ to $x = b$, denoted by $\int_a^b f(x)dx$, is the limit (as n increases indefinitely) of a sum of n terms:

$$\int_a^b f(x)dx = \lim_{n=\infty} [f(x_1)\Delta x + f(x_2)\Delta x + f(x_3)\Delta x + \ldots + f(x_n)\Delta x],$$

built up as follows: Divide the interval from a to b into n equal parts, and call each part Δx, $= (b - a)/n$; in each of these intervals take a value of x (say $x_1, x_2, \ldots x_n$), find the value of the function $f(x)$ at each of these points, and multiply it by Δx, the width of the interval; then take the limit of the sum of the terms thus formed, when the number of terms increases indefinitely, while each individual term approaches zero.

Geometrically, $\int_a^b f(x)dx$ is the area bounded by the curve $y = f(x)$, the x-axis, and the ordinates $x = a$ and $x = b$ (Fig. 8); that is, briefly, the "area under the curve, from a to b." The **fundamental theorem** for the evaluation of a definite integral is the following:

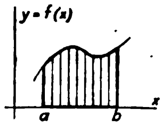

FIG. 8.

$$\int_a^b f(x)dx = \left[\int f(x)dx\right]_{x=b} - \left[\int f(x)dx\right]_{x=a};$$

that is, the definite integral is equal to the difference between two values of any one of the indefinite integrals of the function in question. In other words, the limit of a sum can be found whenever the function can be integrated.

Properties of Definite Integrals.

$$\int_a^b = -\int_b^a; \quad \int_a^c + \int_c^b = \int_a^b.$$

THE MEAN-VALUE THEOREM FOR INTEGRALS.

$$\int_a^b F(x)\ f(x)dx = F(X)\int_a^b f(x)dx,$$

provided $f(x)$ does not change sign from $x = a$ to $x = b$; here X is some (unknown) value of x intermediate between a and b.

THEOREM ON CHANGE OF VARIABLE. In evaluating $\int_{x=a}^{x=b} f(x)dx$, $f(x)dx$ may be replaced by its value in terms of a new variable t and dt, and $x = a$ and $x = b$ by the corresponding values of t, provided that throughout the interval the relation between x and t is a one-to-one correspondence (that is, to each value of x there corresponds one and only one value of t, and to each value of t there corresponds one and only one value of x).

Differentiation with Respect to the Upper Limit. If b is variable, then $\int_a^b f(x)dx$ is a function of b, whose derivative is

$$\frac{d}{db}\int_a^b f(x)dx = f(b).$$

Differentiation with Respect to a Parameter.

$$\frac{\partial}{\partial c}\int_a^b f(x,c)dx = \int_a^b \frac{\partial f(x,c)}{\partial c}dx.$$

Functions Defined by Definite Integrals. The following definite integrals have received special names, and their values have been tabulated; see, for example, B. O. Peirce's "Table of Integrals."

1. Elliptic integral of the first kind $= F(u, k) = \int_0^u \frac{dx}{\sqrt{1-k^2\sin^2 x}} (k^2 < 1)$

2. Elliptic integral of the second kind $= E(u, k) = \int_0^u \sqrt{1 - k^2 \sin^2 x}\, dx$ $(k^2 < 1)$

3, 4. Complete elliptic integrals of the first and second kinds; put $u = \pi/2$ in (1) and (2).

5. The Probability integral $= \frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx$

6. The Gamma function $= \Gamma(n) = \int_0^\infty x^{n-1}e^{-x}dx$

Approximate Methods of Integration. Mechanical Quadrature.

(1) Use Simpson's rule. See p. 106.

(2) Expand the function in a power series, and integrate term by term.

(3) Plot the area under the curve $y = f(x)$ from $x = a$ to $x = b$ on squared paper and measure this area roughly by "counting squares," or more accurately, by the use of a planimeter ($14 to $35; instruction for use with each instrument).

(4) Coradi's Mechanical Integraph ($240) provides a means of drawing on paper the curve $y = \int f(x)dx$, when the curve $y = f(x)$ is given, and can be used to facilitate the solution of certain differential equations. Full instructions for use with each instrument.

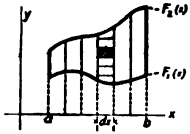

Fig. 9.

Double Integrals. The notation $\int\int f(x, y)dy\,dx$ means $\int\{\int f(x, y)dy\}dx$, the limits of integration in the inner, or first, integral being functions of x (or constants).

Example. To find the weight of a plane area whose density, w, is variable, say $w = f(x, y)$. The weight of a typical element, $dx\,dy$, is $f(x, y)dx\,dy$. Keeping x and dx constant, and summing these elements from, say, $y = F_1(x)$ to $y = F_2(x)$, as determined by the shape of the boundary, the weight of a typical strip perpendicular to the x-axis is $dx\int_{y=F_1(x)}^{y=F_2(x)} f(x,y)dy$. Finally, summing these strips from, say, $x = a$ to $x = b$, the weight of the whole area is $\int_{x=a}^{x=b}\{dx\int_{y=F_1(x)}^{y=F_2(x)} f(x, y)dy\}$, or, briefly, $\int\int f(x, y)dy\,dx$.

DIFFERENTIAL EQUATIONS

An **ordinary differential equation** is one which contains a single independent variable, or argument, and a single dependent variable, or function, with its derivatives of various orders. A **partial differential equation** is one which contains a function of several independent variables, and its partial derivatives of various orders. The order of a differential equation is the order of the highest derivative which occurs in it. A solution of a differential equation is any relation between the variables, which, when substituted in the given equation, will satisfy it. The general solution of an ordinary differential equation of the nth order will contain n arbitrary constants. A differential equation is usually said to be solved when the problem is reduced to a simple quadrature, that is, an integration of the form $y = \int f(x)dx$.

Methods of Solving Ordinary Differential Equations

Differential Equations of the First Order

(1) If possible, separate the variables; that is, collect all the x's and dx on one side, and all the y's and dy on the other side; then integrate both sides, and add the constant of integration.

(2) If the equation is homogeneous in x and y, the value of dy/dx in terms of x and y will be of the form $\frac{dy}{dx} = f\left(\frac{y}{x}\right)$. Substituting $y = xt$ will enable the variables to be separated. Solution: $\log_e x = \int \frac{dt}{f(t) - t} + C$.

(3) The expression $f(x,y)dx + F(x,y)dy$ is an *exact differential* if $\frac{\partial f(x,y)}{\partial y} = \frac{\partial F(x,y)}{\partial x} (= P$, say). In this case the solution of $f(x,y)dx + F(x,y)dy = 0$ is

$$\int f(x,y)dx + \int [F(x,y) - \int P dx]dy = C$$

or

$$\int F(x,y)dy + \int [f(x,y) - \int P dy]dx = C$$

(4) Linear differential equation of the first order: $\frac{dy}{dx} + f(x)\cdot y = F(x)$.

Solution: $y = e^{-P}\left\{\int e^P F(x)dx + C\right\}$, where $P = \int f(x)dx$.

(5) Bernoulli's equation: $\frac{dy}{dx} + f(x)\cdot y = F(x)\cdot y^n$. Substituting $y^{1-n} = v$ gives $\frac{dv}{dx} + (1 - n)f(x)\cdot v = (1 - n)F(x)$, which is linear in v and x.

(6) Clairaut's equation: $y = xp + f(p)$, where $p = dy/dx$. The solution consists of the family of lines given by $y = Cx + f(C)$, where C is any constant, together with the curve obtained by eliminating p between the equations $y = xp + f(p)$ and $x + f'(p) = 0$, where $f'(p)$ is the derivative of $f(p)$.

Differential Equations of the Second Order

(7) $\frac{d^2y}{dx^2} = -n^2y$. Solution: $y = C_1 \sin(nx + C_2)$

or $y = C_3 \sin nx + C_4 \cos nx$

(8) $\frac{d^2y}{dx^2} = +n^2y$. Solution: $y = C_1 \sinh (nx + C_2)$

or $y = C_3 e^{nx} + C_4 e^{-nx}$

(9) $\frac{d^2y}{dx^2} = f(y)$. Solution: $x = \int \frac{dy}{\sqrt{C_1 + 2P}} + C_2$, where $P = \int f(y)\, dy$.

(10) $\frac{d^2y}{dx^2} = f(x)$. Solution: $y = \int P dx + C_1 x + C_2$, where $P = \int f(x) dx$

or $y = xP - \int x f(x) dx + C_1 x + C_2$

(11) $\frac{d^2y}{dx^2} = f\left(\frac{dy}{dx}\right)$. Putting $\frac{dy}{dx} = z$, $\frac{d^2y}{dx^2} = \frac{dz}{dx}$, $x = \int \frac{dz}{f(z)} + C_1$ and $y = \int \frac{z dz}{f(z)} + C_2$; then eliminate z from these two equations.

(12) The equation for damped vibration: $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = 0$.

Case I. If $a^2 - b^2 > 0$, let $m = \sqrt{a^2 - b^2}$. Solution:

$y = C_1 e^{-bx} \sin (mx + C_2)$ or $y = e^{-bx}[C_3 \sin (mx) + C_4 \cos (mx)]$

Case II. If $a^2 - b^2 = 0$, solution is $y = e^{-bx}[C_1 + C_2 x]$.

Case III. If $a^2 - b^2 < 0$, let $n = \sqrt{b^2 - a^2}$. Solution:

$y = C_1 e^{-bx} \sinh (nx + C_2)$ or $y = C_3 e^{-(b+n)x} + C_4 e^{-(b-n)x}$

(13) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = c$. Solution: $y = \frac{c}{a^2} + y_1$, where y_1 = the solution of the corresponding equation with second member zero [see (12) above].

(14) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = c \sin(kx)$. Solution:

$y = R \sin(kx - S) + y_1$, where $R = c/\sqrt{(a^2 - k^2)^2 + 4b^2k^2}$,

$\tan S = \frac{2bk}{a^2 - k^2}$, and y_1 = the solution of the corresponding equation with second member zero [see (12) above].

(15) $\frac{d^2y}{dx^2} + 2b\frac{dy}{dx} + a^2y = f(x)$. Solution: $y = y_0 + y_1$, where y_0 = any particular solution of the given equation, and y_1 = the general solution of the corresponding equation with second member zero [see (12) above].

If $b^2 > a^2$, $y_0 = \frac{1}{2\sqrt{b^2 - a^2}}\left\{ e^{m_1 x}\int e^{-m_1 x} f(x)dx - e^{m_2 x}\int e^{-m_2 x} f(x)dx \right\}$.

where $m_1 = -b + \sqrt{b^2 - a^2}$ and $m_2 = -b - \sqrt{b^2 - a^2}$.

If $b^2 < a^2$, let $m = \sqrt{a^2 - b^2}$; then $y_0 =$

$\frac{1}{m}e^{-bx}\left\{ \sin (mx)\int e^{bx} \cos (mx)\cdot f(x)dx - \cos (mx)\int e^{bx} \sin (mx)\cdot f(x)\, dx \right\}$.

If $b^2 = a^2$, $y_0 = e^{-bx}\left\{ x\int e^{bx} f(x)\, dx - \int x\cdot e^{bx} f(x)\, dx \right\}$.

GRAPHICAL REPRESENTATION OF FUNCTIONS

For graphical methods in statistics, etc., see W. C. Brinton's "Graphical Methods for Presenting Facts"

EQUATIONS INVOLVING TWO VARIABLES

The Curve $y = f(x)$. To represent graphically any function, y, of a single variable, x, lay off the values of x as **abscissae** along a uniformly graduated horizontal axis, whose positive direction (as usually chosen) runs to the right, and at each point on this x-axis erect a perpendicular (called an **ordinate**) whose length represents the value of y at that point. The unit of measurement for the y-scale, whose positive direction (as usually chosen) runs upward, need not be the same as the unit for the x-scale. Draw a smooth curve through the extremities of the ordinates; this is the **graph** of the given function in rectangular co-ordinates, or the **curve** of the function.

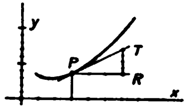

FIG. 1.

To measure graphically the rate of change of the function at any point P (Fig. 1), draw the tangent at P; then **rate of change** at $P = RT/PR$, where RT and PR are measured in units of the y-axis and x-axis, respectively. This ratio, which is positive if RT runs upward, negative if RT runs downward, is equal to the derivative of the function at the point P (see p. 157).

Graphs of Important Functions. Figs. 2–9 show the graphs (in rectangular co-ordinates) of the most important elementary functions, namely:

The **linear function,** $y = mx + b$ (Fig. 2).

The **power functions,** $y = x^n$ [n positive (parabolic type); n negative (hyperbolic type)] (Fig. 3).

The **exponential function,** $y = 10^x$ or $y = e^x$, and the **logarithmic function,** $y = \log_{10} x$ or $y = \log_e x$ (Fig. 4).

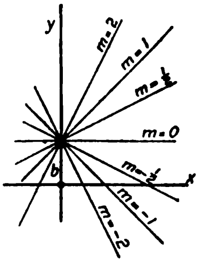
The **trigonometric functions** (Fig. 5), and the inverse trigonometric functions (Fig. 6).

The **hyperbolic functions** (Figs. 7 and 8) and the inverse hyperbolic functions (Fig. 9).

Various **special functions** (Figs. 10–12).

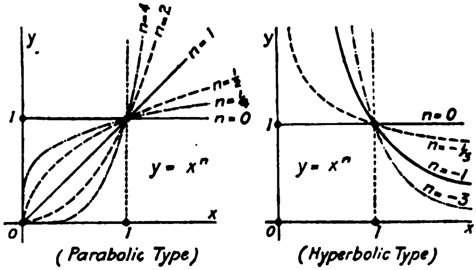
By a slight modification, each of these diagrams may be made to represent a somewhat more general function than that for which it is primarily intended. For, if x is replaced by $x - a$ in the equation, this merely requires re-numbering the x-axis so that each number is moved a units to the left; and similarly, if y is replaced by $y - b$ in the equation, this merely requires re-numbering the y-axis so that each number is moved b units downward. (Such a change is called a translation of the curve to the right, or upward.) Further, if x is replaced by x/c [or y by y/c] in the equation, it is merely necessary to multiply each of the numbers written along the x-axis [or y-axis] by c, in order to adapt the graph to the new equation. (Such a change is called a "stretching" of the curve along one of the axes.)

Empirical Curves. Any set of values of two variables x and y can be represented by plotting the points (x,y) on rectangular co-ordinate paper, and drawing a smooth curve through these points. The points which correspond to actual data should be clearly indicated by small circles or crosses, intermediate points being spoken of as interpolated points. While this process of graphically interpolating a continuous series of points *between* given values is usually fairly safe, the process of extrapolation—that is, extending the curve *beyond* the range of the given values, is dangerous.



Linear function, $y = mx + b$.

FIG. 2.



Power function, $y = x^n$.

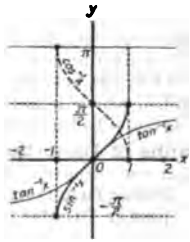
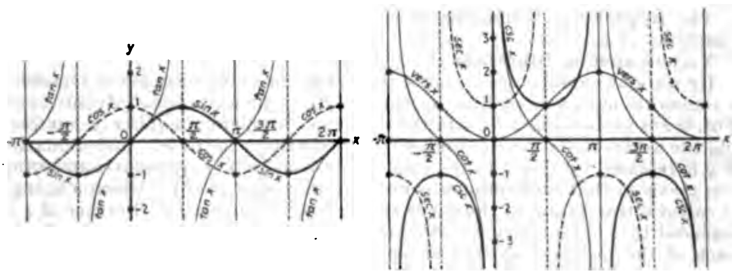
FIG. 4.



Inverse trigonometric functions.

FIG. 6.

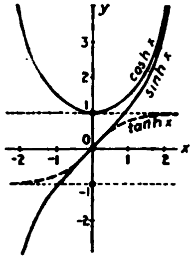


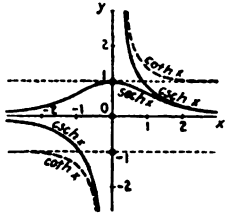
Trigonometric functions.

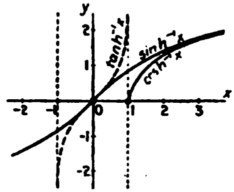
FIG. 5.

To Find a Mathematical Equation to Fit a Given Empirical Curve. This problem is one which in general requires much patience and ingenuity. Only the simplest cases can be mentioned here.

CASE 1. If the given empirical curve is a straight line, then the law connecting the given values of x and y is $y = mx + b$, where m = the slope of the line, and b = the value of y at the point where the line crosses the y-axis. If







Hyperbolic functions and inverse hyperbolic functions.

FIG. 7. FIG. 8. FIG. 9.

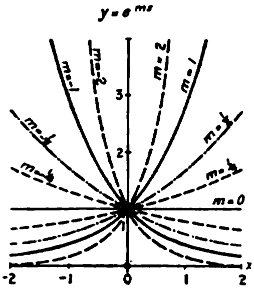


FIG. 10.

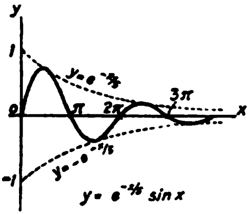

FIG. 11.

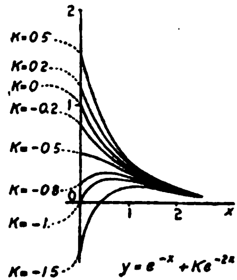

FIG. 12.

the points lie only approximately on a straight line, the best position for this line can usually be found by stretching a black thread among the points; or, assume a law of the form $y = mx + b$, and, by substituting in this formula n pairs of values of x and y, obtain n equations connecting the coefficients m and b; various pairs of these equations may then be solved for m and b, and the average of the results taken. Or, if great accuracy is required, all n of the equations may be solved for m and b by the method of least squares (p. 121).

If any law of the form $f(x,y) = m \cdot F(x,y) + b$ is suspected, where $f(x,y)$ and $F(x,y)$ are any expressions involving either x or y or both x and y, such a law may be tested by plotting $F(x,y)$ instead of x, and $f(x,y)$ instead of y, on rectangular cross-section paper, and seeing whether or not the points lie on a straight line. If they do, the form of the law is verified, and the values of m and b can be read from the figure as before. For example, if $y^2 = mxy + b$, a straight line will be obtained by plotting y^2 against xy. Again, if $xy = bx + my$, a straight line will be obtained by plotting y against y/x, since the equation may be written $y = b + m\,(y/x)$.

CASE 2. If a law of the form $y = cx^n$ is suspected, plot the points (x,y) on logarithmic paper (see below).

CASE 3. If a law of the form $y = c \cdot 10^{mx}$ [or $y = c \cdot e^{mx}$] is suspected, plot the points (x,y) on semi-logarithmic paper (see below).

CASE 4. If the given curve resembles the logarithmic curve, $y = \log x$, interchange x and y and proceed as in Case 3.

CASE 5. If the given curve is a wavy line, resembling a sine or cosine curve, try an equation of the form $y = a \sin bx$ or $y = a \cos bx$. If the heights of the waves diminish as x increases, try an equation of the form $y = ae^{-nx} \sin bx$. [NOTE. Any periodic function (satisfying certain simple conditions) can be expressed by a Fourier's series (p. 162)].

CASE 6. A great variety of functions can be represented approximately by a polynomial of the form $y = a + bx + cx^2 + dx^3 + ex^4 + \ldots$, the first three or four terms being usually sufficient. To determine the coefficients $a, b, c, \ldots$, most accurately, substitute in the formula all the given pairs of values of x and y, and solve the resulting equations for $a, b, c, \ldots$ by the method of least squares (p. 121).

CASE 7. Many simple curves can be represented approximately by an equation of the hyperbolic form, $xy = c + bx + ay$, where a, b, and c are determined by substituting the co-ordinates of three conspicuous points of the curve. The lines $x = a$ and $y = b$ are the asymptotes of the hyperbola. The equation may also be written $(x - a)(y - b) = k$, where $k = ab + c$.

Logarithmic Cross-section Paper. In this form of cross-section paper (Fig. 13), the distance from the origin to any point on the x- or y-axis is equal to the logarithm of the number written against that point. Thus, in Fig. 13 the distances (shown for clearness on two auxiliary scales X and Y) are the logarithms of the numbers written along x and y.

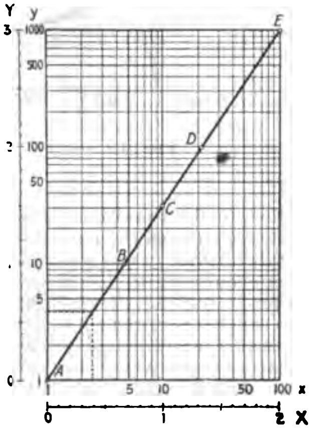

FIG. 13.

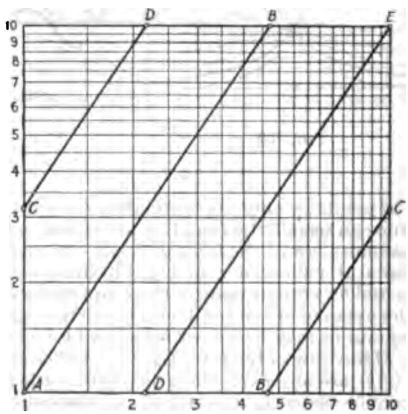

FIG. 14.

Accurately made logarithmic paper can be obtained from the principal dealers in draftmen's supplies. Logarithmic paper can be easily constructed, in case of need, by copying the logarithmic scale from any ordinary slide rule. The actual figures along the x- and y-axes are usually left for the user to insert; in so doing, notice that the numbers . . ., 0.01, 0.1, 1, 10, 100, . . ., or such of them as may be needed to cover any given range of values, must be placed at the points of division which separate the main squares. It is often convenient, however, to omit the decimal point, numbering each square independently from 1 to 10. The length of the side of one square is called the *unit* or *base* of the logarithmic paper; the larger the unit, the finer the possible subdivisions of the scale.

To plot a point (x,y) on logarithmic paper, for example, the point (3,5), means to find the point of intersection of the vertical line marked $x = 3$ and the horizontal line marked $y = 5$. In interpolating between two lines, account should be taken of the fact that the divisions are not of uniform length.

Any equation of the form $y = cx^n$ when plotted on logarithmic paper will be represented by a straight line whose slope is n. For, if $y_1 = cx_1^n$ and $y_2 = cx_2^n$, then $y_1/y_2 = (x_1/x_2)^n$, or $(\log y_1 - \log y_2)/(\log x_1 - \log x_2) = n$. The slope must be measured by aid of an auxiliary *uniform* scale.

EXAMPLE. Let $y = x^{3/2}$. When $x = 1$, $y = 1$; plot this point A on the logarithmic paper, and draw the straight line AE with a slope equal to $3/2$ (Fig. 13). By the aid of this line, the value of y for any value of x between 1 and 100 can be read off directly; for example, if $x = 2.50$, $y = 3.95$, as shown by dotted lines, so that $(2.50)^{3/2} = 3.95$. To find the value of y for any value of x outside this range, note that moving the decimal point 2 places in x is equivalent to moving it 3 places in y. The line shown in Fig. 13 is thus equivalent to a complete table of three-halves powers.

It will be noticed that this line crosses four squares of the logarithmic paper. By superposing these four squares the whole diagram may be condensed into a single square (Fig. 14), in which, however, the scales for x and y now give only the sequence of digits in the answer, the position of the decimal point having to be determined by inspection.

To determine whether a given set of values, x and y, satisfies a law of the form y = cx^n, plot the values on logarithmic paper, and see whether they lie on a straight line; if they do, then the given values satisfy a law of this form; moreover, the slope of the line gives the value of n, and the value of y when $x = 1$ gives the value of c.

If the plotted points fail to lie exactly in line, but form a curve slightly concave upward, try subtracting some constant b from all the y's, that is, move each point downward a distance equal to b units of the y-scale at that point. If it proves possible to choose b so that the resulting points lie in line, then the original values obey a law of the form $y - b = cx^n$, where n is again the slope of the line, and c is the value of $y - b$ when $x = 1$. (Conversely, if the curve is concave *downward*, try *adding* b to all the y's; that is, move each point *upward;* if the new points lie in line, the original values obey a law of the form $y + b = cx^n$.) Another method of "straightening" the curve consists of adding some constant, $\pm a$, to all the values of x, which has the effect of shifting all the points to the right or left (by varying amounts); if this method succeeds, the original values obey a law of the form $y = c(x + a)^n$.

Semi-logarithmic Cross-section Paper*. This form of paper (Fig. 15) has a logarithmic scale along y and a uniform scale along x. The "**scale value,**" k, of the paper is the number which stands, on the x-axis, at a distance from the origin equal to the width of one of the main horizontal strips. Thus, in Fig. 15, each number shown along the auxiliary scale Y is the logarithm of the corresponding number along y, and each number shown along the auxiliary scale X is $1/k$th of the corresponding number along x (here $k = 5$). The number k, which may be chosen at pleasure, should be taken equal to some simple integer, as 1, 2, or 5, or some integral power of 10.

In preparing the paper for use it is important to notice that the numbers . . ., 0.01, 0.1, 1, 10, 100, . . . (or such of them as may be needed in any given case) must be placed along the y-axis at the points which mark the main lines of division between the horizontal strips; while the numbers . . ., $-2k$, $-k$, 0, $+k$, $+2k$, . . . (or such of them as may be needed) must be placed along the x-axis at uniform intervals, each interval (from 0 to k, from k to $2k$, etc.) being equal to the width of one of the main horizontal strips. The width of one of these strips is called the *unit* or *base* of the semi-

*Made by the Educational Exhibition Co., 26 Custom House St., Providence, R. I.

logarithmic paper; the larger the unit, the finer the possible subdivisions of the scale.

To plot a point (x,y), as $x = 3$, $y = 5$, on semi-logarithmic paper means to find the point of intersection of the vertical line marked $x = 3$ with the horizontal line marked $y = 5$.

Any equation of the form $y = c\cdot 10^{mx}$ [or $y = c\cdot e^{mx}$] when plotted on semi-logarithmic paper with scale value k, will be represented by a straight line whose slope is km [or $0.4343\ km$.]. By a suitable choice of the scale value k, any given range of values of x can be brought within the size of the paper. Note that $e = 10^{0.4343}$.

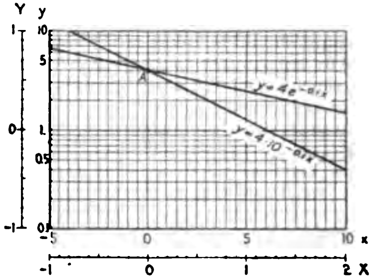

FIG. 15.

EXAMPLE. Given $y = 4\cdot 10^{-0.1x}$ [or $y = 4\cdot e^{-0.1x}$]. In Fig. 15, when $x = 0$, $y = 4$. By plotting this point (A) on the semi-logarithmic paper, with scale value 5, and drawing through it a straight line with slope equal to -0.5 [or -0.217] a graphical representation is obtained from which, for any value of x, the corresponding value of y can be read off. If it is desired to condense the figure, several horizontal strips may be superposed on a single strip; this of course renders the decimal point in the y-scale undetermined (unless a separate y-scale is provided for each section of the graph).

In order to determine whether a given set of values of x and y satisfy a law of the form $y = c\cdot 10^{mx}$ [or $y = c\cdot e^{mx}$], plot the values of x and y on semi-logarithmic paper, with a suitable scale value k, and see whether they lie on a straight line; if they do so, the law is satisfied, and the values of m and c may be found as follows: m = the slope of the line divided by k [or the slope of the line divided by $0.4343k$], and c = the value of y when $x = 0$.

If the plotted points fail to lie exactly in line, but form a curve slightly concave upward, try subtracting some constant b from all the y's, and plot the values thus modified; if b can be so chosen that the revised points lie in line, then the original values obey a law of the form $y - b = c\cdot 10^{mx}$ [or $y - b = c\cdot e^{mx}$], where m and c are to be found as before. If the curve is concave downward, add b, instead of subtracting; and replace $y - b$ by $y + b$ in the law.

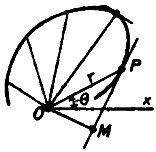

FIG. 16.

Curves in Polar Co-ordinates. Any function, r, of a single variable, θ, can be represented by a curve in polar co-ordinates (p. 137). Lay off the given values of θ as angles, the initial line Ox running toward the right, and the counterclockwise direction about the origin being taken as positive. Along the terminal side of each angle θ, lay off the corresponding value of r, forward if r is positive, backward if r is negative; and pass a smooth curve through the points thus determined.

The rate of change of r with respect to θ at a given point P is represented graphically as follows (Fig. 16): On the tangent at P drop a perpendicular OM from the origin; then $r(MP/OM)$ represents the rate of change, $dr/d\theta$, provided θ is measured in radians. Specially ruled polar co-ordinate paper is supplied by dealers in drafting supplies.

EQUATIONS INVOLVING THREE VARIABLES

The Surface $z = f(x, y)$. Any function, z, of two variables, x and y, may be represented by a surface, as follows: Plot the given pairs of values of x and y as points in a horizontal x, y plane, called the base plane; at each of these points erect an ordinate, parallel to a vertical axis z, and representing by its length the value of z at that point. Then conceive a smooth surface passed through the extremities of these ordinates: this surface is said to represent the function. In practice, the ordinates may be made by implanting stiff vertical rods in a horizontal board of soft wood which serves as the base plane; the surface may then be constructed by filling in the spaces with plaster of Paris. Or, more simply, pieces of cardboard may be cut out to represent parallel plane sections of the surface, and then stood on edge in slots cut in the board to receive them. The units employed along x, y, and z need not be equal to each other.

Contour-line Charts. All the points of a surface $z = f(x, y)$ which are at any given height above the base plane form a curve on the surface, called a contour line of the surface. If each of these contour lines be projected on the base plane, and each labeled with the value of z to which it corresponds, a complete representation of the function $z = f(x, y)$ is obtained, all in one plane. A topographical map, with contour lines showing elevations above the sea, and a weather map, with contour lines showing barometric pressure, are familiar examples. If there are several values of z corresponding to any given point (x, y), there will be several contour lines whose projections pass through that point.

Contour-line Charts for Simultaneous Equations [of the form $z = f(x,y)$, $w = F(x,y)$]. In Fig. 17, plot the function $z = f(x,y)$ by contour lines on an x,y plane, and plot the function $w = F(x,y)$ by contour lines on the same x,y plane. Then every point on the diagram (either directly or by interpolation) is the intersection of four curves—an x-curve, a y-curve, a z-curve, and a w-curve. Here, by "curve" is meant any line, straight or curved. By the aid of such a diagram, when the values of any two of these four variables are given, the values of the other two can be found. The method of use consists simply in entering the diagram along the two given curves (or lines), tracing them to their point of intersection, and then coming out again along the two curves (or lines) whose values are required. The best manner of numbering the curves is indicated in the figure.

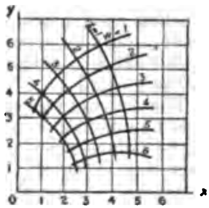

FIG. 17.

Alignment Charts for Three Variables, t, u, v. Any relation between three variables, t, u, v, which can be thrown into one of the forms listed in later paragraphs, can be represented graphically by a very convenient form of diagram called an alignment chart. In the simplest form of an alignment chart for three variables there are three scales (straight or curved), along which the values of the three variables, t, u, v, are marked in such a way that any three values of t, u, v which satisfy the given equation are represented by three points which lie in line. Hence, if the values of any two of the variables are given, the corresponding value of the third can be found by simply drawing a straight line through the two given points and reading the value of the point where it crosses the third scale.

The most important methods of constructing alignment charts for three variables are described below. Where several methods are applicable in a given case, the best one must be determined largely by trial. For further information see M. d'Ocagne, "Traité de Nomographie" (Gauthier-Villars, Paris); Carl Runge, "Graphical Methods" (Columbia University Press); J. B. Peddle, "Construction of Graphical Charts" (McGraw-Hill); see also page 185.

Notation. In each of the equations which follow, U stands for any function of u alone, V for any function of v alone, and $F_1(t)$, $F_2(t)$ for any functions of t alone. Any of these functions may reduce to a constant. The axes of x, y, and y' which are mentioned are of merely temporary use in constructing the diagram, and the letters x, y, y' should not be written on the chart. It is not necessary that the axes be at right angles, provided the x of a point is always measured parallel to the x-axis, and its y parallel to the y-axis.

Method 1. Given, an equation which can be thrown into the form

$$U \cdot F_1(t) + V \cdot F_2(t) = 1,$$

where, for the given range of values of u and v, the largest variations in U and V are less than a certain number m.

Draw a pair of (temporary) x,y axes (Fig. 18), and through the point $x = 1$ draw a third axis, which may be called the axis of y', parallel to the axis of y. In ordinary cases, the unit of measurement along x should be nearly equal to the full width of the paper. Now choose a unit for y and y' such that m times this unit will about equal the height of the paper, and plot, in the usual way, the points (x,y) given by

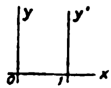

FIG. 18.

$$x = \frac{F_2(t)}{F_1(t) + F_2(t)}, \quad y = \frac{1}{F_1(t) + F_2(t)},$$

labeling each point with the value of t to which it corresponds. Connect these points by a smooth curve, which gives the t-scale of the diagram. [If $F_1(t)/F_2(t)$ = a constant, the t-scale will prove to be a straight line parallel to the y-axis.]

Then, using the same units as above, plot along y the points given by $y = U$, labeling each point with the corresponding value of u; and plot along y' the points given by $y' = V$, labeling each of these points with the corresponding value of v. This gives the u- and v-scales of the diagram. The three scales being thus constructed, the x-axis may now be erased, and the diagram is ready for use. Any three points t, u, v which lie in line correspond to three values of t, u, v, which satisfy the given equation. The numbering on each scale should be shown at sufficiently frequent intervals to permit of easy interpolation.

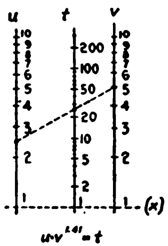

FIG. 19.

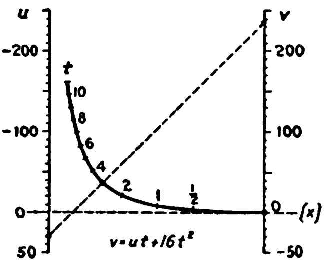

FIG. 20.

EXAMPLE 1 (Fig. 19). Let $uv^{1.41} = t$. By taking the logarithm of both sides, and dividing through by $\log t$, reduce the equation to the form $(\log u)\,(1/\log t) + (\log v) \times (1.41/\log t) = 1$. Here $U = \log u$, $V = \log v$, $F_1(t) = 1/\log t$, $F_2(t) = 1.41/\log t$, and $x = 1.41/2.41 = 0.585$, $y = (1/2.41)\log t$.

EXAMPLE 2 (Fig. 20). Let $v = ut + 16t^2$, which reduces to the form $(-u/16)(1/t) + (v/16)(1/t^2) = 1$. Here $U = -u/16$, $V = v/16$, $F_1(t) = 1/t$, $F_2(t) = 1/t^2$ and $x = 1/(1+t)$, $y = t^2/(1+t)$.

NOTE. If $m = \infty$, values of u and v which give large values of U and V cannot be shown within the limits of the paper. In such cases, the chart may be supplemented by a second chart, made according to Method 2, below.

Method 2. Given, an equation which can be thrown into the form

$$\frac{F_1(t)}{U} + \frac{F_2(t)}{V} = 1,$$

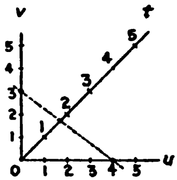
where, for the given range of values of u and v, the largest variation in U is less than a certain number m. and the largest variation in V is less than a certain number n.

Draw a pair of temporary x,y axes, and having chosen a unit for the x-axis equal to about $(1/m)$th of the width of the paper, and a unit for the y-axis equal to about $(1/n)$th of the height, plot the points (x,y) given by

$$x = F_1(t), \quad y = F_2(t),$$

labeling each point of this curve with the value of t to which it corresponds. Connect these points by a smooth curve, which gives the t-scale of the diagram. [If $F_1(t)/F_2(t) =$ a constant, the t-scale will be a straight line through the origin.]

Then, using the same units as above, plot along x the values of U, labeling each point with the corresponding value of u; and plot along y the values of V, labeling each point with the corresponding value of v. This gives the u- and v-scales of the diagram. On the chart as thus completed, any three points t, u, v which lie in line correspond to three values of t, u, v which satisfy the given equation.



$t = uv/(u+v)$

FIG. 21.

EXAMPLE (Fig. 21). Let $t = (uv)/(u+v)$, which may be written in the form $t/u + t/v = 1$. Here $U = u$, $V = v$, $F_1(t) = t$, $F_2(t) = t$.

NOTE. If $m = \infty$ and $n = \infty$, values of u and v which give large values of U and V cannot be shown within the limits of the paper. In such cases the chart may be supplemented by a second chart, made according to Method 1, above.

Method 3. Given, an equation which can conveniently be thrown into the form

$$F_2(t) = V \cdot F_1(t) + U,$$

where, for the given range of values of t, the largest variation in $F_1(t)$ is less than a certain number m, and the largest variation in $F_2(t)$ is less than a certain number n.

Draw a pair of temporary x,y axes, and, having chosen a unit for x equal to about $(1/m)$th of the width of the paper and a unit for y equal to about $(1/n)$th of the height, plot the points (x,y) given by

$$x = F_1(t), \quad y = F_2(t),$$

labeling each point of the curve with the value of t to which it corresponds. Connect these points by a smooth curve, which forms the t-scale. Next, using the same unit for y as above, plot along the y-axis the values of U, labeling each point with the corresponding value of u. This gives the u-scale. Finally, with the origin as center, and any convenient radius, draw a circle cutting the x-axis in A. Along this circular arc, starting from A in the counterclockwise direction, lay off the angles whose slopes are equal to V, labeling each point of the arc with the value of v to which it corresponds.

This gives the v-scale, which in this case, however, plays a peculiar rôle, since, in using this form of chart, two straight lines are required instead of one. Thus:

In order to determine whether three values, t, u, v, satisfy the given equation, lay one straight line through the points t and u, and another straight line through the point v and the origin; if these lines are parallel, the three values of t, u, v satisfy the equation. It will be noticed that the function of the v-scale here is to measure, in a certain sense, the slope of the line joining t and u. A chart of this type may be called "an alignment chart with a sliding scale for one of the variables."

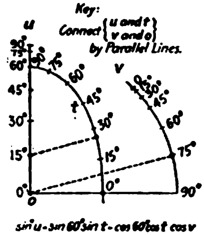


FIG. 22.

EXAMPLE (Fig. 22). Let $\sin u = \sin 60° \sin t - \cos 60° \cos t \cos v$, which may be put in the form

$$(\sin 60° \sin t) = \cos v\,(\cos 60° \cos t) + \sin u.$$

Here $F_1(t) = \cos 60° \cos t$, $F_2(t) = \sin 60° \sin t$, $U = \sin u$, $V = \cos v$.

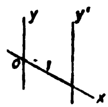

FIG. 23.

Method 4. Given, an equation which can be reduced to the form

$$U \cdot F(t) + V = 0,$$

where, for the given range of values of u and v, the largest variations in U and V are less than a certain number m.

In Fig. 23, draw temporary axes x, y, and y', and choose the units as in Method 1. To construct the t-scale, which will now coincide with the x-axis, plot along x the points for which

$$x = \frac{1}{1 + F(t)},$$

labeling each point with the value of t to which it corresponds. The u-scale, along the axis of y, and v-scale, along the axis of y', are constructed exactly as in Method 1, and the finished chart is used in the same way.

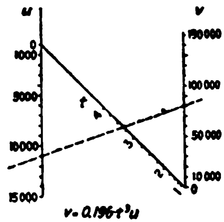

FIG. 24.

EXAMPLE (Fig. 24). Let $v = 0.196\, t^2 u$, where u is to range from 0 to 15,000 and v from 0 to 150,000. The equation may be written in the form $(-10\,u)(0.0196t^2) + v = 0$. Here $U = -10\,u$, $V = v$, $F(t) = 0.0196t^2$.

NOTE. If $m = \infty$, values of u and v which give large values of U and V cannot be shown within the limits of the paper.

EQUATIONS INVOLVING FOUR VARIABLES

[For simultaneous equations of the form $z = f(x,y)$, $w = F(x,y)$, see p. 179.]

Alignment Charts for Four Variables. The extension of the methods of the alignment chart to the case of four variables, say r, s, u, v, consists essentially in replacing the t-scale of the earlier diagram by a network of two scales, one for r and one for s. The point where a curve $r = r_1$ and a curve $s = s_1$ intersect may be spoken of as the point (r_1, s_1). In the following equations, U denotes as before any function of u alone, V any function of v alone; while $F_1(r,s)$ and $F_2(r,s)$ represent any functions of r and s.

Method 1a. Given, an equation of the form

$$U \cdot F_1(r,s) + V \cdot F_2(r,s) = 1.$$

Draw axes x, y, and y' as in Method 1, and plot the network of curves given by the equations

$$x = \frac{F_2(r,s)}{F_1(r,s) + F_2(r,s)}, \qquad y = \frac{1}{F_1(r,s) + F_2(r,s)}.$$

[To do this (Fig. 25), find the point (x,y) that corresponds to each given pair of values of r and s, by direct substitution in the equations for x and y. Connect all the points for which $r = 1$ by a curve, and label it $r = 1$; connect all the points for which $r = 2$ by another curve, and label it $r = 2$; etc. This gives the family of r-curves. Similarly, through all the points for which $s = 1$ draw a curve labeled $s = 1$; through all the points for which $s = 2$ draw a curve labeled $s = 2$; etc. This gives the family of s-curves, intersecting the family of r-curves. Note, however, that if it is possible to eliminate s (or r) from the equations that give x and y, the resulting equation in x, y, and r (or x, y, and s) can often be plotted directly for each given value of r (or of s).]

Next, construct the u- and v-scales along the axes of y and y' as in Method 1. [The letters x, y, and y', and the units used in plotting along these axes, should be omitted from the finished diagram, as should also the axis of x.]

In the chart, as thus completed, any three points, (r,s), u, and v which lie in a straight line, correspond to values of r, s, u, v which satisfy the given equation. Hence, when any three of these four values are given, the fourth can be found from the chart.

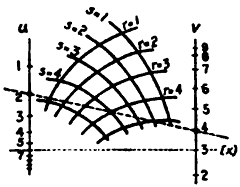

FIG. 25.

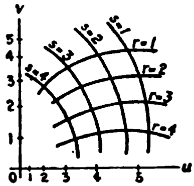

FIG. 26.

Method 2a. Given, an equation of the form

$$\frac{F_1(r,s)}{U} + \frac{F_2(r,s)}{V} = 1.$$

Draw axes of x and y as in Method 2, and plot the network of curves given by

$$x = F_1(r,s), \quad y = F_2(r,s).$$

To do this, follow the plan outlined for a similar case under Method 1a, labeling each curve of the r-family (Fig. 26) with the corresponding value of r, and each curve of the s-family with the corresponding value of s. Next, construct the u- and v-scales along the x- and y-axes, precisely as in Method 2. Then any three points, (r,s), u, and v, which lie in a straight line correspond to values of r, s, u, v which satisfy the given equation.

Method 3a. Given, an equation of the form

$$F_2(r,s) = V \cdot F_1(r,s) + U.$$

Draw axes of x and y, as in Method 3, and plot the network of curves given by $x = F_1(r,s)$, $y = F_2(r,s)$, following the plan outlined for a similar case under Method 1a, and labeling each curve of the r-family (or s-family) with the value of r (or s) to which it corresponds. Next, construct the u-scale along the y-axis, and the v-scale along a circular arc, precisely as in Method 3. Then any three points, (r,s) u, and v, which are so related that the line through (r,s) and u is parallel to the line joining v with the origin, will correspond to values of r, s, u, v which satisfy the given equation.

EXAMPLE for Method 3a (Fig. 27). Let $\cot v = \cot r \cos s + \csc r \sin s \cot u$, which may be written $(\cos r \cot s) = \cot v (\sin r \csc s) - \cot u$. Here $U = -\cot u$, $V = \cot v$, $F_1(r,s) = \sin r \csc s$, $F_2(r,s) = \cos r \cot s$, whence $\dfrac{x^2}{\csc^2 s} + \dfrac{y^2}{\cot^2 s} = 1$, $\dfrac{x^2}{\sin^2 r} - \dfrac{y^2}{\cos^2 r} = 1$, so that the s-curves are ellipses and the r-curves hyperbolas.

Parallel Charts, or Proportional Charts, for Four Variables. In the following methods of representation there are four scales, one for each of the four variables, and the method of using the diagram consists in connecting two pairs of points by parallel lines.

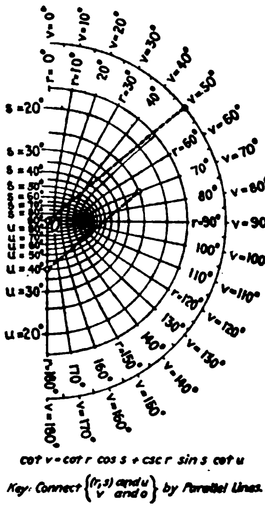

FIG. 27.

Method A. Given, an equation of the form

$$R - S = U - V$$

where R, S, U, V are any functions of the variables r, s, u, v, respectively. [It will be noted that any proportion $R/S = U/V$ can at once be thrown into this form by taking the logarithm of both sides.]

In Fig. 28, draw four vertical axes, y_1, y_2, y'_1, y'_2, such that the distance between y_1 and y'_1 (which may be zero) is equal to the distance beween y_2 and y'_2, and so that the four zero points lie in line. Along these axes, using the same unit for all, plot the points given by $y_1 = R$, $y'_1 = S$, $y_2 = U$, $y'_2 = V$, and label each point with the value of r, s, u, or v to which it corresponds. (The letters y_1, y_2, y'_1, y'_2 are temporary, and should not appear on the diagram.) Then if the line joining two points r and u is parallel to the line joining two points s and v, the four values of r, s, u, v will satisfy the given equation. In this and the following methods, a parallel ruler, or a pair of draftman's triangles, will be useful in reading the chart. A "key" stating which points are to be joined with which, should be clearly given on the diagram.

EXAMPLE (Fig. 28). Let $32.2\, vr = us^2$, or $\log r - 2 \log s = \log u - \log (32.2\, v)$. Here $R = \log r$, $S = 2 \log s$, $U = \log u$, $V = \log (32.2\, v)$.

Method B. Given, an equation of the form

$$\frac{R}{S} = \frac{U}{V}$$

In Fig. 29, draw a pair of axes, x,y, and parallel to them (or coinciding with them) a second pair of axes, x_1,y_1. Using any convenient horizontal unit, plot along x and x_1 the points given by $x = R$, $x_1 = U$, and using any convenient vertical unit, plot along y and y_1 the points given by $y = S$, $y_1 = V$. Label each point with the value of r, s, u, v, to which it corresponds. (The letters x, y, x_1, y_1 should not appear on the diagram.) Then if the line joining two points r and s is parallel to the line joining two points u and v, the four values r, s, u, v will satisfy the given equation.

Method C. Given, an equation of the form

$$R - S = \frac{V}{U}.$$

In Fig. 30, take a pair of axes, x,y, and through the point $x = 1$ draw a third axis, y', parallel to y. Also, take a second pair of axes, x_2,y_2, parallel to (or coinciding with) the axes of x and y. Having chosen a suitable unit for x and x_2, and a suitable unit for y, y', and y_2, lay off the values of R and

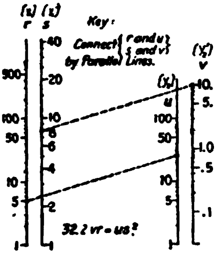

FIG. 28.

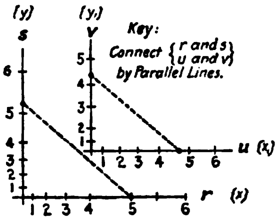

FIG. 29.

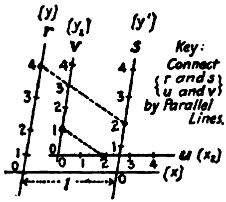

FIG. 30.

S along y and y', respectively, labeling each point with the value of r or s to which it corresponds; and lay off the values of U and V along x_2 and y_2, labeling each point with the value of u or v to which it corresponds. Then if the line joining two points r and s is parallel to the line joining two points u and v, the four values r, s, u, v will satisfy the given equation. This form of chart is sometimes called a "Z-chart."

For further examples, see R. C. Strachan, "Nomographic Solutions for Formulas of Various Types," Trans. Am. Soc. Civil Engineers, vol. 78, 1915.

VECTOR ANALYSIS

Many problems involving directed magnitudes can be advantageously treated by the methods of vector analysis. The following is a brief summary of the principal definitions and formulæ.

A set of arrows, each arrow having a given *length* and pointing in a given *direction*, is called a set of **vectors**, provided they combine by addition according to the parallelogram law (see below). Notation: $\mathbf{a}$ or $\bar{a}$ for a vector; a or $|\mathbf{a}|$ for its length. Two "free" vectors are equal if they have the same length and point in the same direction; two "sliding" vectors are equal if they have the same length and direction, and also lie in the same line.

A **scalar** is any real number, positive, negative, or zero.

Addition of vectors.—If an arrow $\mathbf{a}$ is immediately followed, tip to tail, by a second arrow $\mathbf{b}$, then the arrow which runs from the beginning of $\mathbf{a}$ to the end of $\mathbf{b}$ is called the **sum** of $\mathbf{a}$ and $\mathbf{b}$, denoted by $\mathbf{a} + \mathbf{b}$. Conversely, if $\mathbf{a} + \mathbf{x} = \mathbf{b}$, then $\mathbf{x} = \mathbf{b} - \mathbf{a}$. The laws of operation for $+$ and $-$ are the same as in ordinary algebra (pp. 112, 124). If m is a scalar, then $m\mathbf{a}$ means a vector having the same direction as $\mathbf{a}$, and m times its length.

Multiplication of vectors is of two kinds, as follows:

The **scalar product,** or dot product, of two vectors $\mathbf{a}$ and $\mathbf{b}$, denoted by $\mathbf{a}\cdot\mathbf{b}$—or sometmes by $S\mathbf{ab}$, or by $(\mathbf{ab})$ in round parentheses—is defined as the scalar quantity $ab \cos\theta$, where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$.

EXAMPLE. If $\mathbf{F}$ is a force whose point of application moves along a vector distance $\mathbf{x}$, then $\mathbf{F}\cdot\mathbf{x}$ = *work* done by $\mathbf{F}$ during this displacement.

Peculiarities of scalar products: (1) Since $\mathbf{a}\cdot\mathbf{b}$ is not a vector, expressions like $(\mathbf{a}\cdot\mathbf{b})\cdot\mathbf{c}$ will not occur; (2) from $\mathbf{a}\cdot\mathbf{x} = \mathbf{a}\cdot\mathbf{y}$ we cannot infer that $\mathbf{x} = \mathbf{y}$, hence, quotients will not occur; (3) from $\mathbf{a}\cdot\mathbf{b} = 0$, it follows that $\mathbf{a}$ is **perpendicular** to $\mathbf{b}$ (unless $\mathbf{a}$ or $\mathbf{b}$ is zero).

On the other hand, scalar products are like ordinary products in the following respects: $\mathbf{a}\cdot\mathbf{b} = \mathbf{b}\cdot\mathbf{a}$, and $(\mathbf{a} + \mathbf{b})\cdot(\mathbf{c} + \mathbf{d}) = \mathbf{a}\cdot\mathbf{c} + \mathbf{a}\cdot\mathbf{d} + \mathbf{b}\cdot\mathbf{c} + \mathbf{b}\cdot\mathbf{d}$; also, $m(\mathbf{a}\cdot\mathbf{b}) = (m\mathbf{a}\cdot\mathbf{b}) = \mathbf{a}\cdot(m\mathbf{b})$, where m is any scalar.

The **vector product,** or cross product, of two vectors $\mathbf{a}$ and $\mathbf{b}$, denoted by $\mathbf{a}\times\mathbf{b}$—or sometimes by $V\mathbf{ab}$, or by $[\mathbf{ab}]$ in square brackets—is defined as the *vector* whose length is $ab \sin\theta$, where θ is the angle between $\mathbf{a}$ and $\mathbf{b}$, and whose direction is perpendicular to the plane of $\mathbf{a}$ and $\mathbf{b}$ (in such a sense that a right-handed screw advancing along $\mathbf{a}\times\mathbf{b}$ would turn $\mathbf{a}$ toward $\mathbf{b}$).

EXAMPLE. If $\mathbf{F}$ is a force acting on a particle whose radius vector is $\mathbf{r}$, then $\mathbf{r}\times\mathbf{F}$ = the *torque* of $\mathbf{F}$ about the origin.

Peculiarities of vector products: (1) $\mathbf{a}\times\mathbf{b} = -\mathbf{b}\times\mathbf{a}$, so that the order of the factors is always important; (2) $\mathbf{a}\times\mathbf{a} = 0$; (3) it is not true that $\mathbf{a}\times(\mathbf{b}\times\mathbf{c}) = (\mathbf{a}\times\mathbf{b})\times\mathbf{c}$; (4) from $\mathbf{a}\times\mathbf{x} = \mathbf{a}\times\mathbf{y}$ it does not follow that $\mathbf{x} = \mathbf{y}$; hence, quotients will not occur; (5) from $\mathbf{a}\times\mathbf{b} = 0$, it follows that $\mathbf{a}$ and $\mathbf{b}$ are **parallel** (unless $\mathbf{a}$ or $\mathbf{b}$ is zero).

On the other hand, as in ordinary algebra

$$(\mathbf{a} + \mathbf{b})\times(\mathbf{c} + \mathbf{d}) = \mathbf{a}\times\mathbf{c} + \mathbf{a}\times\mathbf{d} + \mathbf{b}\times\mathbf{c} + \mathbf{b}\times\mathbf{d},$$

provided the order of factors in each product is preserved; also, $m(\mathbf{a}\times\mathbf{b}) = (m\mathbf{a})\times\mathbf{b} = \mathbf{a}\times(m\mathbf{b})$, where m is any scalar. Further laws are:

$$\mathbf{a}\cdot(\mathbf{b}\times\mathbf{c}) = \mathbf{b}\cdot(\mathbf{c}\times\mathbf{a}) = \mathbf{c}\cdot(\mathbf{a}\times\mathbf{b}); \text{ and } \mathbf{a}\times(\mathbf{b}\times\mathbf{c}) = (\mathbf{a}\cdot\mathbf{c})\mathbf{b} - (\mathbf{a}\cdot\mathbf{b})\mathbf{c}.$$

Vector Differentiation. If $\mathbf{r} = \mathbf{f}(t)$ gives a vector $\mathbf{r}$ as a function of a scalar t, then $d\mathbf{r}/dt = \lim\{[\mathbf{f}(t + \Delta t) - \mathbf{f}(t)]/\Delta t\}$ as Δt approaches zero.

$$d(\mathbf{a} + \mathbf{b}) = d\mathbf{a} + d\mathbf{b}, \quad d(m\mathbf{a}) = m(d\mathbf{a}) + (dm)\mathbf{a},$$

$$d(\mathbf{a}\cdot\mathbf{b}) = (d\mathbf{a})\cdot\mathbf{b} + \mathbf{a}\cdot(d\mathbf{b}), \quad d(\mathbf{a}\times\mathbf{b}) = (d\mathbf{a})\times\mathbf{b} + \mathbf{a}\times(d\mathbf{b}).$$

EXAMPLE. If $\mathbf{r} = \mathbf{f}(t)$ gives the position-vector of a moving particle as a function of the time t, then $d\mathbf{r}/dt$ = its vector velocity, $\mathbf{v}$, and $d\mathbf{v}/dt$ = its vector acceleration, $\mathbf{a}$. If $\mathbf{m}$ and $\mathbf{n}$ are unit vectors in the direction of the tangent and normal to the path at the time t, then $\mathbf{v} = v\mathbf{m}$, where $v = ds/dt$ = the (scalar) path-velocity, and $d\mathbf{m} = [(ds/R)]\mathbf{n}$, where R = the (scalar) radius of curvature of the path. Then

$$\mathbf{a} = \frac{d(v\mathbf{m})}{dt} = \frac{dv}{dt}\mathbf{m} + v\frac{d\mathbf{m}}{dt} = \frac{dv}{dt}\mathbf{m} + \frac{v^2}{R}\mathbf{n}.$$

Here dv/dt and v^2/R are the familiar expressions for the components of acceleration along the tangent and normal.

HARRISON W. HAYWARD

KINEMATICS

Motion in a Straight Line—Rectilinear Motion

The position of a moving point at any instant may be stated by giving its distance and direction from some fixed point in its path which is taken as an origin. This distance s can be taken as a function of the time t, giving the equation of position $s = f(t)$.

Velocity. The velocity v of a moving point is the rate at which the distance s changes with respect to the time t, and may be uniform or varying.

$$v = ds/dt; \quad s = \int v dt.$$

A Space-Time Curve offers a convenient means for the study of the motion of a point. The **slope of the curve** at any point will represent the **velocity** at that time. In Fig. 1(a) the slope is constant, as the graph is a straight line; the velocity is therefore uniform. In Fig. 1(b) the slope of the curve varies from point to point, so the velocity must vary also. At p and q the slope is zero, therefore the velocity of the point at the corresponding times must also be zero.

The Acceleration a of a moving point is the rate at which its velocity v changes with respect to the time t, and may be uniform or varying, positive or negative.

For rectilinear motion, $a = dv/dt = d^2s/dt^2$; $s = \int\int a dt^2 = \int v dt$.

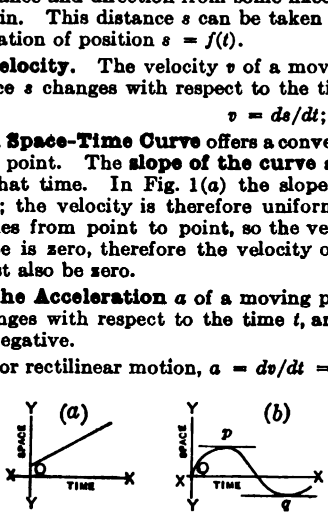

FIG. 1.

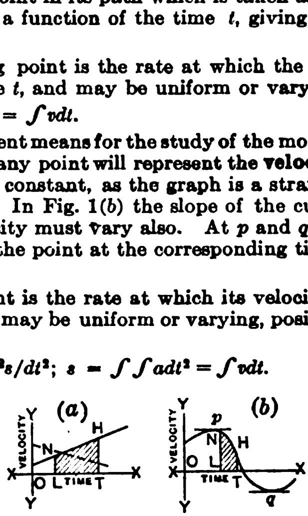

FIG. 2.

A Velocity-Time Curve offers a convenient means for the study of acceleration. The **slope of the curve** at any point will represent the **acceleration** at that time. In Fig. 2(a) the slope is constant, so the acceleration must be constant. In the case represented by the full line, the acceleration is positive, so the velocity is increasing. The dotted line shows a negative acceleration and therefore a decreasing velocity. In Fig. 2(b) the slope of the curve varies from point to point, so the acceleration must also vary. At p and q the slope is zero, therefore the acceleration of the point at the corresponding times must also be zero and the velocity uniform. The area under the velocity-time curve between any two ordinates such as NL and HT will represent the distance moved in time interval LT. In the case of the uniformly accelerated motion shown by the full line in Fig. 2(a), the area $LNHT$ is $\frac{1}{2}(NL + HT) \times (OT - OL)$ = mean velocity multiplied by the time interval = space passed over during this time interval. In Fig. 2(b) the mean velocity can be obtained from the equation of the curve by means of the calculus, or graphically by use of instruments.

An Acceleration-Time Curve (Fig. 3) may be constructed by plotting accelerations as ordinates, and times as abscissæ. The area under this curve between any two ordinates will represent the total increase in velocity during the time interval. The area $ABCD$ represents the total increase in velocity between time t_1 and time t_2.

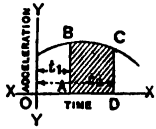

FIG. 3.

General Expressions Showing the Relations Between Space, Time, Velocity and Acceleration, for Rectilinear Motion

Given $s = f(t)$; $v = ds/dt$, and $a = dv/dt = d^2s/dt^2$.

Given $v = f(t)$; $s = s_0 + \int_0^t vdt$, and $a = dv/dt$.

Given $v = f(s)$; $t = \int_{s_0}^s ds/v$, and $a = vdv/ds$.

Given $a = f(t)$; $v = v_0 + \int_0^t adt$, and $s = s_0 + \int_0^t vdt$.

Given $a = f(s)$; $v = \sqrt{v_0^2 + 2\int_{s_0}^s ads}$, and $t = \int_{s_0}^s ds/v$.

Given $a = f(v)$; $s = s_0 + \int_{v_0}^v \frac{v}{a}dv$, and $t = \int_{v_0}^v dv/a$

Special Motions

Uniform Motion. If the **velocity** is **constant** the **acceleration** must be **zero**, and the point has uniform motion. The space-time curve becomes a straight line inclined toward the time axis [Fig. 1(a)]. The velocity-time curve becomes a straight line parallel to the time axis. For this motion $a = 0$, $v =$ constant, and $s = s_0 + vt$.

Uniformly Accelerated or Retarded Motion. If the **velocity** is **not uniform** but the **acceleration** is **constant,** the point has uniformly accelerated motion; the acceleration may be either positive or negative. The space-time curve becomes a parabola and the velocity-time curve becomes a straight line inclined toward the time axis, Fig. 2(a). The acceleration-time curve becomes a straight line parallel to the time axis. For this motion $a =$ constant, $v = v_0 + at$, $s = s_0 + v_0t + \frac{1}{2}at^2$.

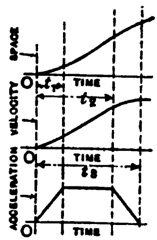

FIG. 4.

If the Point Starts from Rest, $v_0 = 0$. Care should be taken concerning the sign + or − for acceleration.

Example. Starting motion of a street car or hauling engine —see Fig. 4 During the period of time O to t_1, the acceleration increases from 0 to a maximum approximately in a straight line, the velocity-time curve is a parabola and the space-time curve one of the third degree. From t_1 to t_2 the acceleration is constant, the velocity increases uniformly, and the space-time curve is a parabola. From t_2 to t_3 the acceleration decreases from its maximum to 0 approximately in a straight line, and the space-time and velocity-time curves are like those from O to t_1. This concludes the start and a condition of equilibrium follows, with the acceleration zero, the velocity constant, and the space increasing uniformly.

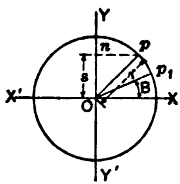

FIG. 5.

Periodic Motion (Simple Harmonic Motion). If a point travels uniformly in a circle, the motion of its projection upon any diameter is a simple harmonic one. In Fig. 5, the line Op revolves about O with a uniform angular velocity ω; n is the projection of point p upon diameter YY'. As p moves about O its projection moves from O to Y, back to O, then to Y' and back to O again. This cycle of motion may be repeated indefinitely. If ωt is the variable angle XOp, the displacement s of n from O is $r \sin \omega t$, where $r = Op$. Velocity $v = ds/dt$, $\therefore v = \omega r \cos \omega t$. Acceleration $a = dv/dt$, $\therefore a = -\omega^2 r \sin \omega t = -\omega^2 s$. These equations assume that Op starts from position OX. If there is a lead angle $XOp' = B$, or a negative angle known as a lag, the expression will become $s = r \sin (\omega t + B)$, $v = \omega r \cos (\omega t + B)$, $a = -\omega^2 r \sin (\omega t + B) = -\omega^2 s$. When ωt has increased by 2π, *i.e.*, after the time $t = 2\pi/\omega$ has elapsed, s, v, and a regain their original values. t is called the **period** of the motion. The angle $(\omega t + B)$ is the **phase angle.**

Composition and Resolution of Velocities

A velocity can be represented by a **vector,** which is a straight line having an arrow representing the direction of the motion and a length representing its magnitude.

Resultant. A velocity is said to be the resultant of two other velocities when it is represented by a vector that is the geometric sum of the vectors representing the other two velocities. This is the **parallelogram of motion.** In Fig. 6, v_r is the resultant of v_1 and v_2 and is represented by the diagonal of a parallelogram of which v_1 and v_2 are the sides; or it is the third side of a triangle of which v_1 and v_2 are the other two sides.

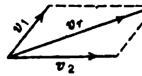

FIG. 6.

Polygon of Motion. The parallelogram of motion may be extended to the polygon of motion. Let v_1, v_2, v_3, v_4 [Fig. 7(*a*)] show the directions of four velocities imparted in the same plane to point O. If the lines v_1, v_2, v_3, v_4 [Fig. 7(*b*)] are drawn parallel to and proportional to the velocities imparted to point O, v_r will represent the resultant velocity imparted to O. It will make no difference in what order the velocities are taken in constructing the motion polygon. As long as the arrows showing the direction of the motion follow each other in order about the polygon, the resultant velocity of the point will be represented in magnitude by the closing side of the polygon, but opposite in direction.

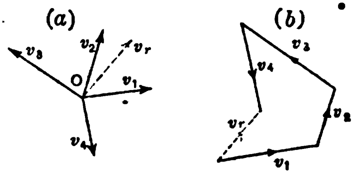

FIG. 7.

Resolution of Velocities. Velocities may be resolved into **component velocities** in the same plane, as shown by Fig. 8. Let the velocity of point O be v_r. In Fig. 8(*a*) this velocity is resolved into two components in the same plane as v_r and at right angles to each other.

$$v_r = \sqrt{(v_1)^2 + (v_2)^2}$$

In Fig. 8(*b*) the components are in same plane as v_r, but are not at right angles to each other. In this case,

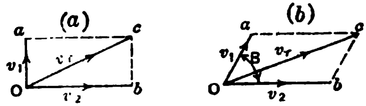

FIG. 8.

$$v_r = \sqrt{(v_1)^2 + (v_2)^2 + 2v_1v_2 \cos B.}$$

If the components v_1 and v_2 and angle B are known, the direction of v_r can be determined. $\sin boc = (v_1/v_r)\sin B$. $\sin coa = (v_2/v_r)\sin B$. Where v_1 and v_2 are at right angles to each other, $\sin B = 1$.

Composition and Resolution of Accelerations. Accelerations may be combined and resolved in the same manner as velocities, but in this case the lines or vectors represent accelerations instead of velocities. Velocities and accelerations may be resolved into components *not* in the same plane by what is known as the **parallelopiped of motion.** In this case the **resultant of three motions not in the same plane** is the diagonal of a parallelopiped whose sides are lines whose length and direction represent the motions. See Fig. 9. Oa, Oc and Ob represent three velocities or accelerations; then Od represents the resultant velocity or acceleration. When the velocities or accelerations are at right angles to each other, the angles that the resultant Od makes with these axes are A, B and C, respectively. Then $\cos A = Oa/Od$, $\cos B = Ob/Od$, $\cos C = Oc/Od$, and

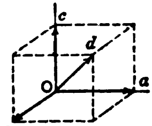

FIG. 9.

$$Od = \sqrt{Oa^2 + Ob^2 + Oc^2}.$$

Curvilinear Motion

The Linear Velocity $v = ds/dt$ is the same as for rectilinear motion, and its direction is tangent to the path of the point. In Fig. 10(a), let $p_1p_2p_3$ be the path of a moving point, and v_1, v_2, v_3 represent its velocity at points p_1, p_2, p_3, respectively. If O be taken as a pole [Fig. 10(b)] and vectors v_1, v_2, v_3 representing the velocities of the point at p_1, p_2, and p_3 be drawn, the curve connecting the terminal points of these vectors is known as the **hodograph** of the motion. This velocity diagram is applicable only to motions all in the same plane.

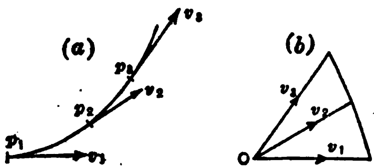

FIG. 10.

Acceleration. Tangents to the curve, Fig. 10(b), indicate the directions of the **momentary accelerations.** The direction of the tangents does not, as a rule, coincide with the direction of the velocities as represented by tangents to the path. If the acceleration a at some point in the path is resolved by means of a parallelogram into components tangent and normal to the path, the normal acceleration $a_n = v^2/r$, where r = radius of curvature of the path at the point in question, and the tangential acceleration $a_t = dv/dt$, where v = velocity tangent to the path at the same point. $a = \sqrt{a_n^2 + a_t^2}$. The normal acceleration is constantly directed toward the center of the path.

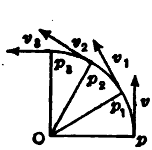

FIG. 11.

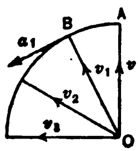

FIG. 12.

Example. Find the acceleration of a point moving in a circle with uniform velocity. In Fig. 11, p, p_1, p_2, p_3 is the circular path of a point. v, v_1, v_2, v_3 represent the uniform velocities at p, p_1, p_2, p_3. Construct the hodograph of the motion, as in Fig. 12. At point p_1 the acceleration is in the direction of the tangent to the hodograph at B, shown by line a_1. Let $pp_1 = s$, $AB = s_1$ and $Op = r$; then $s/r = s_1/v$. $\therefore s_1 = sv/r$. $ds_1/dt = (ds/dt)(v/r) = v^2/r$ and as $ds_1/dt = a_n$, $a_n = v^2/r$ and is in a direction toward the center of the circle. $a_t = 0$.

Motion of a Particle in a Circular Path. If a point moves in a circle of radius r, its angular velocity being ω, angular acceleration a_a, and linear velocity v, $v = \omega r$, $a_t = a_a r$, $a_n = v^2/r = r\omega^2$.

Uniform Rotary Motion. In the case of uniform rotary motion, equal circular paths are traveled in equal intervals of time. ∴ Angular acceleration $a_a = 0$ and $a_t = a_a r = 0$. $a_n = v^2/r$. The **angular velocity** is usually **expressed in radians per sec.**, and when the number (N) of revolutions per min. (r.p.m.) is known, the angular velocity is $\omega = 2\pi N/60 = 0.10472N$; linear velocity $v = \omega r$.

Composition of Motions

A point may have several motions imparted to it at the same time by different means, in which case its motion is the resultant of the different component motions. Each of these components, by what is known as the **principle of independence**, exerts its full influence. The polygon or parallelopiped of motion may be used for the composition of motions.

Many **examples of combined motion** occur, *e.g.*, velocity given by gravity to a body having a horizontal motion; combined rotation and rectilinear motion of a point on a rolling wheel; a point whose motion is governed by the action of two or more cams; the movement of persons or machinery on board trains or boats; movement of a projectile.

Relative Motions. In order that a motion shall be fully determined, it is necessary that the base to which it is referred be carefully stated. The majority of engineering problems assume the earth as the reference base.

Motion of Rigid Bodies

A body is said to be rigid when the distances between all of its particles are invariable. Theoretically, rigid bodies do not exist, but materials used in engineering are practically rigid under their working stresses.

Elementary Motion. If a body moves so that a straight line connecting any two of its particles remains fixed in direction, it is said to have a motion of **translation.** If the motion is indefinitely small—distance $= ds$ and time $= dt$—it may be considered to have **elementary translation**; $ds/dt =$ velocity of translation. The elementary translation is fully determined by a line drawn from any point in the rigid body, representing the velocity in magnitude and direction.

If a body moves so that all its particles describe circles whose planes are at right angles to a straight line XX which contains simultaneously the centers of all the circles, it is said to have a **rotary motion** about the axis XX. If the motion is indefinitely small—angle of rotation $= d\theta$ and time $= dt$—it is called **elementary rotation.** The path ds of a point distant r from the axis of rotation is $ds = r\,d\theta$, and $d\theta/dt =$ elementary angular velocity of rotation. Elementary rotation is completely determined by a straight line whose length is equal to ω drawn on the axis of rotation with an arrow so placed that when looking in the direction of the arrow rotation takes place in a plane at right angles to that line and in the direction of the hands of a clock.

The motion of a body in space is determined by the motion of three points of the body which do not lie in the same straight line. **The instantaneous axis** is the axis about which a body is revolving at a given instant. If a body is being translated at a given instant, the instantaneous axis is at an infinite distance.

Motion in a Plane

A Plane Motion is one in which all points of the moving body remain at constant distances from a fixed plane.

Angular Displacement. The angular displacement of any body moving in a plane is the angle described by any line drawn in the body parallel to the plane of the motion.

Angular Velocity is the rate at which the angular displacement θ varies with respect to the time t. Angular velocity $\omega = d\theta/dt$.

Angular Acceleration is the rate at which the angular velocity ω varies with respect to the time t. Angular acceleration $a_a = d\omega/dt = d^2\theta/dt^2$.

Instantaneous Axis. When the axis about which any body may be considered to rotate changes its position, any one position is known as an instantaneous axis, and the line through all positions of the instantaneous axis in space as the **centrode.**

When the motion of two points in the same plane of a rigid body having plane motion is known, the instantaneous axis for the body will be at the intersection of the lines drawn from each point and perpendicular to its line of motion. See Fig. 13, in which A and B are two points on the rod AB, v_1 and v_2 representing their velocities. O is the instantaneous axis for AB; $\therefore$ point C will move as shown in a line perpendicular to OC.

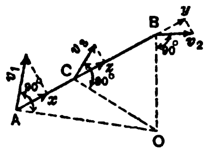

FIG. 13.

Linear Velocities of points in a body rotating about an instantaneous axis are proportional to their distances from this axis. In Fig. 13, $v_1 : v_2 : v_3 = AO : OB : OC$. If the motions of A and B were parallel, the lines OA and OB would also be parallel and there would be no instantaneous axis. The motion of the rod would be translation, and all points would be moving with the same velocity in parallel straight lines.

If a body has plane motion, the components of the velocities of any two points in the body along the straight line joining them must be equal. Ax must be equal to By and Cz in Fig. 13.

Centrode. If the path of the instantaneous center be plotted, the centrode for the motion of the body is obtained. See Fig. 14. Consider A_0B_0 to be fixed and let C_0D_0 rotate about it. Its motion being determined by the links AD and BC, the path of the instantaneous center for CD can be plotted as the curve xy. CD can be considered to be fixed and the centrode for AB found at eo. If the bars AB and CD are fixed to these centrodes and they are rolled upon each other, the relative motion of the two bars A_0B_0 and C_0D_0 will be the same as if they were connected by the links AD and BC. This principle is made use of in the **design of elliptic gears for quick-return motions.** If a wheel rolls along a track, the centrode is the surface of the track.

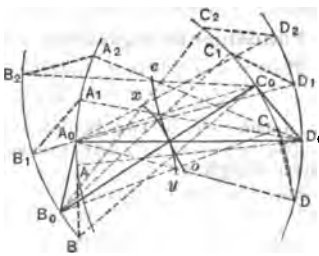

FIG. 14.

The angular velocity of a body at any time can be found by dividing the linear velocity of any point by the distance of the point from the instantaneous center. See Fig. 15, in which the wheel rolls along the track XX. Point A has a linear velocity of v ft. per sec.; O is the instantaneous center. v/AO = angular velocity of wheel. If v_1 is the velocity of point B, the angular velocity of wheel $= v_1/BO = v/AO$.

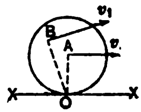

FIG. 15.

For **linkages**, see p. 652.

PHYSICAL MECHANICS

General Laws

Every particle of matter remains either at rest or moves uniformly in a straight line unless acted upon by some external influence. All variations of velocity, either in magnitude or direction, require the action of **force**.

Laws of Gravity. A body falling in a vacuum moves with a uniformly accelerated motion, the acceleration of the fall being the same for all bodies at the same place. Common values taken for this acceleration (usually designated as g) are 32.16 ft. per sec. per sec. or 9.81 meters per sec. per sec.

$g = 32.1721 - 0.08211 \cos 2a - 0.000003h$, where a is the latitude in degrees, and h the height in feet above sea level.

If a body is suspended by an elastic cord, the latter is elongated by the action of what is known as a force, in this case by the force of gravity. The suspended body is not only acted upon by gravity, but by a force exerted upon it by the cord, which imparts to it the same acceleration upward as gravity does downward, thereby maintaining the body at rest. The two forces are equal in magnitude.

Action is Equal to Reaction. The forces exerted by two bodies upon each other act in the same straight line, are equal in magnitude, and are opposite in direction.

Relations Between Mass, Acceleration and Force. When acted upon by a constant unbalanced force, a body will move with a **uniformly accelerated motion. The accelerations produced in any body by different forces are proportional to the forces,** so that $a_1/p_1 = a_n/p_n$ = constant = $1/m$, where p_1, p_n are the forces applied and a_1, a_n are the resulting accelerations. The constant ratio m is known as the **mass** of the body.

Fundamental Equation: Force = Mass × Acceleration.

Mass = w/g, where w = weight and g = falling acceleration due to gravity.

$$F = (w/g)a = ma = mdv/dt = md^2s/dt^2.$$

In the case of two bodies at the same place, $w_1 = m_1g$, $w_2 = m_2g$ and $m_1/m_2 = w_1/w_2$; *i.e.*, **the masses of the two bodies are proportional to their weights.**

Example. If an unbalanced force of 5 lb. acts upon a body weighing 10 lb., what will be the acceleration of the body? $5 = 10a/g$; $\therefore a = 5g/10 = g/2$.

Forces, like velocities and accelerations, are quantities in which **direction is a factor,** *i.e.*, their complete determination requires not only a statement of their magnitude, but also of their line of action and direction.

Law of the Conservation of Mass. The mass of a body remains unchanged by any physical or chemical change to which it may be subjected. The **momentum** of a body is the product of its mass and its velocity, $= mv$.

Technical Systems of Measurement

In the **absolute systems**, see p. 73, the units of length, mass and time are arbitrarily taken, the unit of force being derived.

In the **gravitation systems**, see p. 73, the units of force are weights of absolute units of mass, and therefore depend upon the force of gravity and are gravitation units. The word **weight** is then used to denote both the mass of the body and the force with which it is attracted by the earth.

Absolute units are used for most scientific work and **gravitation units for engineering work** other than electrical. w and g both change as a body is moved from place to place, (**see p. 84,**) but the number of units of mass in the body $= w/g =$ constant. w and g vary very little at ordinary altitudes.

STATICS OF RIGID BODIES

General Considerations

If the forces acting on a rigid body do not produce any acceleration, they must neutralize each other, that is, form a **system of forces in equilibrium.** Equilibrium is said to be **stable** when the body with the forces acting upon it returns to its original position after being displaced a very small amount from that position; **unstable** when the body tends to move still further from its original position than the very small displacement; and **neutral** when the forces retain their equilibrium when the body is in its new position.

External and Internal Forces. The forces by which the individual particles of a body act on each other are known as internal forces. All other forces are called external forces. If a body is supported by other bodies while subject to the action of forces, deformations and forces will be produced at the points of support or contact and these internal stresses will be distributed throughout the body until equilibrium exists and the body is said to be in a state of tension, compression or shear. The forces exerted by the body on the supports are known as **reactions.** They are equal in magnitude and opposite in direction to the forces with which the supports act on the body, known as **supporting forces.** The supporting forces are external forces applied to the body.

In considering a body at a definite section, it will be found that all the internal forces act in pairs, the two forces being equal and opposite. The external forces act singly.

General Law. When a body is at rest, the forces acting externally to it must form an equilibrium system. This law will hold for any part of the body, in which case the forces acting at any section of the body become external forces when the part on either side of the section is considered alone. In the case of a **rigid body,** any two forces of the same magnitude but acting in opposite directions in any straight line, may be added or removed without change in the action of the forces acting on the body, providing the strength of the body is not affected.

Composition, Resolution and Equilibrium of Forces

(For graphical methods, see p. 200)

The **resultant** of several forces acting at a point is a force which will produce the same effect as all the individual forces acting together.

Forces Acting on a Body at the Same Point. The resultant R of two forces F_1 and F_2 applied to a rigid body at the same point is represented in magnitude and direction by the diagonal of the parallelogram formed by F_1 and F_2. See Figs. 16 and 17.

$R = \sqrt{F_1^2 + F_2^2 + 2F_1F_2 \cos a}$; $\sin a_1 = (F_2 \sin a)/R$; $\sin a_2 = (F_1 \sin a)/R$.

When $a = 90$ deg., $R = \sqrt{F_1^2 + F_2^2}$, $\sin a_1 = F_2/R$ and $\sin a_2 = F_1/R$;

$\left.\begin{array}{l}\text{When } a = 0 \text{ deg., } R = F_1 + F_2 \\ \text{When } a = 180 \text{ deg., } R = F_1 - F_2\end{array}\right\}$ Forces act in same straight line.

A force R may be resolved into two component forces intersecting anywhere on R and acting in the same plane as R, by the reverse of the operation shown by Figs. 16 and 17; and by repeating the operation with the components, R may be resolved into any number of component forces intersecting R at the same point and in the same plane.

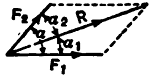

FIG. 16.

Resultant of Any Number of Forces Applied to a Rigid Body at the Same Point. Resolve each of the given forces F into components along three rectangular co-ordinate axes. If A, B and C are the angles made with XX, YY and ZZ, respectively, by any force F, the components will be $F \cos A$ along XX, $F \cos B$ along YY, $F \cos C$ along ZZ; add the components of all the forces along each axis algebraically and obtain $\Sigma F \cos A = \Sigma X$ along XX, $\Sigma F \cos B = \Sigma Y$ along YY, and $\Sigma F \cos C = \Sigma Z$ along ZZ.

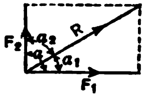

FIG. 17.

The resultant $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2 + (\Sigma Z)^2}$. The angles made by the resultant with the three axes are A_r with XX, B_r with YY, C_r with ZZ, where

$$\cos A_r = \Sigma X/R, \quad \cos B_r = \Sigma Y/R, \quad \cos C_r = \Sigma Z/R.$$

The **direction of** the **resultant** can be determined by plotting the algebraic sums of the components.

If the forces are all in the same plane the components of each of the forces along one of the three axes (say, ZZ) will be 0, that is, angle $C_r = 90°$ and $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2}$, $\cos A_r = \Sigma X/R$, and $\cos B_r = \Sigma Y/R$.

For equilibrium, it is necessary that $R = 0$; that is to say, ΣX, ΣY, and ΣZ must each be equal to zero.

General Law. In order that a number of forces acting at the same point shall be in equilibrium, the algebraic sum of their components along any *three* co-ordinate axes must each be equal to zero. When the forces all act in the same plane, the algebraic sum of their components along any *two* co-ordinate axes must each equal zero.

When the Forces Form a System in Equilibrium. Three unknown forces can be determined if the lines of action of the forces are *all* known and are in different planes. If the forces are all in the same plane, the lines of action being known, only *two* unknown forces can be determined. If the lines of action of the unknown forces are *not* known, only *one* unknown force can be determined in either case.

Couples and Moments

Couple. Two forces of equal magnitude, Fig. 18, which act in opposite and parallel directions form a couple. **A couple cannot be reduced to a single force.**

Displacement and Change of a Couple. The forces forming a couple may be moved about and their magnitude and direction changed, provided that they always remain parallel to each other, remain either in the original plane or one parallel to it, and provided that the product of one of the forces and the perpendicular distance between the two is constant and the direction of rotation remains the same.

Moment of a Couple. The moment of a couple is the product of the magnitude of one of the forces and the perpendicular distance between the lines of action of the forces. Fa = moment of couple; a = arm of couple. If the forces are measured in pounds and the distance a in feet, the **unit of rotation moment** is the foot-pound. If the force is measured in kilograms and the distance in meters, the unit is the meter-kilogram. In the C. G. S. system the unit of rotation moment is 1 cm.-dyne.

Rotation Moments of Couples acting in the same plane are considered to be **positive or negative**, according to whether they appear to rotate in the direction of the hands of a clock or in the reverse direction. The couple shown in Fig. 18 is positive. The magnitude, direction and sense of rotation of a couple are completely determined by its moment axis, or moment vector, which is a line drawn perpendicular to the plane in which the couple acts, with an arrow indicating the direction from which the couple will appear to have right-handed rotation; the length of the line represents the magnitude of the moment of the couple. See Fig. 19, in which AB represents the magnitude of the moment of the couple. Looking along the line in the direction of the arrow, the couple will have right-handed rotation in any plane perpendicular to the line.

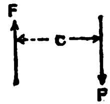

FIG. 18.

FIG. 19.

Composition of Couples. Couples may be combined by adding their moment vectors geometrically, in accordance with the parallelogram rule, in the same manner in which forces are combined.

Couples lying in the same or parallel planes are added algebraically. Let $+40$, -60, and $+100$ ft.-lb. be the moments of three couples in the same or parallel planes; their resultant is a single couple lying in the same or in a parallel plane, whose moment is $\Sigma M = +40 - 60 + 100 = +80$ ft.-lb.

If the polygon formed by the moment vectors of several couples closes itself, the couples form an equilibrium system. Two couples will balance each other when they lie in the same or parallel planes, and have the same moment in magnitude, but opposite in sign.

Combination of a Couple and a Single Force in the Same Plane. (See Fig. 20.) Given a force $F = 20$ lb. acting as shown distant x from YY, and a couple whose moment is -60 ft.-lb. in the same or a parallel plane, to find the resultant. A couple may be changed to any other couple in the same or a parallel plane having the same moment and same sign. Let the couple consist of two forces of 20 lb. each and let the arm be 3 ft. Place the couple in such a manner that one of its forces is opposed to the given force at p. This force of the couple and the given force being of the same magnitude and opposite in direction, will neutralize each other, leaving the other force of the couple acting at a distance of 3 ft. from p and parallel and equal to the given force $F = 20$.

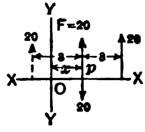

FIG. 20.

General Rule. The resultant of a couple and a single force lying in the same or parallel planes is a single force, equal in magnitude, in the same direction and parallel to the single force, and acting at a distance from the line of action of the single force equal to the moment of the couple divided by the single force. The moment of the resultant force about any point on the line of action of the given single force must be of the same sense as that of the couple, positive if the moment of the couple is positive, and negative if moment of couple is negative. If the moment of the couple in Fig. 20 had been $+ 60$ instead of $- 60$, the resultant would have been a force of 20 lb. acting in the same direction and parallel to F, but at a distance of 3 ft. to the left of it (shown dotted), making the moment of the resultant about any point on F positive.

To Effect a Parallel Displacement of a Single Force F over a distance a, a couple whose moment is Fa must be added to the system. The sense of the couple will depend upon which way it is desired to displace force F.

The Moment of a Force with Respect to a Point is the product of the force F and the perpendicular distance from the point to the line of action of the force.

The Moment of a Force with Respect to a Straight Line. If the force is resolved into components parallel and perpendicular to the given line, the moment of the force with respect to the line is the product of the magnitude of the perpendicular component and the distance from its line of action to the given line.

Forces with Different Points of Application

Composition of Forces. If each force F is resolved into components parallel to three rectangular co-ordinate axes XX, YY and ZZ, the magnitude of the resultant is $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2 + (\Sigma Z)^2}$, and its line of action makes angles A_r, B_r and C_r with axes XX, YY and ZZ, where $\cos A_r = \Sigma X/R$, $\cos B_r = \Sigma Y/R$, and $\cos C_r = \Sigma Z/R$; and there are three couples which may be combined by their moment vectors into a single resultant couple having the moment $M_r = \sqrt{(M_x)^2 + (M_y)^2 + (M_z)^2}$, whose moment vector makes angles of A_m, B_m and C_m with axes XX, YY and ZZ, such that $\cos A_m = M_x/M_r$, $\cos B_m = M_y/M_r$, and $\cos C_m = M_z/M_r$. If this single resulting couple is in the same plane as the single resulting force at the origin or a plane parallel to it, the system may be reduced to a single force R acting at a distance from $R = M_r/R$. If the couple and force are not in the same or parallel planes, it is impossible to reduce the system to a single force. If $R = 0$, that is, if ΣX, ΣY and ΣZ all equal zero, the system will reduce to a single couple whose moment is M_r. If $M_r = 0$, that is, if M_x, M_y and M_z all equal zero, the resultant will be a single force R.

When the Forces are All in the Same Plane, one of the angles A_r, B_r or $C_r = 0$, say, $C_r = 90°$. Then $R = \sqrt{(\Sigma X)^2 + (\Sigma Y)^2}$, $M_r = \sqrt{M_x^2 + M_y^2}$ and the final resultant is a force equal and parallel to R, acting at a distance from R equal to M_r/R.

A system of forces in the same plane can always be replaced by either a couple or a single force. If $R = 0$ and $M_r > 0$, the resultant is a couple. If $M_r = 0$ and $R > 0$, the resultant is a single force.

A rigid body is in equilibrium when acted upon by a system of forces whenever $R = 0$ and $M_r = 0$, *i.e.*, when the following six conditions hold true: $\Sigma X = 0$, $\Sigma Y = 0$, $\Sigma Z = 0$, $M_x = 0$, $M_y = 0$ and $M_z = 0$. When the system of forces is in the same plane, equilibrium prevails when the following three conditions hold true: $\Sigma X = 0$, $\Sigma Y = 0$, $\Sigma M = 0$.

Forces Applied to Support Rigid Bodies

The external forces in equilibrium acting upon a body may be statically determinate or indeterminate according to the number of unknown forces existing. When the forces are all in the same plane and act at a common point, two unknown forces may be determined if their lines of action are known, one if unknown.

When the forces are all in the same plane and are parallel, two unknown forces may be determined if the lines of action are known, one if unknown.

When the forces are anywhere in the same plane, three unknown forces may be determined if their lines of action are known, if they are not parallel or do not pass through a common point; if the lines of action are unknown, only one unknown force can be determined.

If the forces all act at a common point but are in different planes, three unknown forces can be determined if the lines of action are known, one if unknown.

If the forces act in different planes but are parallel, three unknown forces can be determined if their lines of action are known, one if unknown.

The first step in the solution of problems in statics is the determination of the supporting forces. The following data are required for the complete knowledge of supporting forces: magnitude, direction, and point of application. According to the nature of the problem, none, one, or two of these quantities are known.

One Fixed Support. The point of application, direction, and magnitude of the load are known. See Fig. 21. As the body on which the forces act is in equilibrium, the supporting force P must be equal in magnitude and opposite in direction to the resultant of the loads L.

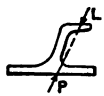

FIG. 21.

In the case of a **rolling surface,** the point of application of the support is obtained from the center of the connecting bolt A (Fig. 22), both the direction and magnitude being unknown. The point of application and line of action of the support at B are known, being determined by the rollers.

When three forces acting in the same plane on the same rigid body are in equilibrium, their lines of action must pass through the same point O. The load L is known in magnitude and direction. The line of action of the support at B is known on account of the rollers. The point of application of the support at A is known. The three forces are in equilibrium and are in the same plane, and therefore the lines of action must meet at the point O.

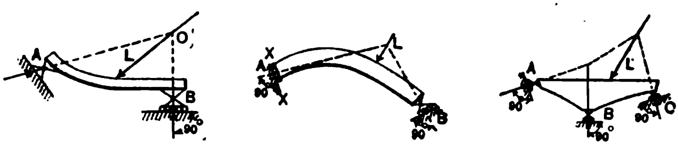

FIG. 22. FIG. 23. FIG. 24.

In the case of the rolling surfaces shown in Fig. 23, the direction of the support at A is known, the magnitude and point of application unknown. The line of action and point of application of the supporting force at B are known, its magnitude unknown. The lines of action of the three forces must meet in a point, and the supporting force at A must be perpendicular to the plane XX. In the case shown in Fig. 24, the directions and points of application of the supporting forces are known, and the magnitudes unknown. The lines of action of resultant of supports A and B, the support at C and load L must meet at a point. Resolve the resultant of supports at A and B into components at A and B, their direction being determined by the rollers.

If a member of a truss or frame in equilibrium is pinned at two points and loaded at these two points only, the line of action of the forces exerted on the member or by the member at these two points must be along a line connecting the pins.

If the external forces acting upon a rigid body in equilibrium are all in the same plane, the equations $\Sigma X = 0$, $\Sigma Y = 0$, and $\Sigma M = 0$ must be satisfied. When trusses, frames and other structures are under discussion, these equations are usually used as $\Sigma V = 0$, $\Sigma H = 0$, $\Sigma M = 0$, where V and H represent vertical and horizontal components, respectively.

The **supports** are said to be **determinate statically** when the laws of equilibrium are sufficient for their determination. When the conditions are not sufficient for the determination of the supports or other forces, the structure is said to be **statically indeterminate** and the unknown forces can only be determined by considerations involving the elasticity of the material.

When several bodies are so connected to one another as to make up a rigid structure, the forces at the points of connection must be considered as internal forces and are not taken into consideration in the determination of the supporting forces for the structure as a whole.

The distortion of any practically rigid structure under its working loads is so small as to be negligible when determining supporting forces. When the forces acting at the different joints in a built-up structure cannot be determined by dividing the structure up into parts, the structure is said to be **statically indeterminate internally**. A structure may be statically indeterminate internally and still be statically determinate externally.

Fundamental Problems in Graphical Statics

A force may be represented by a straight line in a determined position, and its magnitude by the length of the straight line. The direction in which it acts may be indicated by an arrow.

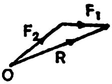

FIG. 25.

Polygon of Forces. The parallelogram of two forces intersecting each other (see Fig. 8) leads directly to the graphic composition by means of the triangle of forces. In Fig. 25, R is called the **closing side**, and represents the resultant of the forces F_1 and F_2 in magnitude and direction. Its position is given by the point of application O. By means of repeated use of the triangle of forces and by omitting the closing sides of the individual triangles, the magnitude and direction of the resultant R of any number of forces in the same plane and intersecting at a single point can be found. In Fig. 26 the lines representing the forces start from point O, and in the force polygon, Fig. 27, they are joined in any order, the arrows showing their directions following around the polygon in the same direction. The magnitude of the resultant at the point of application of the forces is represented by the closing side R of the force polygon; its direction, as shown by the arrow, is counter to that in the other sides of the polygon.

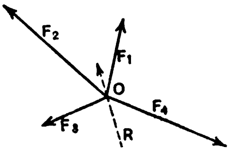

FIG. 26.

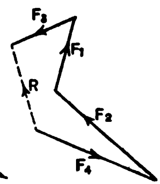

FIG. 27.

If the forces are in equilibrium, R must equal zero, *i.e.*, **the force polygon must close.**

If in a closed polygon one of the forces is reversed in direction, this force becomes the resultant of all the others.

If the **forces** do **not** all lie **in the same plane,** the diagram becomes a polygon in space. If the projections of the forces be drawn on any two planes, say horizontal and vertical, the closing lines of the projected polygons are the projections of the closing line of the force diagram in space.

Funicular Polygon

Composition of Forces in a Plane. In Fig. 28, to determine the resultant R of the forces F_1, F_2, F_3 and F_4—all in the same plane, construct the force polygon shown at (*b*). R will represent the magnitude and direction of the resultant force, and its location in (*a*) may be determined as follows: In Fig. 28(*b*) assume any convenient point, O, as a **pole**, draw the straight lines $O0$, $O1$, $O2$, $O3$ and $O4$, and in Fig. 28(*a*) draw the lines s_0, s_1, s_2, s_3, s_4, parallel to the similarly lettered lines in Fig. 28(*b*). The location of s_0 in Fig. 28(*a*) is optional, so long as it intersects the line of action of F_1. R must pass through the intersection of s_0 and s_4 and be parallel to R in Fig. 28(*b*).

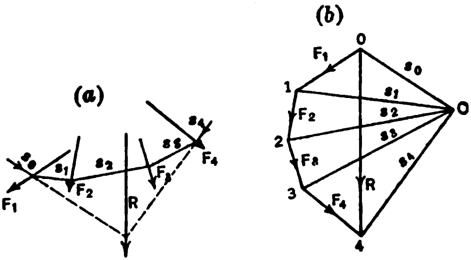

FIG. 28.

The figure $O01234$ is called the **polygon of forces** or **force polygon,** the lines s_0, s_1, s_2, s_3, s_4 in Fig. 28(*b*) are **rays,** and the series of lines s_0, s_1, s_2, s_3, s_4, in Fig. 28(*a*) is called a **string polygon** or **funicular polygon,** s_0, s_1, s_2, s_3, s_4 in (*a*) being **known as strings.** The following three cases may be met:

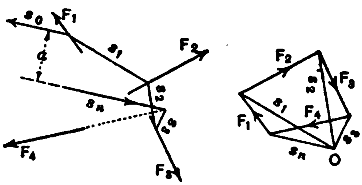

FIG. 29.

(*a*) The general case, where the starting point of the polygon of forces does not coincide with the terminal point. The resultant is a single force, as shown by Fig. 28. (*b*) The polygon of forces closes and the end strings of the funicular polygon are parallel. In this case (Fig. 29) the resultant is a couple whose moment is $s_0a = s_na$. (*c*) The polygon of forces closes and the funicular polygon also closes, the result being **equilibrium.** See Fig. 30. The two coinciding terminal sides of the funicular polygon are called the **closing sides** or strings.

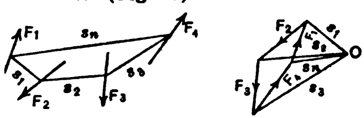

FIG. 30.

Let a polygon of forces and a funicular polygon be drawn for the system of forces shown in Fig. 31 with poles at both O and O_1. The intersections of the corresponding strings of the funicular polygons all lie in the same straight line A_0A_n parallel to OO_1. This line is the **polar axis** of both funicular polygons.

Let the starting point of the force polygon be taken as a pole; then the sides of the funicular polygon will always give the line of action of the resultants of all the forces preceding. The last side will coincide with the resultant of all the forces.

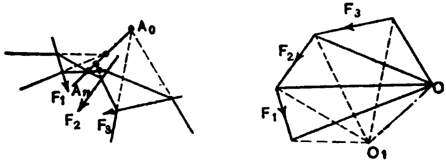

FIG. 31.

To determine the supporting forces for a rigid body when the external forces are all in the same plane and are statically determinate, see Fig. 32. Let F_1 and F_2 be two forces acting on beam which is supported at A by a roller and at B by a pin. Construct a force polygon, Fig. 32(b), using any convenient point O for a pole, and the funicular polygon shown in Fig. 32(a). This latter must start at B, as this is the only point on the line of action of the unknown support at B that is known. Draw the strings parallel to the corresponding rays of the force polygon and find that the last string intersects the line of action of the left-hand support at P. If the forces are in equilibrium, both force and funicular polygons must close. The closing side of the funicular polygon is PB. OX, Fig. 32(b), is drawn parallel to PB until it meets a line drawn from 1 parallel to the supporting force at A. The line $X3$ closes the force polygon and gives the magnitude and direction of the supporting force at B. It is necessary that either the lines of action of both unknown supports, or the line of action of one and the point of application of the other, be known in order to use this construction.

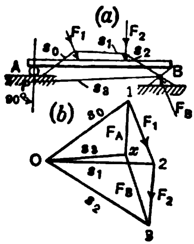

FIG. 32.

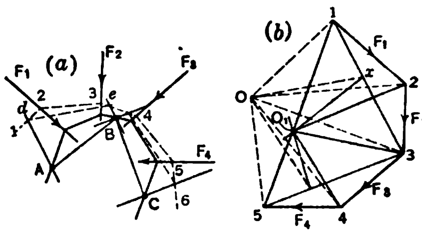

FIG. 33.

To draw a **funicular polygon through three points,** see Fig. 33. Given the forces F_1, F_2, F_3, and F_4, Fig. 33(a), let it be required to draw a funicular polygon passing through points A, B and C. Construct a force polygon, Fig. 33(b), using O as a pole, and a corresponding funicular polygon, 1, 2, 3, 4, 5, 6, Fig. 33(a). Consider the forces between points A and B; if they are to be balanced by two forces each parallel to their resultant and acting through A and B, these two forces can be determined by drawing lines parallel to 1 3, Fig. 33(b), through A and B, Fig. 33(a). The points where these lines are intersected by the funicular polygon are d and e; the closing side of a funicular polygon for these two forces is de and the magnitude of the balancing forces can be determined as $1x$ and $x3$, Fig. 33(b), by drawing from O a line parallel to *de* and intersecting 1 3 which is parallel to the forces at *d* and *e*. If the funicular polygon had passed through A and B, the same balancing forces for F_1 and F_2 parallel to 1 3 must be found so that the locus of the poles of all the funicular polygons for F_1 and F_2 that will pass through A and B must lie on a line drawn from x and parallel to AB. In the same manner the locus of the poles of all the funicular polygons for F_3 and F_4 can be determined, and the intersection of these two loci will be the pole O_1 required.

Moment of Any System of Forces in a Plane. The resultant moment M of the forces F_1, F_2, F_3 (Fig. 34) with reference to point A can be determined as follows: Fig. 34(b) is a force polygon for F_1, F_2, F_3, using any convenient point O as a pole. Fig. 34(a) shows a corresponding funicular polygon. Through points A and P of (a) draw lines parallel to the resultant of the forces R in (b); point P is the intersection of the end strings of the funicular polygon, and m and q are the points where the line drawn through point A intersects the end strings. Consider the shaded triangles; the homologous sides are parallel, the triangles are therefore similar, and $mq/x = R/p$. $\therefore (mq)p = Rx$; but Rx is the moment of the resultant of the forces with respect to A; $\therefore (mq)p$ must also be the same moment. mq is known as the **intercept** and p is known as the **pole distance.** In the case of parallel forces, the pole distance will be a constant; therefore, the moment at different points will vary as the intercept.

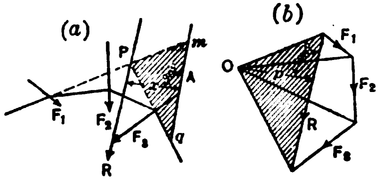

FIG. 34.

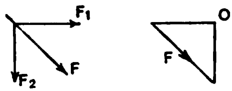

FIG. 35.

Resolution of Forces. Forces may be resolved into components in the same plane by means of the funicular polygon. See Fig. 35.

The funicular polygon is of great service in the solution of **stone arch and dam problems,** in determining the line of resistance at the joints. Bending moments and shearing forces for beams and other structures may also be determined graphically by its use.

Determination of Stresses in Members of a Statically Determinate Plane Structure with Loads at Rest

It will be assumed that the loads are applied at the joints of the structure, *i.e.*, at the points where the different members are connected, and that the connections are pins with no friction. The stresses in the members must then be along lines connecting the pins, unless any member is loaded at more than two points by pin connections. If the members are straight, the forces exerted on them or by them must coincide with the axes of the members. In other words, there shall be no bending stresses in any of the members of the structure.

Equilibrium. In order that the whole structure shall be in equilibrium, it is necessary that the external forces (loads and supports) shall form a balanced system. Graphical and analytical methods are both of service.

Supporting Forces. When the supporting forces are to be determined, it is not necessary to pay any attention to the make-up of the structure under consideration so long as it is practically rigid; the loads may be taken as they occur, or the resultant of the loads may be used instead. When the stresses in the members of the structure are being determined, the loads *must* be distributed at the joints where they belong.

Method of Joints. When all the external forces have been determined, any joint at which there are not more than two unknown forces may be taken and these unknown forces determined by the methods of the stress polygon, resolution or moments. In Fig. 36, let O be the joint of a structure and F be the only known force; but let $O1$ and $O2$ be two members of the structure joined at O. Then the lines of action of the unknown forces are known and their magnitude may be determined (*a*) by a **stress polygon** which, for equilibrium, must close; (*b*) by resolution into H and V components, using the condition of equilibrium $\Sigma H = 0$, $\Sigma V = 0$; or (*c*) by moments, using any convenient point on the line of action of $O1$ or $O2$ and the condition of equilibrium $\Sigma M = 0$. No more than *two* unknown forces can be determined.

FIG. 36.

In this manner, proceeding from joint to joint, the stresses in all the members of the truss can usually be determined if the structure is statically determinate internally. The structure may be divided into two parts by passing a section through it cutting some of its members; one part may then be treated as a rigid body and the external forces acting upon it determined. Some of these forces will be the stresses in the members themselves. For example, let xx (Fig. 37) be a section taken through a truss loaded at P_1, P_2 and P_3, and supported on rollers at S. As the whole truss is in equilibrium, any part of it must be also, and consequently the part shown to the left of xx must be in equilibrium under the action of the forces acting externally to it. Three of these forces are the stresses in the members aa, bb, and bc, and are the unknown forces to be determined. They can be determined by applying the condition of equilibrium for forces acting in the same plane but not at the same point. $\Sigma H = 0, \Sigma V = 0, \Sigma M = 0$. The three unknown forces can be determined only if they are not parallel or do not pass through the same point; if, however, the forces are parallel or meet in a point, two unknown forces only can be determined. The conditions of equilibrium when using the funicular polygon construction are that both the funicular and force polygons must close. Sections may be passed through a structure cutting members in any convenient manner; as a rule, however, cutting not more than three members.

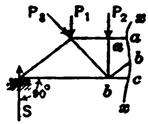

FIG. 37.

For the determination of stresses in framed structures, see p. 224.

Center of a Set of Parallel Forces; Center of Gravity

The center of a set of parallel forces is the point through which the resultant of the forces always passes, no matter how the forces are turned, providing that they always remain parallel and their points of application remain in the same relation to each other.

The resultant R of the two parallel forces F_1 and F_2 (Fig. 38) divides the line connecting the points of application A_1, A_2 into two segments a_1 and a_2 at the point S. $F_1a_1 = F_2a_2$. The point S is independent of the direction of the parallel forces, provided they always remain parallel and applied at A_1 and A_2. The point S, through which the resultant always passes, is called **the center of the parallel forces** F_1 **and** F_2.

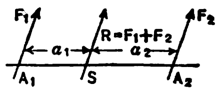

FIG. 38.

The **static moment** of a line, surface or solid with respect to an axis is the length of the line, the area of the surface or the weight of the solid multiplied by the distance from the axis to the center of gravity of the line, surface or solid.

Centers of Gravity of Lines. To find the center of gravity of a line, divide it into an indefinitely large number of indefinitely short lengths, to be known as elementary divisions. Multiply the length of each elementary division by its perpendicular distance from some reference axis in a plane containing the line. When the line is all on one side of the axis, add these products (or moments, as they are usually designated), but when the line is on both sides of

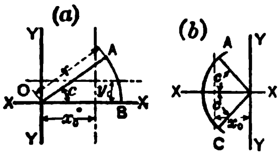

FIG. 39.

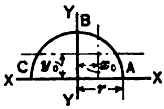

FIG. 40.

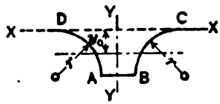

FIG. 41.

the axis, subtract the moments of the part on one side from the moments of the part on the other. Divide this sum or difference by the total length of the line, and the quotient will be the perpendicular distance from the axis to the center of gravity of the line, and should be measured on the side of the axis that has the greater moment if the line is on both sides of the axis.

Centers of Gravity of Plane Areas. Proceed in the same manner as for lines, dividing the area into elementary areas. If the plane area has an axis of symmetry, the center of gravity lies on this axis.

Centers of Gravity of Technically Important Lines, Areas and Solids

CENTERS OF GRAVITY OF LINES

Straight Line. The center of gravity is at its middle point.

Circular Arc AB, Fig. 39(a): $x_0 = r \sin c/\text{rad } c$; $y_0 = 2r \sin^2 \frac{1}{2}c/\text{rad } c$. (rad c = angle c measured in radians; see p. 44.)

Circular Arc AC, Fig. 39(b): $x_0 = r \sin c/\text{rad } c$; $y_0 = 0$.

Quadrant, AB, Fig. 40: $x_0 = y_0 = 2r/\pi = 0.6366\, r$.

Semi-circumference, AC, Fig. 40: $y_0 = 2r/\pi = 0.6366r$; $x_0 = 0$.

Combination of Arcs and Straight Line, Fig. 41: AD and BC are two quadrants of radius r. $y_0 = \{(AB)r + 2[0.5\pi r(r - 0.6366r)]\} + [AB + 2\,(0.5\pi r)]$.

CENTERS OF GRAVITY OF PLANE AREAS

Triangle. Center of gravity (C. G.) lies at the intersection of the lines joining the vertices with the mid-points of the sides, and at a distance from any side equal to one-third of the corresponding altitude.

Parallelogram. C. G. lies at the point of intersection of the diagonals.

Trapezoid, Fig. 42. C. G. lies on the line joining the middle points m and n of the parallel sides. The distances h_a and h_b are

$$h_a = h(a + 2b)/3\,(a + b);\ h_b = h(2a + b)/3(a + b).$$

Draw $BE = a$ and $CF = b$; EF will then intersect mn at C. G.

Any Quadrilateral. The C. G. of any quadrilateral may be determined by the general rule for areas, or graphically by dividing it into two sets of triangles by means of the diagonals. Find the C. G. of each of the four triangles and connect the C. G's. of the triangles belonging to the same set. The intersection of these lines will be C. G. of area. Thus, in Fig. 43, O, O_1, O_2 and O_3 are respectively the centers of gravity of the triangles ABD, ABC, BDC and ACD. The intersection of O_1O_3 with OO_2 gives C. G.

Segment of a Circle, Fig. 44: $x_0 = \frac{2}{3}r \sin^3 c/(\text{rad}\, c - \cos c \sin c)$. A segment may be considered to be a sector from which a triangle is subtracted, and the general rule applied.

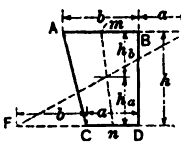

FIG. 42.

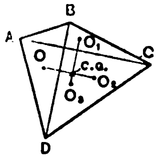

FIG. 43.

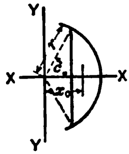

FIG. 44.

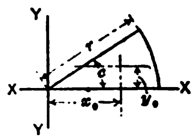

FIG. 45.

Sector of a Circle, Fig. 45: $x_0 = \frac{2}{3}r \sin c/\text{rad}\, c$; $y_0 = \frac{4}{3}r \sin^2 \frac{1}{2}c/\text{rad}\, c$.

Semi-circle, $x_0 = \frac{4}{3}r/\pi = 0.4244r$; $y_0 = 0$.

Quadrant (90-deg. sector): $x_0 = y_0 = \frac{4}{3}r/\pi = 0.4244r$.

Parabolic Half Segment, Fig. 46, Area ABO: $x_0 = \frac{3}{5}x_1$; $y_0 = \frac{3}{8}y_1$.

Parabolic Spandrel, Fig. 46, Area AOC: $x'_0 = \frac{3}{10}x_1$; $y'_0 = \frac{3}{4}y_1$.

Quadrant of an Ellipse, Fig. 47, Area OAB: $x_0 = \frac{4}{3}(a/\pi)$; $y_0 = \frac{4}{3}(b/\pi)$.

The center of gravity of a figure such as that shown in Fig. 48 may be determined as follows: Divide the area $OABC$ into a number of parts by lines drawn perpendicular to the axis XX, *e.g.*, 11, 22, 33, etc. These parts

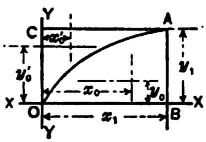

FIG. 46.

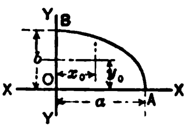

FIG. 47.

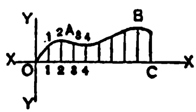

FIG. 48.

will be approximately either triangles, rectangles or trapezoids. The area of each division may be obtained by taking the product of its mean height and its base. The center of gravity of each area may be obtained as previously shown. The sum of the moments of all the areas about XX and YY, respectively, divided by the sum of the areas will give approximately the distances from the center of gravity of the whole area to the axes XX and YY. The greater the number of areas taken the more nearly exact the result.

CENTERS OF GRAVITY OF SOLIDS

Prism or Cylinder With Parallel Bases. C. G. lies in the center of the line connecting the centers of gravity of the bases.

Oblique Frustum of a Right Circular Cylinder, Fig. 49. Let 1 2 3 4 be the plane of symmetry. The distance from the base to the C. G. is

$\frac{1}{2}h + (r^2 \tan^2 c/8h)$, where c is the angle of inclination of the oblique section to the base. The distance of the C. G. from the axis of the cylinder is $\frac{1}{4} r^2 \tan c/h$.

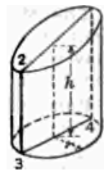

FIG. 49.

Pyramid or Cone. C. G. lies in the line connecting the C. G. of base with the vertex and at a distance of one-fourth of the altitude above the base.

Truncated Pyramid. If h is the height of the truncated pyramid and A and B the areas of its bases, the distance of its C. G. from the surface of A is

$$h(A + 2\sqrt{AB} + 3B)/4(A + \sqrt{AB} + B).$$

Truncated Circular Cone. If h is the height of the frustum and R and r the radii of the bases, the distance from the surface of the base whose radius is R to the center of gravity is $h(R^2 + 2Rr + 3r^2)/4(R^2 + Rr + r^2)$.

Segment of a Sphere, Fig. 50, volume ABC: $x_0 = 3(2r - h)^2/4(3r - h)$.

Hemisphere. $x_0 = 3r/8$.

Hollow Hemisphere. $x_0 = 3(R^4 - r^4)/8(R^3 - r^3)$, where R and r are respectively the outer and inner radii.

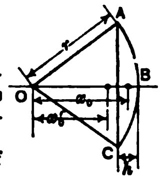

FIG. 50.

Sector of a Sphere, Fig. 50, volume $OABCO$: $x'_0 = \frac{3}{8}(2r - h)$.

Ellipsoid, with semi-axes a, b and c. For each octant, distance from center of gravity to each of the bounding planes $= \frac{3}{8} \times$ length of semi-axis perpendicular to the plane considered.

The formulæ given for the determination of the centers of gravity of lines and areas can be used to determine the areas and volumes, of surfaces and solids of revolution, respectively by employing the theorems of Pappus, p. 111.

Determination of Center of Gravity of a Body by Experiment. The center of gravity may be determined by hanging the body up from different points and plumbing down; the point of intersection of the plumb lines will give the center of gravity. The C. G. may also be determined as shown in Fig. 51. The body is placed on knife edges which rest on platform scales. The sum of the weights registered on the two scales $(w_1 + w_2)$ must equal the weight (w) of the body. Taking a moment axis at either end (say, O), $w_2A/w = x_0 =$ distance from O to plane containing the center of gravity.

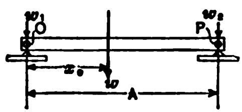

FIG. 51.

Graphical Determination of the Centers of Gravity of Plane Areas. See p. 211 and Fig. 62.

Moment of Inertia

The Moment of Inertia of a Solid Body with respect to a given axis is the limit of the sum of the products of the weights or masses of each of the elementary particles into which the body may be conceived to be divided and the square of their distance from the given axis.

If dw or dm represents the weight or mass of an elementary particle and y its distance from an axis, the moment of inertia I of the body about this axis will be $I_w = \int y^2 dw$ in weight units, and $I_m = \int y^2 dm$ in mass units.

If the lengths are measured in feet and the weights in pounds, the unit for I_w is the lb. ft^2.

If $I_w = r^2w$ or $I_m = r^2m$, the quantity r is called the **radius of gyration** or the **radius of inertia.** Also $I_w = I_m \times g$.

If a body is considered to be composed of a number of parts, its moment of inertia about an axis is equal to the sum of the moments of inertia of the several parts about the same axis, or $I = I_1 + I_2 + I_3 + \ldots\ldots I_n$.

The Moment of Inertia of an Area with respect to a given axis is the limit of the sum of the products of the elementary areas into which the area may be conceived to be divided and the square of their distance (y) from the axis in question. $I = \int y^2dA = r^2A$, where r = radius of gyration.

Relation Between the Moments of Inertia of an Area and a Solid. The moment of inertia of a solid of elementary thickness about an axis is equal to the moment of inertia of the area of one face of the solid about the same axis multiplied by the weight per unit volume of the solid times the elementary thickness of the solid.

Moments of Inertia About Parallel Axes. The moment of inertia of an area or solid about any given axis is equal to the moment of inertia about a parallel axis through the center of gravity plus the square of the distance between the two axes times the area or weight.

In Fig. 52(a), the moment of inertia of the area $ABCD$ about axis YY is equal to I_0 (or the moment of inertia about Y_0Y_0 through the center of gravity of the area and parallel to YY) plus x_0^2A, where A = area of $ABCD$. In Fig. 52(b), the moment of inertia of the weight w about $YY = I_0 + x_0^2w$. Y_0Y_0 passes through C. G. of weight and is parallel to YY. If mass units are used, $I = I_0 + x_0^2m$.

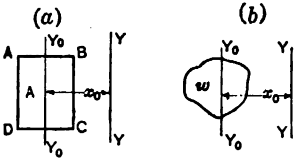

FIG. 52.

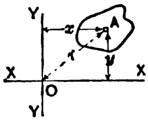

FIG. 53.

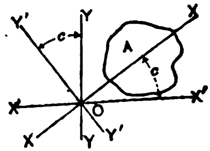

FIG. 54.

Polar Moment of Inertia. The polar moment of inertia, Fig. 53, is taken about an axis perpendicular to the plane of the area. Referring to Fig. 53, if I and J be the moments of inertia of the area A about YY and XX, respectively, then the polar moment of inertia of area about $O = I + J$, or the polar moment of inertia is equal to the sum of the moments of inertia about any two axes at right angles to each other in the plane of the area and intersecting at the pole.

Moment of Deviation, or Product of Inertia. This quantity will be represented by K and is $\int\int xydydx$, where x and y are the co-ordinates of any elementary part into which the area may be conceived to be divided. K may be positive or negative, depending upon the position of the area with respect to the co-ordinate axes XX and YY.

Relation Between Moments of Inertia About Axes Inclined to Each Other. Referring to Fig. 54, let I and J be the moments of inertia of the area A about YY and XX, respectively, I_1 and J_1 the moments about $Y'Y'$ and $X'X'$, and K and K_1 the products of inertia for XX and YY, and $X'X'$ and $Y'Y'$, respectively. Also, let c be the angle between the respective pairs of axes, as shown. Then,

$$I_1 = I\cos^2 c + J\sin^2 c + 2K\cos c\sin c,$$
$$J_1 = I\sin^2 c + J\cos^2 c - 2K\cos c\sin c,$$
$$K_1 = (J - I)\cos c\sin c + K(\cos^2 c - \sin^2 c)$$

Principal Moments of Inertia. In every plane area, a given point being taken as the origin, there is at least one pair of rectangular axes in the plane of the area about one of which the moment of inertia is a maximum, and a minimum about the other. These moments of inertia are called the **principal moments of inertia**, and the axes about which they are taken are the **principal axes of inertia.** One of the conditions for principal moments of inertia is that the product of inertia K shall equal zero. **Axes of symmetry** of an area are always principal axes of inertia.

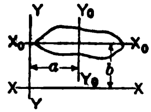

FIG. 55.

Relation Between Products of Inertia for Parallel Axes. In Fig. 55, X_0X_0 and Y_0Y_0 pass through the center of gravity of the area parallel to the given axes XX and YY. If K be the product of inertia for XX and YY, and K_0 that for X_0X_0 and Y_0Y_0, then $K = K_0 + ab\int dA$.

Ellipse of Inertia. In Fig. 56, let $I = \int x^2dA$ and $J = \int y^2dA$ be the moments of the area about the principal axes XX and YY. The moment of inertia about axis $AA = I\sin^2 c + J\cos^2 c$, as $K = 0$. The polar equation of an ellipse constructed on the semi-axes a and b will be $a^2\sin^2 c + b^2\cos^2 c = (a^2b^2)/r^2$, r being the radius vector of any point on the ellipse and c the angle that it makes with XX. Lay off $a = \sqrt{I}$ and $b = \sqrt{J}$; then the moment of inertia about $AA = (a^2b^2)/r^2 = (IJ)/r^2$.

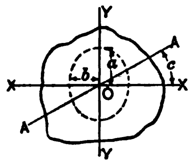

FIG. 56.

The moment of inertia of the area about any axis in the plane and passing through O will be inversely proportional to the square of the semi-diameter cut by that axis from an ellipse constructed with $a = \sqrt{I}$ and $b = \sqrt{J}$, a and b being the semi-major and semi-minor axes, respectively.

The following **conclusions** may be drawn: If the principal moments of inertia are equal, the ellipse of inertia becomes a circle and the moments of inertia about all axes in the plane and passing through O are the same. If the moments of inertia about more than two axes in the plane and passing through O are equal, the moments of inertia about all axes in the plane and passing through O are the same. There are two axes in the plane making equal and opposite angles with a principal axis and passing through O, about which the moments of inertia are equal.

The Moment of Inertia of Any Area may be considered to be made up of the sum or difference of the known moments of inertia of simple figures. For example, the dimensioned figure shown in Fig. 57 represents the section of a rolled shape with hole *oprs*, and may be divided into the semi-circle *abc*, rectangle *edkg*, and triangles *mfg* and *hkl*, from which the rectangle *oprs* is to be subtracted. Referring to axis XX,

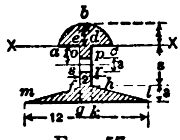

FIG. 57.

$$I_{xx} = \pi 4^4/8 \text{ for semi-circle } abc; \quad = (2 \times 11^3)/3 \text{ for rectangle } edkg;$$
$$= 2\,[(5 \times 3^3)/36 + 10^2(5 \times 3)/2] \text{ for the two triangles } mfg \text{ and } hkl.$$

From the sum of these there is to be subtracted $I_{xx} = [(2 \times 3^3)/12 + 4^2(2 \times 3)]$ for the rectangle *oprs*.

If the moment of inertia of the whole area is required about an axis parallel to XX, but passing through the center of gravity of the whole area, $I_0 = I_{xx} - x_0^2A$, where x_0 = distance from XX to center of gravity. The **moments of inertia of built-up sections** used in structural work may be found in the same manner, the moments of inertia of the different **rolled sections** being given on pp. 1289 to 1297.

Moments of Inertia of Solids. For moments of inertia of solids about parallel axes, $I_x = I_0 + x_0^2w$ or $I_x = I_0 + x_0^2m$, see p. 208. If I_m = moment of inertia in mass units and I_w = moment of inertia in weight units, $I_w = I_m \times g$, and $I_m = I_w/g$.

Moment of Inertia with Reference to Any Axis. Let a mass particle dm of a body have x, y and z as co-ordinates, XX, YY and ZZ being the co-ordinate axes and O the origin. Let $X'X'$ be any axis passing through the origin and making angles of A, B and C with XX, YY and ZZ, respectively. The moment of inertia with respect to this axis then becomes =

$$I_x' = \cos^2 A\int(y^2 + z^2)dm + \cos^2 B\int(z^2 + x^2)dm + \cos^2 C\int(x^2 + y^2)dm$$
$$-2\cos B\cos C\int yzdm - 2\cos C\cos A\int zxdm - 2\cos A\cos B\int xydm.$$

Let the moment of inertia about $XX = I_x = \int(y^2 + z^2)dm$, about $YY = I_y = \int(z^2 + x^2)dm$, and about $ZZ = I_z = \int(x^2 + y^2)dm$.

Let the products of inertia about the three co-ordinates axes be

$$K_{yz} = \int yzdm, \quad K_{zx} = \int zxdm, \text{ and } K_{xy} = \int xydm;$$

then the moment of inertia I_x' becomes equal to

$$I_x\cos^2 A + I_y\cos^2 B + I_z\cos^2 C - 2K_{yz}\cos B\cos C - 2K_{zx}\cos C\cos A - 2K_{xy}\cos A\cos B.$$

The moment of inertia of any solid may be considered to be made up of the sum or difference of the moments of inertia of simple solids of which the moments of inertia are known.

Moments of Inertia of Important Solids (Homogeneous)

w = weight per unit of volume of the body. W = total weight of body.
r = radius. $I = I_w$ = moment of inertia in weight units.

Solid Circular Cylinder about its axis:
$I = \pi r^4wa/2 = Wr^2/2$. (a = length of axis of cylinder.)

Solid Circular Cylinder about an axis through the center of gravity and perpendicular to axis of cylinder: $I = W[r^2 + (a^2/3)]/4$.

Hollow Circular Cylinder about its axis:
$I = \pi wa(r_1^4 - r_2^4)/2$. ($r_1$ and r_2 = outer and inner radii; a = length.)

Thin Hollow Circular Cylinder about its axis: $I = Wr^2$.

Solid Sphere about a diameter: $I = 8w\pi r^5/15 = 2Wr^2/5$.

Thin Hollow Sphere about a diameter: $I = 2Wr^2/3$.

Thick Hollow Sphere about a diameter:
$I = 8w\pi(r_1^5 - r_2^5)/15$. ($r_1$ and r_2 are outer and inner radii.)

Rectangular Prism about an axis through center of gravity and perpendicular to a face whose dimensions are a and b: $I = W(a^2 + b^2)/12$.

Solid Right Circular Cone about an axis through its apex and perpendicular to its axis:
$I = 3W[(r^2/4) + h^2]/5$. (h = altitude of cone, r = radius of base.)

Solid Right Circular Cone about its axis of revolution: $I = 3Wr^2/10$.

Ellipsoid with semi-axes a, b, and c: I about diameter $2c$ (z-axis) =
$I = 4w\pi abc\,(a^2 + b^2)/15$.
[Equation of ellipsoid: $(x^2/a^2) + (y^2/b^2) + (z^2/c^2) = 1$].

Ring with Circular Section, Fig. 58:

$I_{yy} = \frac{1}{4}w\pi^2 Ra^2(4R^2 + 3a^2)$;

$I_{xx} = w\pi^2 Ra^2[R^2 + (5a^2/4)]$.

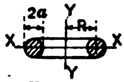

FIG. 58.

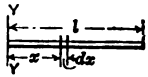

FIG. 59.

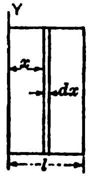

FIG. 60.

Approximate Moments of Inertia of Solids. In order to determine the moment of inertia of a solid, it is necessary to know all its dimensions. In the case of a rod of weight W, Fig. 59, and length l, with shape and size of the cross-section unknown, making the approximation that the weight is all concentrated along the axis of the rod, the moment of inertia about YY will be $I_{yy} = \int_0^l (W/l)x^2dx = Wl^2/3$.

A Thin Plate may be treated in the same way (Fig. 60):

$$I_{yy} = \int_0^l (W/l)x^2dx$$

Here the weight of the plate is assumed as concentrated at its middle layer.

Thin Ring, or Cylinder (Fig. 61): Assume the weight, W, of the ring or cylinder to be concentrated at a distance r from O. The moment of inertia about an axis through O perpendicular to plane of ring or along axis of cylinder will be $I = Wr^2$; this will be greater than the exact moment of inertia, and r is sometimes taken as the distance from O to the center of gravity of the cross-section of the rim.

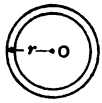

FIG. 61.

Graphical Determination of the Centers of Gravity and Moments of Inertia of Plane Areas. Required, to find the center of gravity of the area MNP, Fig. 62, and its moment of inertia about any axis XX.

Draw any line SS parallel to XX and at a distance d from it. Draw a number of lines such as AB and EF across the figure parallel to XX. From E and F draw ER and FT perpendicular to SS. Select as a pole any point O on XX, preferably the point nearest the area, and draw OR and OT, cutting EF at E' and F'. If the same construction is repeated, using other lines parallel to XX, a number of points will be obtained, which, if connected by a smooth curve, will give the area $M'N'P'$. Project E' and F' on to SS by lines $E'R'$ and $F'T'$. Join F' and T' with O, obtaining E'' and F'', connect the points obtained using other lines parallel to XX and obtain an area $M''N''P''$. The area $M'N'P' \times d$ = moment of area MNP about the line XX, and the distance from XX to the center of gravity of MNP = area $M'N'P' \times d$/area MNP. Also, area $M''N''P'' \times d^2$ = moment of inertia of MNP about XX. The areas $M'N'P'$ and $M''N''P''$ can best be obtained by use of a planimeter.

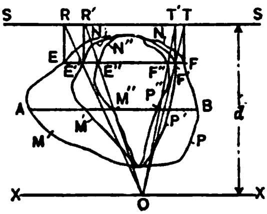

FIG. 62.

DYNAMICS OF RIGID BODIES

Motion Under Unbalanced Forces

If a body is acted upon by a system of forces forming a balanced system, it will either remain at rest or move uniformly in a straight line. Only unbalanced forces change the motion of a body.

Uniformly Accelerated or Retarded Motion requires the action of a constant unbalanced force. A common example of **uniformly accelerated**

motion is the action of gravity on a **falling body.** If the action of gravity is wholly unresisted, the velocity v at the end of time t (in sec.), starting from rest, will be $v = gt$, where g = acceleration due to gravity. If the body has an initial velocity v_0, $v = v_0 + gt$. An example of **uniformly retarded motion** is that of a body projected into the air vertically with a velocity v_0; its velocity after any time t will be $v = v_0 - gt$. If s = space passed through, $s = \frac{1}{2}gt^2$ for a falling body starting from rest, and $s = v_0t + \frac{1}{2}gt^2$ if starting with an initial velocity v_0. For a body projected vertically upward, $s = v_0t - \frac{1}{2}gt^2$.

General Formulæ for the Motion of a Body Under the Action of a Constant Unbalanced Force

s = space in ft., a = acceleration in ft. per sec. per sec., v = velocity in ft. per sec., v_0 = initial velocity in ft. per sec., h = height in ft., F = force, m = mass, w = weight, g = acceleration due to gravity.

Initial velocity = 0:	Initial velocity = v_0:
$F = ma = (w/g)a.$	$F = ma = (w/g)a.$
$v = at.$	$v = v_0 + at.$
$s = \frac{1}{2}at^2 = \frac{1}{2}vt.$	$s = v_0t + \frac{1}{2}at^2 = v_0t + \frac{1}{2}vt.$

$v = \sqrt{2as} = \sqrt{2gh}$ (falling freely from rest).

If a body is to be moved in a straight line by a force, the line of action of this force must pass through its center of gravity.

General Rule for the Solution of Problems When the Forces Are Constant in Magnitude and Direction. Resolve all the forces acting on the body into two components, one in the direction of the body's motion and one at right angles to it. Add the components along the body's motion algebraically and find the **unbalanced force,** if any exists.

Examples. (*a*) The body in Fig. 63 weighs 100 lb., is subjected to external forces F and F_1, and the coefficient of friction between the body and the inclined plane is 0.1. Required, the velocity of the body at the end of five (5) sec. if it starts from rest.

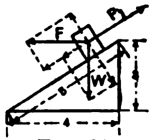

FIG. 63.

First, determine all of the forces acting externally to the body. These are F = 40 lb., F_1 = 80 lb., W = 100 lb., and the force with which the plane reacts upon the body. Resolve the forces into components along the plane and normal to it. The components along the plane are 32 lb. and 60 lb. acting down, 80 lb. acting up, and that component of the plane's resistance which acts against motion. This component of the plane's resistance is the normal component of the pressure between the surfaces multiplied by 0.1, which is the coefficient of friction. The components normal to the plane are 24 lb. acting away and 80 lb. acting toward the plane. The normal pressure is 80 − 24 = 56 lb., and the friction is 56 × 0.1 = 5.6 lb. The unbalanced force acting on the body along the plane is 60 + 32 − 80 − 5.6 = 6.4 lb. and acts downward.

$$F = ma = (100/g)a \quad \therefore a = 0.064g$$

The body is acted upon by constant forces and starts from rest, therefore $v = at$ and $s = \frac{1}{2}at^2$. If $t = 5$, $v = 0.064g \times 5 = 0.32g$, $s = (1/2)0.32g \times 5 = 0.8g$; taking g = 32.16, $v = 0.32 \times 32.16 = 10.29$ ft. per sec., $s = 0.8 \times 32.16 = 25.73$ ft.

(*b*) Find the constant force necessary to start from rest a train weighing 100 tons and give it a speed of 30 miles per hour in 1 min.; track to be level and straight, train resistance to be constant and equal to 12 lb. per ton. The external forces acting upon the train are the resistance of 100 × 12 = 1200 lb., the constant force F pulling the train along the level track, the force of gravity equal to weight of train, and the reaction of the track. The forces normal to the track form a balanced system, but, as the train is to be started from rest and given a velocity, the forces acting along the track must form an unbalanced system. A velocity of 30 miles per hour = 44 ft. per sec.; to acquire this velocity in 60 sec. requires an acceleration of 44/60, as $a = v/t$. The unbalanced force to give the train this acceleration is $F = ma = (100 \times 2000/g)(44/60) = 4580$ lb. The total tractive force required is therefore $4580 + 1200 = 5780$ lb. If the train is on a grade, the problem is the same, with the addition of another force acting along the track, that is, the component of the weight along the track.

The so-called **laws of inclined planes** are simply derived by the above method. In Fig. 64 the weight W slides down the plane without friction. The unbalanced component of the forces acting along the plane is $W \sin B$, $\therefore a = g \sin B$, $v = (g \sin B)t$, and $s = (\frac{1}{2}g \sin B)t^2$ as the body starts from rest. The time necessary to pass over a distance s is $t = \sqrt{2s/g \sin B}$, and $v = at = \sqrt{2gs \sin B} = \sqrt{2gH}$, showing that if the body slides without friction from T to A, its velocity will be the same as if it fell through the same vertical distance TN. With initial velocity v_0, $v = v_0 \pm (g \sin B)t$, and $s = v_0 t + (\frac{1}{2}g \sin B)t^2$.

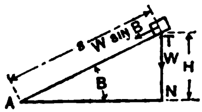

FIG. 64.

Tension in a Rope Connected to a Moving Body. The force with which the rope acts on the body is equal and opposite to the force with which the body acts on the rope, and each is equal to the tension in the rope. In Fig. 65, neglecting the weight of pulley A and the cord, find the tension in the cord. The unbalanced force acting on the two weights is $20 - 5 = 15$ lb. and acts on the two weights. $\therefore 15 = (25/g)a$, and $a = 3g/5$. w_1 is accelerated in an upward direction and w_2 downward. $T_1 = w_1 +$ the unbalanced force necessary to give w_1 an upward acceleration of $(3g/5) = 5 + (5/g) \times (3g/5) = 8$ lb. $T_2 = w_2 -$ the unbalanced force necessary to give w_2 a downward acceleration of $(3g/5) = 20 - (20/g) \times (3g/5) = 8$ lb. If a body is moved uniformly upward by a rope, the tension in the rope is equal to the weight of the body, without regard to the velocity.

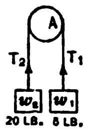

FIG. 65.

If a weight is to be pulled up an inclined plane by means of a rope, the tension in the rope is equal to the component of the weight along the plane plus the normal pressure between the surfaces times the coefficient of friction, plus the unbalanced force necessary to give the weight the acceleration that it has. If the weight is to move uniformly up the plane there will be no acceleration, and the tension in the rope must simply balance all resistance to motion.

Harmonic Motion

Forces Necessary to Cause Harmonic Motion. In Fig. 66, point A moves uniformly in the circle $X'YXY'$, and point P moves to and fro along $X'CX$.

Let ω be the angular velocity of point A. Consider that it starts from X' and moves to A in time t; then the angle $B = \omega t$. If $CA = r$, $X'P = r - CP = r - r \cos \omega t = s$. The velocity v of the point P will equal $ds/dt = \omega r \sin \omega t$, and the acceleration $a = dv/dt = -\omega^2 r \cos \omega t$. The unbalanced force acting on the body P at any time $= F = ma = m\omega^2 r \cos \omega t = (w/g)\omega^2 r \cos \omega t = m\omega^2 CP$, showing that the force varies as the distance of the body from the center of its path, being 0 at the center and $(w/g)\ \omega^2 r$ at the ends of the path. The velocity is 0 at the ends and a maximum at the middle, where $v = \omega r$.

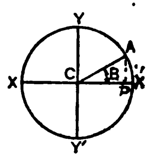

FIG. 66.

When a body is acted upon by varying forces, methods similar to those adopted for constant forces are used, but, in general, more simple solutions can be found by using the principles of work and energy.

Work and Energy

Work. When a body is displaced against resistance or accelerated, work must be done upon it. The work done by a constant force is the force F multiplied by the distance through which the force moves, or work $= Fs$. The work done by a force that varies $= \int F ds$ when the force F is expressed as a function of the space s. In the **work diagram,** Fig. 67, the ordinates are forces at different times and the abscissæ are spaces passed over. The area under the curve represents the work done, which is equal to $\int F ds$.

Units of Work. When the force of 1 lb. acts through the distance of 1 ft., **1 ft.-lb.** of work is done. The **foot-ton** unit is sometimes used. In countries using the metric system the unit employed is the **meter-kilogram.**

Energy. A body is said to possess energy when it can do work. A body may possess this capacity through its **position** or **condition.** When a body is so held that it can do work, if released, it is said to possess energy of position or **potential energy.** When a body is moving with some velocity, it is said to possess energy of motion or **kinetic energy.** An example of potential energy is a body held suspended by a rope; the position of the body is such that if the rope be removed work can be done by the body.

Energy is expressed in the same units as work. The kinetic energy of a body is expressed by the formula $E = \frac{1}{2}mv^2 = \frac{1}{2}(w/g)v^2$.

If a force which varies acts through a space on a body of mass m, the work done is $\int_{s_1}^{s_2} F ds$, and if the work is all used in giving kinetic energy to the body it is equal to $\frac{1}{2}m(v_2^2 - v_1^2) =$ **change in kinetic energy,** where v_2 and v_1 are the velocities at distances s_2 and s_1 respectively. For the kinetic energy of rotation, see p. 217.

If a force which varies acts for a certain time on a body of mass m, the quantity $\int_{t_0}^{t_1} F dt = m(v_1 - v_0)$, = the **change in momentum** of the body.

Certain problems in which the velocity of a body at any point in its straight-line path when acted upon by varying forces is required, can be easily solved by the use of a **work diagram.**

In Fig. 67, let a body weighing 100 lb. start from rest at A and be acted upon by a force that varies in accordance with the diagram $AFGBA$. Let the resistance to motion be a constant force $= x$. Find the velocity of the body at point B. The area $AFGBA$ represents the work done upon the body and the area $AEDBA$ ($=$ force $x \times$ distance AB) represents the work that must be done to overcome resistance. The difference of these areas, or $EFGDE$, will represent work done in excess of that required to overcome resistance, and consequently is equal to the increase in kinetic energy. Equating the work represented by the area $EFGDE$ to $\frac{1}{2}wv^2/g$ and solving for v, will give the required velocity at B. If the body did not start from rest this area would represent the change in kinetic energy, and the velocity could be obtained by the formula: Work $= \frac{1}{2}(w/g)(v_1^2 - v_0^2)$, v_1 being the required velocity.

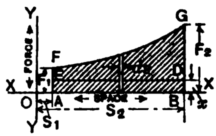

FIG. 67.

General Rule for Rectilinear Motion. Resolve each force acting on the body into components, one of which acts along the line of motion of the body and the other at right angles to the line of motion. Take the sum of all the components acting in the direction of the motion and multiply this sum by the distance moved through for constant forces. (Take the average force times distance for forces that vary.) This product will be the total work done upon the body. If there is no unbalanced component there will be no change in velocity and consequently no change in kinetic energy. If there is an unbalanced component the change in kinetic energy will be this unbalanced component multiplied by the distance moved through.

Conservation of Energy. The sum of the kinetic and potential energies of a body acted on by gravity alone is constant.

If a body is at a certain height h above the ground and is motionless, its potential energy is equal to the work done in raising it to that height. If the body falls to the ground its velocity v when it strikes will be $\sqrt{2gh}$, and its kinetic energy will be $wv^2/2g$. The potential energy before starting to drop is, therefore, the same as its kinetic energy when it reaches the earth. At any point during its fall its total energy, obtained by adding the kinetic and potential energies, will be the same $wv^2/2g$, where v is the velocity that the body would have if it fell freely to the earth from the original height.

The work done by a system of forces acting on a body is equal to the algebraic sum of the work done by each force taken separately.

Power is the rate at which work is performed, or the number of units of work performed in unit time. The unit of power employed by engineers is the **horse power,** or 33,000 ft.-lb. per min. = 550 ft.-lb. per sec.

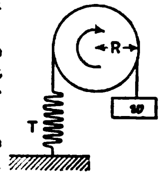

FIG. 68.

Friction Brake. In Fig. 68 a pulley revolves under the band and in direction of the arrow, exerting a pull of T on the spring. The friction of the band on the rim of the pulley is $(T - w)$, where w is the weight attached to one end of the band. Let the pulley make N r.p.m.; then the work done per minute against friction by the rim of the pulley is $2\pi RN(T-w)$, and the horse power absorbed by brake $= 2\pi RN(T-w)/33{,}000$.

Centrifugal Force

Centrifugal and Centripetal Forces. When a body revolves about an axis, some connection must exist capable of applying force enough to the body to constantly deviate it toward the axis. This deviating force is known as **centripetal force.** The equal and opposite resistance offered by the body to the connection is called a **centrifugal force.** The acceleration toward the axis necessary to keep a particle moving in a circle about that axis is v^2/r, therefore the force necessary is $ma = mv^2/r = wv^2/gr$. This force is constantly directed toward the axis.

The centrifugal force of a solid body revolving about an axis is the same as if the whole mass of the body were concentrated at its center of gravity. Centrifugal force $= wv^2/gr = mv^2/r = w\omega^2r/g$, where w and m are the weight and mass of the whole body, r is the distance from the axis about which the body is rotating to the center of gravity of the body, ω the angular velocity of the body about the axis in radians, and v the linear velocity of the center of gravity of the body.

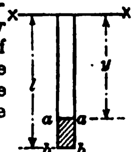

FIG. 69.

Examples (Uniform angular velocity). (1) In Fig. 69 a homogeneous rod of length l revolves about XX at a speed of N r.p.m.; find the pressure on the axis XX due to centrifugal force (C. F.). As the whole body is deviated toward XX, the force necessary must be C. F. $= (w/g)(2\pi N/60)^2(l/2)$ w being the weight deviated, $2\pi N/60$ = the angular velocity and $l/2$ the distance from axis to center of gravity.

(2) Find the tension in the rod at aa, distant y from the axis. The force with which the length y of the rod acts on the length ab is the deviating force necessary to keep $aabba$ constantly accelerated toward the axis. This force $= \frac{w'}{g}\left(\frac{2\pi N}{60}\right)^2\left[y + \frac{(l-y)}{2}\right]$, w' being the weight of $aabba$, and $\left[y + \frac{(l-y)}{2}\right]$ being the distance from XX to the center of gravity of $aabba$.

(3) In Fig. 70 find the pressure on the axis YY and maximum tension due to centrifugal force. Determine the center of gravity of the body; let it be r_0 from the axis YY; then the pressure on the axis will be $(w/g)(2\pi N/60)^2 r_0$. To determine the maximum tension due to centrifugal force, determine which part of the body on one side of the axis has the greater moment about the axis; the maximum tension will be on this side of the axis, and the pressure on the axis will be the difference between the tensions on the two sides.

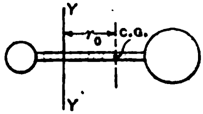

FIG. 70.

The tension in a belt due to centrifugal force is wv^2/g, where w = weight of material per cu. ft., and v = velocity in ft. per sec. It should be noted that the tension **is independent of the diameter of the pulley** upon which the belt runs.

A body revolving about an axis passing through its center of gravity exerts no pressure on the axis due to centrifugal force.

Conical Pendulum. In the simple revolving pendulum shown in Fig. 71 a ball weighing w lb. revolves about YY at a speed of N r.p.m.; find the angle a. The forces acting upon the mass of the ball are the weight w and the tension T in the cord. As the ball stands out at a constant angle, the vertical component of T must equal w, leaving the horizontal component of T unbalanced. This unbalanced component is the deviating force necessary to keep the weight revolving about YY. This deviating force is the centripetal force.

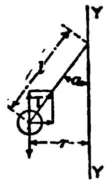

FIG. 71.

$T \sin a =$ C. F. and $T \cos a = w$, but C. F. $= w\omega^2 r/g$; $\therefore T \sin a = w\omega^2 r/g$, $T = w\omega^2 r/g \sin a$, and $\sin a = w\omega^2 r/gT$; $r = l \sin a$, and $\omega = 2\pi N/60$. From these formulæ the tension and angle can be found if N is known, or the tension and number of revolutions per minute can be determined if the angle is known. It should be noted that $\omega^2 l$ must be greater than g.

Balancing

A rotating body is said to be in **standing balance** when its center of gravity coincides with the axis upon which it revolves. Standing balance may be obtained by resting the axis carrying the body upon two horizontal plane surfaces, as in Fig. 72. If the center of gravity of the wheel A coincides with the center of the shaft B, there will be no movement, but if the center of gravity does not coincide with the center of the shaft, the shaft will roll until the center of gravity of the wheel comes directly under the center of the shaft. The center of gravity may be brought to the center of the shaft by adding or taking away weight at proper points on the diameter passing through the center of gravity and the center of the shaft. Weights may be added to or subtracted from any part of the wheel so long as its center of gravity is brought to the center of the shaft.

FIG. 72.

A rotating body may be in standing balance and not in **running balance.** In Fig. 73, AA and BB are two disks whose centers of gravity are at o and p, respectively. The shaft and the disks are in standing balance if the disks are of the same weight and the distances of o and p from the center of the shaft are equal, and o and p lie in the same axial plane but on opposite sides of the shaft. Let the weight of each disk be w and the distances of o and p from the center of the shaft each be equal to r. The force exerted on the shaft by AA is equal to $w\omega^2r/g$, where ω is the angular velocity of shaft. Also, the force exerted on shaft by $BB = w\omega^2r/g$. These two equal and opposite parallel forces act at a distance x apart, and constitute a couple with a moment tending to rotate the shaft, as shown by the arrows, of $(w\omega^2r/g)x$. A couple cannot be balanced by a single force, so two forces at least must be added to or subtracted from the system to get running balance.

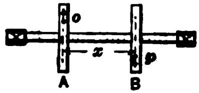

FIG. 73.

For an example of balancing by counterweights, see p. 1207.

Curvilinear Motion

An Unresisted Projectile has a motion compounded of the vertical motion of a falling body, and of the horizontal motion due to the horizontal component of the velocity of projection. In Fig. 74 the only force acting after the projectile starts is gravity, which causes an acceleration downward. The horizontal component of the original velocity v_0 is not changed by gravity. The projectile will rise until the velocity given to it by gravity is equal to the vertical component of the starting velocity v_0 and the equation $v_0 \sin a = gt$, gives the time t required to reach the highest point in the curve. The same time will be taken in falling if the surface XX is level, and the projectile will therefore be in flight $2t$ sec. The distance $s = v_0 \cos a \times 2t$, and the maximum height of ascent $h = (v_0 \sin a)^2/2g$. The expressions for the co-ordinates of any point on the path of the projectile are: $x = (v_0 \cos a)t$, and $y = (v_0 \sin a)t - \frac{1}{2} gt^2$, giving $y = x \tan a - (gx^2/2v_0^2 \cos^2 a)$ as the equation for the curve of the path. The radius of curvature of the highest point may be found by using the general expression C. F. $= wv^2/gr$ and solving for r, v being taken equal to $v_0 \cos a$.

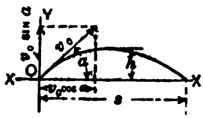

FIG. 74.

Simple Circular Pendulum. The time of a single oscillation in one direction $= t = \pi \sqrt{l/g}$, where l is the length of the pendulum and the length of the swing is not great as compared to l.

Rotation of Solid Bodies About Axes

If a body rotates about an axis under the action of a constant force F, the relations between the angular acceleration a_a, the angular velocity ω, the angle moved through θ, and the kinetic energy of rotation E, are $Fl = a_a I/g$; $\omega = a_a t$, or $= \omega_0 + a_a t$; $\theta = \frac{1}{2} a_a t^2 = \frac{1}{2}\omega t$, or $= \omega_0 t + \frac{1}{2} a_a t^2$; $E = \omega^2 I/2g$; where Fl is the unbalanced turning moment, I is the moment of inertia of the body in weight units, and ω_0 is the initial angular velocity.

General Rule for Rotating Bodies. Determine all the external forces acting and their moments about the axis of rotation. If these moments are balanced, there will be no change of motion. If the moments are unbalanced, this unbalanced moment or **torque** will cause an angular acceleration about the axis.

Rotation About an Axis Passing Through the Center of Gravity. The rotation of a body about its center of gravity can only be caused or changed by a **couple.** See Fig. 75. If a single force F is applied to the rim of the wheel, the axis immediately acts on the wheel with an equal force to prevent translation, and the result is a couple (moment Fr) acting on the body and causing rotation about its center of gravity. **The work done by the couple causing rotation is $M\theta$,** where M is the moment of the couple and θ is the angular space passed over, in radians. If there is no unbalanced moment there must exist either rest or uniform rotation.

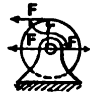

FIG. 75.

In calculations pertaining to **hoisting machinery**, it is sometimes necessary to determine the total weight to be accelerated. This consists of the combined weight of the load to be hoisted, the rope or chain and the cage or skip (if used) *plus* a certain weight w_1 equivalent to that of the hoisting drum if concentrated at a point in its circumference. This latter may be determined as follows: Energy in ft.-lb. of rotating drum $= E = I\omega^2/2 = w\omega^2r^2/2g$, where r = radius of gyration of drum, in ft.; ω = angular velocity, and w = weight in lb. The product wr^2 is sometimes known as the **flywheel effect.** Let R = radius of drum from shaft axis to rope center, in ft. Then, considering the weight concentrated at radius R, for the same quantity of energy, $E = w_1\omega^2R^2/2g$, whence $w_1R^2 = wr^2$, or $w_1 = wr^2/R^2$. For example, in a large electric mine hoist, w = 16,000 lb., r = 6.4 ft. and R = 8 ft. $\therefore$ equivalent weight at $R = w_1 = (16{,}000 \times 6.4 \times 6.4)/(8 \times 8) = 10{,}240$ lb.

Center of Percussion

Combined Rotation and Translation. Any body that is revolving about an axis not passing through its center of gravity may be considered to have a motion of translation and a motion of rotation about its center of gravity combined. The body shown in Fig. 76 is revolving about C with an angular velocity ω, but this motion may be considered to be made up of a translation with the velocity ωl of the center of gravity of the body about C and a revolution about the center of gravity with the same angular velocity (ω) as that with which the body rotates about C.

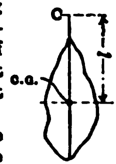

FIG. 76.

The kinetic energy of the body is $\omega^2 I/2g$, in which I is the moment of inertia of the body with respect to C. This is the same as $\frac{1}{2}wv^2/g + \omega^2 I_0/2g$, where $v = \omega l$ and I_0 = moment of inertia of the body with respect to an axis passing through its center of gravity and parallel to the axis at C. The motion of translation requires a single force applied at the center of gravity of the body, and the motion of rotation about the center of gravity requires the action of a couple, therefore the combined motion must be caused by the resultant of a single force and a couple.

The point of application of this resultant is known as the **center of percussion,** and may be **defined** as the point of application of all of the forces tending to cause a body to rotate about a certain axis. It is the point at which a suspended body may be struck without causing any pressure on the axis passing through the point of suspension.

Center of Percussion. The distance from the axis of suspension to the center of percussion is $l = I/wx_0$, where I = moment of inertia of the body about its axis of suspension, w = total weight of the body and x_0 = distance from the axis of suspension to the center of gravity of the body.

Examples. (1) Find the center of percussion of the homogeneous rod (Fig. 77) of length L and weight w, suspended at XX.

$$l = \frac{I}{wx_0}; \quad I(\text{approx.}) = \frac{w}{L}\int_0^L x^2dx; \quad x_0 = \frac{L}{2}; \quad \therefore l = 2\int_0^L x^2dx = 2L/3.$$

(2) Find the center of percussion of a solid cylinder, of weight w, resting on a horizontal plane. In Fig. 78, the instantaneous center of the cylinder is at A. The center of percussion will therefore be at a height above the plane equal to $l = I/wx_0$. Since $I = (wr^2/2) + wr^2$ and $x_0 = r$, $l = 3r/2$.

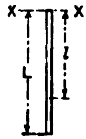

FIG. 77.

(3) In Fig. 79, a solid cylinder weighing 100 lb. is moved along a horizontal plane by a horizontal force of 12 lb. applied at the axis. If the cylinder rolls without slipping, how far may it be moved in 10 sec. and what must be the friction?

The forces acting are F, gravity, and the reaction of the plane. The vertical component of the reaction of the plane balances gravity, leaving the horizontal component of the reaction of plane and F as the forces causing rotation about the instantaneous center O. The resultant R of the 12-lb. force and the friction must be applied at the center of percussion, which is at the distance I/wx_0 from O or 3 ft. The resultant can be found by taking moments about O. $3R = 2 \times 12$; $\therefore R = 8$ lb. The friction must be $12 - 8 = 4$ lb. acting to the left, because 8 lb. is the resultant of $F = 12$ lb. and the friction. This resultant of 8 lb. at a distance of 3 ft. from O has the same effect as the two forces of 12 lb. and 4 lb. acting together. This single force of 8 lb. must be also the resultant of a couple and a single force at the axis, see Fig. 79(b). The single force of 8 lb. acting to the right at the axis causes translation, and the couple whose moment is 8×1 causes rotation about the center of gravity. The linear acceleration along the plane is found by using the 8-lb. force. $F = ma$ $\therefore 8 = 100a/g$, $a = 8g/100$, and $v = (8g/100) \times 10 = (4g/5)$ ft. per sec. $S = ½ (80g/100)$.

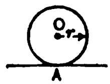

FIG. 78.

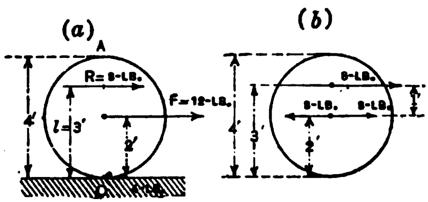

FIG. 79.

Wheel or Cylinder Rolling Down a Plane. In this case the component of the weight along the plane tends to make it roll down, and is treated as a force causing rotation. The forces acting on the body should be resolved into components along the line of motion and perpendicular to it. If the forces are all known, their resultant is at the center of percussion. If one force is to be determined (the exact conditions as regards slipping or not slipping must be known), the center of percussion can be determined and the unknown force found.

When weights act as shown in Fig. 80, where the pulley over which the ropes run has appreciable weight, it is necessary to take into account the moment of the force required to accelerate the pulley itself.

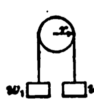

FIG. 80.

In Fig. 80, the unbalanced force $w_1 - w_2$ is accelerating the pulley as well as the two weights. Therefore, $w_1 - w_2 = (w_1 + w_2)a/g + a_aI/gr$, where $(w_1 + w_2)a/g$ is the unbalanced force necessary to give the two weights the acceleration a, and a_aI/g is the unbalanced moment necessary to give the pulley the angular acceleration a_a.

Relation Between the Center of Percussion and Radius of Gyration. $l = I/wx_0 = r^2/x_0 \therefore r^2 = x_0 l$, where r = radius of gyration. Therefore the radius of gyration is a mean proportional between the distance from the axis of oscillation to the center of percussion and the distance from the same axis to the center of gravity.

Interchangeability of Center of Percussion and Axis of Oscillation. If a body is suspended from an axis, the center of percussion for that axis can be found. If the body be suspended from this center of percussion as an axis, the original axis of suspension will then become the center of percussion. The center of percussion is sometimes known as the **center of oscillation.**

Time of Oscillation of a Compound Pendulum. The length of an equivalent simple pendulum is the distance from the axis of suspension to the center of percussion of the body in question. To find the **time of oscillation** of a body about a given axis, find the distance $l = I/wx_0$ from that axis to the center of percussion of the swinging body. The length of the simple pendulum that will oscillate in the same time is this distance l. The time of oscillation for the equivalent simple pendulum is $t = \pi\sqrt{l/g}$. This is the time necessary for a single swing, not over and back.

Determination of Moment of Inertia by Experiment. To find the moment of inertia of a body, suspend it from some axis not passing through the center of gravity and, by swinging it, determine the time of a single oscillation in seconds. The known values will then be t = time of single oscillation, x_0 = distance from axis to center of gravity, and w = weight of rod. The length of the equivalent simple pendulum is $l = I/wx_0$. Substituting this value of l in $t = \pi\sqrt{l/g}$ gives $t = \pi\sqrt{I/wx_0g}$, from which $t^2 = \pi^2 I/wx_0g$, or $I = wx_0gt^2/\pi^2$.

Impulse and Momentum

Impulse of a force $= F(t_2 - t_1)$ when the force is constant and $t_2 - t_1$ is the time interval during which it acts. If the force is not constant in magnitude but always acts in the same direction, impulse $= \int_{t_1}^{t_2} F dt$.

Impulses may be added algebraically by means of a polygon, or an impulse may be resolved into components by means of a parallelogram. The moment of an impulse may be found in the same manner as the moment of a force by representing the impulse by a line and taking the product of the magnitude of the impulse by the perpendicular distance from the line representing it to the point about which the moment is to be taken.

Momentum. The momentum of a particle is mv, where m = mass of the particle and v = its velocity. Momentums can be represented by lines (vectors) and added and resolved in the same manner as forces by means of polygon and parallelogram. The moment of momentum can be determined by the same methods as used for the moment of a force or moment of an impulse, the momentum being represented by a line. **Angular momentum** is the product of the component of momentum at right angles to the radius, and the radius.

Impact

The straight line perpendicular to the common contact plane of two colliding bodies and passing through the point of contact, is called the **line of impact.** If the centers of gravity of the bodies lie on this line, the impact is called **central impact**; in any other case, **eccentric impact.** If the directions of the motions of the two bodies coincide with the line of impact, the impact is said to be **direct**; in any other case, **oblique.**

Direct Central Impact. When two masses m_1 and m_2 having velocities u_1 and u_2 and moving in the same line meet each other, the relation between the velocities u_1 and u_2 before and v_1 and v_2 after collision is expressed by the equation: $m_1v_1 + m_2v_2 = m_1u_1 + m_2u_2$. If $v' =$ velocity of m_1, $v'' =$ velocity of m_2 at any time during impact, and $v =$ common velocity at instant of greatest compression, $m_1v_1 + m_2v_2 = m_1u_1 + m_2u_2 = m_1v' + m_2v''$, and $v = (m_1u_1 + m_2u_2)/(m_1 + m_2)$. **The sum of the momentums of the two masses before, after and during impact is the same.**

A second relation between the velocities is $e = (v_2 - v_1)/(u_1 - u_2)$, e being called the **coefficient of impact**, or the **coefficient of restitution.** Its value depends on the elastic or plastic properties of the bodies which come in collision, being 0 for inelastic bodies (nearly 0 for soft substances such as putty or lead) and 1 for perfectly elastic bodies.

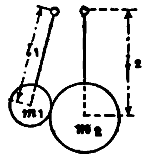

FIG. 81.

To determine the coefficient of restitution between two materials, let m_2 be so large in comparison to m_1 that it may be considered as infinite, *e.g.*, a foundation weighing many tons and a ball weighing a few ounces. Let m_2 be stationary, making u_2 and $v_2 = 0$; the formula $e = (v_2 - v_1)/(u_1 - u_2)$ will then reduce to $e = -v_1/u_1$. Drop the ball from the height H upon m_2 and note the rebound h. Then $u_1 = \sqrt{2gH}$ downward and $v_1 = \sqrt{2gh}$ upward, and $e = -v_1/u_1 = \sqrt{h/H}$. For central impact when the bodies are swinging (see Fig. 81), $v_1 + eu_1 = v_2 + eu_2$, and also if I_1 and $I_2 =$ moments of inertia of m_1 and m_2, $(I_1v_1/gl_1^2) + (I_2v_2/gl_2^2) = (I_1u_1/gl_1^2) + (I_2u_2/gl_2^2)$.

Impact of Perfectly Inelastic Bodies. The two masses move after the impact with a common velocity $u = u_1 = u_2 = (m_1v_1 + m_2v_2)/(m_1 + m_2)$, and the **loss of kinetic energy due to impact** $= E = \frac{1}{2}m_1m_2(v_1 - v_2)^2/(m_1 + m_2)$.

If $v_2 = 0$, $u = m_1v_1/(m_1 + m_2)$ and the loss of energy $= \frac{1}{2}m_1m_2v_1^2/(m_1 + m_2)$.

Perfectly Elastic Impact. In this case, the loss of energy $E = 0$. The velocities after impact become: $u_1 = v_1 - [2m_2(v_1 - v_2)/(m_1 + m_2)]$, and $u_2 = v_2 + [2m_1(v_1 - v_2)/(m_1 + m_2)]$. For $v_2 = 0$, $u_1 = (m_1 - m_2)v_1/(m_1 + m_2)$, and $u_2 = 2m_1v_1/(m_1 + m_2)$; there is no loss of energy and the body m_1 retraces its path.

Imperfectly Elastic Impact. If the coefficient of impact is e, $u_1 = v_1 - [m_2(1 + e)(v_1 - v_2)/(m_1 + m_2)]$; $u_2 = v_2 + [m_1(1 + e)(v_1 - v_2)/(m_1 + m_2)]$. Loss of energy $= m_1m_2(1 - e^2)(v_1 - v_2)^2/2(m_1 + m_2)$.

When a jet of water strikes a flat plate perpendicularly to its surface the force exerted by the water on the plate is wv/g, where w is the weight of water striking the plate in a unit of time and v is the velocity. When the jet is inclined to the surface by an angle A, the pressure is $(wv/g) \cos A$.

Fields of Force—Attraction

The space within which the action of a physical force comes into play on bodies lying within its boundaries is called the **field of the force.**

The **strength** or **intensity of the field** at any given point is the relation between a force F acting on a mass m at that point and the mass. Intensity of field $= i = F/m$; $F = mi$.

The **unit of field intensity** is the same as the unit of acceleration, *i.e.*, 1 ft. per sec. per sec., or 1 m. per sec. per sec. The intensity of a field of force may be represented by a line (or **vector**).

A field of force is said to be **homogeneous** when the intensity at all points is uniform and in the same direction.

A field of force is called a **central field of force** with a center O, if the direction of the force acting on the mass particle m in every point of the field passes through O and its magnitude is a function only of the distance r from O to m. A line so drawn through the field of force that its direction coincides at every point with that of the force prevailing at that point, is called a **line of force.**

Law of Gravitation. Two particles attract each other with a force F proportional to their masses m_1 and m_2 and inversely proportional to the square of the distance r between them, or $F = km_1m_2/r^2$, in which k is the **gravitation constant,** or the force with which two spheres of unit mass attract each other through unit distance. If pounds, feet and seconds are used, $k = 3.31 \times 10^{-11}$; if grams, centimeters and seconds, $k = 6.66 \times 10^{-8}$. The **density of a body** is its mass per unit of volume. Density $= d =$ mass/volume.

EXAMPLES IN ATTRACTION

1. Attraction at any point, O Fig. 82, **due to the thin rod** mn $= F = \dfrac{2kda}{x} \sin \dfrac{A + B}{2}$, where d = density of body, and a = cross-sectional area of the rod. The angle which this force makes with axis $XX = (A - B)/2$.

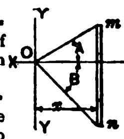

FIG. 82.

2. Attraction due to a **thin circular ring** at a point O on its axis $=$ $F = km \cos A/(r^2 + b^2)$, where b = distance from point to center of ring, r = radius of ring, and A = angle made by a line drawn from circumference of ring to its axis at point O with the axis.

3. Attraction due to a **thin circular plate** at a point O on its axis $=$ $F = 2\pi k(m/A)\ (1 - \cos B)$, where A = area of plate and B = angle made with the axis by a line drawn from circumference of the plate to the axis at point O.

4. Attraction at a point due to a **spherical shell.** If the point is outside of shell, $F = km/b^2$, where m = mass of shell and b = distance from center of shell to the point. If the point is inside of shell, $F = 0$.

5. Attraction at a point due to a **solid sphere.** If point is outside the sphere, $F = km/b^2$, where m = mass of sphere and b = distance from center of sphere to the point. If point is inside of sphere, $F = km'/b^2$, where m' = mass of that part of the sphere that is nearer to the center than the point.

THE GYROSCOPE

By E. V. HUNTINGTON

The elementary facts about gyroscopic forces may be briefly illustrated by the following example. Given, a wheel or disk, of weight w and radius R, spinning rapidly about its axis OA (Fig. 1), and mounted in gimbal rings in such a way that its center is stationary, while its axis is free to point in any direction in space. (See Fig. 2.) Let k = the radius of gyration of the wheel about its axis. (If all the weight is in the rim, $k^2 = R^2$; if the wheel is a homogeneous disk, $k^2 = R^2/2$.) Now suppose the axle end A is constrained to move between two smooth fixed guides, forming a slot as in Fig. 1, and suppose that a force Q is applied to pull the point A along the slot. Then, (1) as far as the motion of A along the slot is concerned, it makes no difference whether the disk is rotating or not; in fact, $Qb = (w/g)(k^2/2)(dv/bdt)$, where Qb is the moment of Q about the center O, and dv/dt is the (linear) acceleration of the point A along the slot; but (2) if the wheel is rotating, then the mere motion of A along the slot will call into play a strong lateral pressure P (called a gyroscopic reaction) against one of the guides.

Which one of the two guides the force P will act against depends on the direction of spin, and is best determined by the following rule (E. V. Huntington, *Eng. News*, July 21, 1910): If the applied force Q is thought of as due to the pressure of a flat board against the side of the revolving axle (the board being perpendicular to Q as shown in dotted line in Fig. 1), then the axle will strive to move in the direction in which it would naturally roll if the board were rough. Thus, in Fig. 1, the axle-end A will push against the *upper* guide, and would actually move in the direction of the P-arrow if the guide were not present.

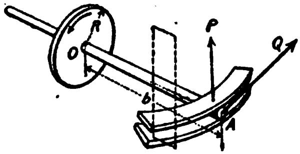

FIG. 1.

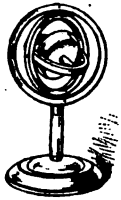

FIG. 2.

The magnitude of the gyroscopic force P at any instant is proportional to the spinning velocity, and also to the velocity of A along the slot, being given by

$$Pb = (w/g)k^2(\pi N/30)(v/b),$$

where Pb = the moment of P about the center, v = the linear velocity of the point A along the slot at the instant in question, N = r.p.m. in the spinning velocity of the wheel, and g = 32.17 ft. per sec. per sec.

It should be noted that the gyroscopic reaction P against the fixed guide does not depend on the magnitude of the accelerating force Q, except in so far as Q is necessary to create the velocity v, in case A starts from rest; when once the velocity v has been established, Q can be made zero, and both v and P will (neglecting friction) continue constant. On the other hand, if the guide is movable, and exerts a pressure $P' = P$ against the axle at A, this force will itself maintain the velocity v (called the precessional velocity) of the point A along the guide. In brief, *the end of the axle of a rotating gyroscope always tends to move at right angles to any force impressed upon it.*

For example, suppose an aeroplane is driven by a right-handed propeller (turning like a right-handed screw when moving forward); if a gust of wind or other force turns the machine to the *left*, the gyroscopic action of the propeller will make the forward end of the shaft strive to *rise;* if the wing surface is large, this motion will be practically prevented by the resistance of the air, and the gyroscopic forces become effective merely as internal stresses, whose maximum value can be computed by the formula above. Similarly, if the aeroplane is dipped *downward*, the gyroscopic action will make the forward end of the shaft strive to turn to the *left*.

In the Brennan monorail car, the slot is parallel to the rail, so that a force Q, applied automatically at the axle end when the car starts to tip, will be converted gyroscopically into a strong righting moment Pb, which forces the car back into a position of lateral equilibrium. Numerical case: If $w = 3200$ lb., $k = 1.4$ ft., $b = 2$ ft., and spinning velocity $= 3000$ r.p.m., then a force Q of 50 lb. acting for ½ sec. will produce at the end of that time a precessional velocity of 1 ft. per sec. along the slot, with a resulting lateral force against the guide of nearly 16,000 lb. The displacement of the point A along the slot will be about 6 deg. An essential feature of the apparatus is a device for bringing the axle back into the ready position after each period of activity.

Other applications are the Whitehead torpedo, the Schlick ship-steadying device, the Griffin grinding mill, the Anschütz gyro-compass, the Sperry gyro-compass, and the Sperry stabiliser for aeroplanes. For the mathematical theory of the gyroscope, see H. Crabtree, "Spinning Tops and Gyroscopic Motion" (Longmans).

STRESSES IN FRAMED STRUCTURES

BY

HARRISON W. HAYWARD

Framed structures may be divided into **two classes**: (*a*) Structures that are **statically determinate** and (*b*) structures that are **statically indeterminate**. The stresses in the members of structures of the first class may be determined by the methods of statics (see p. 195), but structures of the second class require the use of flexure formulæ.

In what follows, structures of the first class only will be considered. The structures will be assumed to be made up of rigid members pinned together at their ends. The forces acting externally to the structure will be assumed as acting in the same plane and at the pin joints only. If these assumptions are made, the stresses in all the members will be either direct tension or compression. The design of the compression members to resist column stresses will be neglected and the weights of the members will be assumed as acting at the joints. Where distributed loads are to be considered, the bending stresses will be neglected and the loads considered to be concentrated at the joints. After the direct stresses are determined, the bending stresses may be found by reference to the theory of beams, pp. 397 to 420.

Two general methods are useful for the determination of the stresses in statically determinate structures: the **method of sections** and the **method of joints**. Most statically determinate structures can be solved by either method, although in some cases the method of joints will fail. That method should be used which will be most convenient for the particular problem at hand, and in many cases both methods may be advantageously used in the same problem.

General Procedure. First determine all the external or outer forces and then determine the inner forces by the most convenient method.

In the simple crane, Fig. 1(*a*), let it be required to determine the stresses in the members AB and AC due to the weight W at A. Let F_1 and F_2 represent the stresses in AB and AC, respectively. The forces acting at point A are F_1, F_2 and W. These forces act at a common point and are all in the same plane; there are two unknown forces of which the line of action is known (see p. 196), therefore the case is statically determinate. Apply the condition of equilibrium (see p. 198) that the algebraic sum of the horizontal and vertical components of the forces acting at a point must equal zero when the forces form an equilibrium system, and obtain:

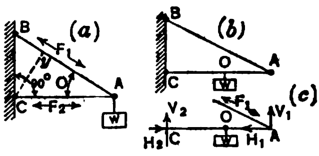

FIG. 1.

$[(F_1 \times BC)/AB] - W = 0$, or $F_1 - [(W \times AB)/(BC] = 0$, from which F_1 (tension) $= W \times AB/BC$; $F_2 - [(W \times AB)/(BC)]\,(AC/AB) = 0$, or $F_2 - [(W \times AC)/BC] = 0$, from which F_2(compression) $= W \times AC/BC$. The same results may be obtained by drawing a polygon of forces for the forces acting at point A (see p. 200).

The method of moments may be used as follows: The algebraic sum of the moments of the forces acting at A taken about any point in their plane must be zero.

$\therefore F_1 \times Cy = W \times AC$, from which $F_1 = (W \times AC)/Cy = (W \times AB)/BC$;
$F_2 \times Bc = W \times AC$, from which $F_2 = (W \times AC)/Bc$.

It should be noted that if a framed structure is to be of any value, the forces acting externally to any part of it must form a system in equilibrium. If the weight W is attached somewhere between A and C, as in Fig. 1(b), the stresses in the members AB and AC cannot both be determined by statics. The stress in AB can be determined and the forces acting on AC can be found. Consider the member AC, Fig. 1(c). This member must be in equilibrium under the action of the forces acting externally to it. Taking moments at C, $W \times CO = V_1 \times AC$, or $V_1 = (W \times CO)/AC$. The line of action of the stress in BA is along AB, therefore when V_1 is determined, H_1 must equal $(V_1 \times AC)/BC$ and $F_1 = (V_1 \times AB)/BC$. $V_2 = W - V_1$ and $H_2 = H_1$. This will allow the stress in AC to be determined by flexure formulæ.

Crane with Single Guy Rope. In Fig. 2, let the stresses in AC, AB and EP be respectively F_1, F_2 and F_3. First determine the stresses F_1 and F_2 by considering the forces acting at point A and applying the conditions for equilibrium for forces in the same plane and acting at the same point. F_1 is compression and F_2 is tension. To determine F_3, consider the forces acting upon the member DE of the structure. Assume a moment axis at point D and apply the condition of equilibrium that the algebraic sum of the moments of forces in the same plane about any point in this plane must be zero; then $(F_2 \times OD) - (F_1 \times TD) = F_3 \times yD$, whence $F_3 = [(F_2 \times OD) - (F_1 \times TD)/yD$, and is tension. The stresses in the member ED cannot be determined by statics, as there are bending stresses.

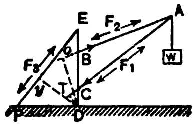

FIG. 2.

Triangular Frame. In Fig. 3, let a single concentrated vertical load W be applied at A. Assume a moment axis at C. Then $(W \times Cd) - (S_2 \times CB) = 0$, or $S_2 = (W \times Cd)/CB$, and $S_1 = W - S_2$. Or, taking a moment axis at B, $(W \times Bd) - (S_1 \times CB) = 0$, and $S_1 = (W \times Bd)/CB$. To determine F_1 and F_3, consider the forces acting at point C and apply conditions for equilibrium for forces in same plane and at the same point. Then $F_1 = (S_1 \times AC)/Ad$ and $F_3 = (F_1 \times Cd)/AC$; also, using point B, $F_2 = (S_2 \times AB)/Ad$ and $F_3 = (F_2 \times Bd)/AB$. If $Cd = Bd$, $F_1 = F_2$ and $S_1 = S_2$. Stresses F_1 and F_2 are compression. Stress F_3 is tension.

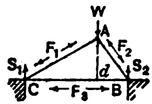

FIG. 3.

Symmetrical King-post Truss. In Fig. 4, the load W is uniformly distributed along CD; one-half of the load therefore may be considered as acting at B. Consider the forces acting at B: stress in AB will be $W/2$, tension in Fig. 4(a) and compression in Fig. 4(b). The stress in AC will equal that in AD and will equal $(W/4) \times AC/AB$, being compression in Fig. 4(a) and tension in Fig. 4(b). The direct stresses in CB and BD can be found by considering the forces acting at points C or D and imposing the condition of equilibrium for forces in same plane and at the same point. These stresses will be the stress in AC or AD multiplied by (BC/AC). (See also p. 1281.)

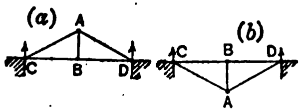

FIG. 4.

Shear Legs and Guy. In Fig. 5, assume that the two legs AD and AC are replaced by a single member Ag which will be in the same plane as AW and AB. The stress in the guy AB will be the same as if the

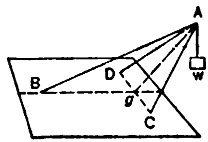

FIG. 5.

two legs were acting and may be determined by considering point A and imposing the condition of equilibrium for the forces W, gA and BA. This will give the stress in the guy AB, and the stress that would be in Ag, if it existed. The two legs AD and AC must support the stress found in Ag, supposing that this member existed alone. Resolve this stress along AD and AC and find the stresses in these members. AD, AC, and Ag are all in the same plane.

Analytical Solution of Trusses

Howe Truss. In Fig. 6, assume the truss to be loaded at the lower panel points as shown, these loads including the weight of the truss. A moment axis at point A will allow the determination of supporting force S_2:

$$S_2 = [(P_1 \times AB) + (P_2 \times AC) + (P_3 \times AD) + (P_4 \times AE) + (P_5 \times AF)]/AG;$$
$$S_1 = P_1 + P_2 + P_3 + P_4 + P_5 - S_2.$$

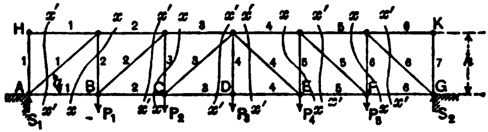

Fig. 6.

Each of the concentrated loads may be divided into parts proportional to the distances from the points A and G to the point of application of the load, and the support for each load found. The total support for all the loads may be obtained from the sums of the partial supporting forces.

Stresses in the Verticals. Pass planes xx through the truss and use method of shears.

In vertical No. 2, stress $= S_1$ (tension)
In vertical No. 3, stress $= S_1 - P_1$ (tension)
In vertical No. 5, stress $= S_2 - P_5$ (tension)
In vertical No. 6, stress $= S_2$ (tension)
In vertical No. 1, stress $= 0$, using joint H
In vertical No. 7, stress $= 0$, using joint K
In vertical No. 4, stress $= P_3$, using joint D, (tension)

Stresses in the Diagonals. Pass planes $x'x'$ through the truss and use method of shears.

In diagonal No.	1	2	3	4	5	6
Vertical component of stress =	S_1,	$S_1 - P_1$,	$S_1 - P_1 - P_2$,	$S_2 - P_5 - P_4$,	$S_2 - P_5$,	S_2

If these vertical components are divided by sin a the stresses in the diagonals can be determined. The stresses will be compression in this case.

Stresses in Upper Chord Members. Pass planes $x'x'$ through the truss and use method of moments.

In upper chord member No. 1, stress $= 0$
In upper chord member No. 2, stress $= (S_1 \times AB)/h$ (compression)
In upper chord member No. 3, stress $= [(S_1 \times AC) - (P_1 \times BC)]/h$ (compression)
In upper chord member No. 4, stress $= [(S_2 \times EG) - (P_5 \times FG)]/h$ (compression)
In upper chord member No. 5, stress $= (S_2 \times FG)/h$ (compression)
In upper chord member No. 6, stress $= 0$

The stresses are all compressions.

Stresses in Lower Chord Members. Use section plane xx. The stresses in the lower chord members Nos. 1, 2, 5 and 6 are equals to the stresses in the upper chord members Nos. 2, 3, 4 and 5, respectively. Stresses in lower chord members 3 and 4 are equal, as can be shown from consideration of joint $D(\Sigma H = 0)$.

To determine the stress in lower chord member No. 3, use section plane $x'x'$ and a moment axis at upper middle panel point.

Stress in No. 3 $= [(S_1 \times AD) - (P_1 \times BD) - (P_2 \times CD)]/h$ (tension).

Whether members are in tension or compression can be determined by methods shown on p. 230.

Warren Truss. In Fig. 7, first determine the two supporting forces S_1 and S_2. Then the stresses in members 1 and 2, and 10 and 11 may be determined by the method of joints, using joint O for 1 and 2 and joint N for 10 and 11. Imposing the conditions of equilibrium for forces in the same plane and acting at the same point,

Stress in member No. 1 $= S_1/\sin a$ (compression)

Stress in member No. 10 $= S_2/\sin a$ (compression)

Stress in member No. 2 = stress in member No. 1 $\times \cos a = S_1 \cot a$ (tension)

Stress in member No. 11 = stress in member No. 10 $\times \cos a = S_2 \cot a$ (tension)

The stresses in the upper chord members 4 and 8 may be determined by passing section planes XX through the truss and taking moments about the joints in the lower chord.

Stress in member No. 4 $= (S_1 \times p)/h$ (compression)

Stress in member No. 8 $= (S_2 \times p)/h$ (compression)

The stresses in member No. 6 may be determined by passing section plane XX through the truss and taking moments about joint C.

Stress in member No. 6 $= [(S_1 \times \frac{3}{2} p) - (P_1 \times p/2)]/h$

$= (S_2 \times \frac{3}{2} p) - (P_2 \times p/2)]/h$, and is tension.

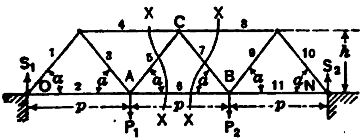

FIG. 7.

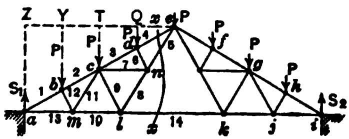

FIG. 8.

Roof Truss. A method of determining the stresses in the members of a roof truss is shown in Fig. 8. After solving for the supporting forces S_1 and S_2, which will be the same and equal to $7P/2$, a stress polygon may be constructed for the forces acting at joint a, which will determine the stresses 1 and 13. A polygon may then be constructed for the forces acting at joint b, which will determine stresses 2 and 12. A polygon for joint m will allow the determination of stresses 10 and 11. The other side of the truss may be treated in the same manner. It is then impossible to go on with the graphical solution, using the method of joints, as more than two unknown forces act at all the other joints. The stress 14 in member lk may be determined by passing the section plane xx through the truss and using the method of sections (see p. 226).

This stress 14 $= [(S_1 \times eZ) - (P \times eY) - (P \times eT) - (P \times eQ)]/S$ (tension). Knowing this stress, a polygon may be constructed for joint e and the solution of the truss completed by the method of joints. A complete analytical solution may be carried out for the joints, using moments or resolution of forces.

Determination of the Diagonal for Tension or Compression. Let the truss in Fig. 9 be loaded with the vertical loads P_1, P_2 and P_3, as shown.

The supporting forces S_1 and S_2 can be determined by taking moments at point a or e for the forces acting externally to the whole truss:

$$S_2 = [(P_1 \times ab) + (P_2 \times ac) + (P_3 \times ad)]/ae;$$
$$S_1 = [(P_3 \times ed) + (P_2 \times ec) + (P_1 \times eb)]/ae.$$

In order that the truss shall be stable, diagonals must be placed in the panels A and B.

Assume that the diagonals are to be tension members. Pass plane XX through the truss and consider the forces acting on the part of the truss to the left of the section. These forces are the load P_1, supporting force S_1, and the stresses in bc, in hg, and in the diagonal that is used.

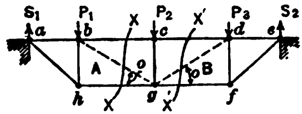

FIG. 9.

Use the method of shears; then the resultant of S_1 and P_1 must be balanced by the vertical component of the stress in the diagonal, bc and hg having no vertical components. The resultant of S_1 and P_1 acts upward, therefore the vertical component of the diagonal must act downward, showing that bg is the required diagonal.

To determine the diagonal for panel B, pass the plane $X'X'$ through the truss and consider the forces acting on the part of the truss to the right. Then the vertical component of the stress in the diagonal must act downward and be equal to $S_2 - P_3$, showing the diagonal gd to be in tension. The stresses in the diagonals may be determined by dividing the vertical components by the sine of the angle o. If compression members are required, use diagonals hc and cf.

When the upper chords are not horizontal and parallel to the lower chord, use the method shown in Fig. 10. The truss in Fig. 10 is symmetrically loaded at the upper panel points. To determine the diagonals for panels A and B, pass plane XX through the truss and consider the forces acting on the portion of the truss to the left of it. Take a moment axis at joint a; then the moment of the stress in the diagonal that is used must be equal and opposite in sense to the moment of P_1. The moment P_1 is $P_1 \times ah$ and is right-handed; therefore, the moment of the stress in the diagonal about a must be left-handed. If the diagonal is to be in compression, use bg; if in tension, use ch. In the same manner, using section plane $X'X'$ and joint e, the diagonal in panel B can be determined. gd will be the compression diagonal and cf the tension member.

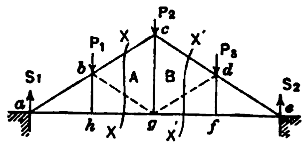

FIG. 10.

Counterbracing. When a truss is to withstand moving loads, it is often necessary to use two diagonals in one panel, or else so design a diagonal as to be able to withstand both tension and compression. In wooden structures the diagonals are designed to resist compression, and in steel structures to withstand tension or compression.

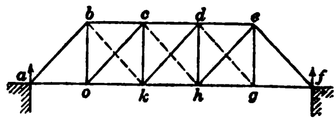

FIG. 11.

In the truss shown in Fig. 11, when the load P is at o, the diagonals oc, kd and he will be in tension; if the load moves to k, the tension diagonals become bk, kd and he; with the load at g, the tension diagonals are bk, ch and dg. As the load P moves from o to g, the stresses in any one set of diagonals

will change from tension to compression, or *vice versa.* In such cases two diagonals must be placed in each panel where the reversal of stress occurs.

Consider the stresses in the members of the truss shown in Fig. 12. This truss is supported on rollers at *a* and fixed at *h*. Vertical loads, as shown, are applied at the points *b, c, e, f* and *g*. A horizontal force of 5000 lb. may be applied at *b*, and act to the right, or at *g* and act to the left. This 5000 lb. may be considered to be wind pressure acting now on one side and now on the other.

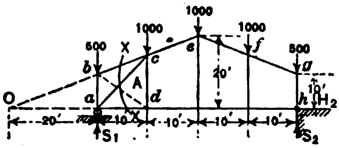

FIG. 12.

First assume the horizontal force to act at point *b*. Then, by taking moments at point *a* for all the forces acting on the truss, $S_2 = (50{,}000 + 10{,}000 + 20{,}000 + 30{,}000 + 20{,}000)/40 = 3250$ upward, and $S_1 = 4000 - 3250 = 750$ upward. H_2 must equal 5000 and act to the left.

Pass plane *XX* through the truss and consider the forces acting upon the part of the truss to the *left* of this section. Take a moment axis at point *O*. Then the moment of the stress in the unknown diagonal must be equal and opposite to the resultant of the moments of all the other forces acting; therefore, the moment of this diagonal must be $50{,}000 + 10{,}000 - 15{,}000 = 45{,}000$ and must be left-handed. *ac* will be the tension diagonal and *bd* the compression diagonal.

Now, assume that the 5000-lb. horizontal force acts at point *g* and to the left. Then $S_2 = (10{,}000 + 20{,}000 + 30{,}000 + 20{,}000 - 50{,}000)/40 = 750$ upward, and $S_1 = 4000 - 750 = 3250$ upward. Pass plane *XX* through the truss and take the forces acting on the part to the left. Take moments about point *O* as before. Then the moment of the unknown diagonal must be $(3250 - 500) \times 20$ and must be right-handed. *bd* will be the tension diagonal and *ac* the compression diagonal. The other panels may be treated in the same manner. This shows that **counterbracing** is sometimes **needed to resist wind pressure** from different sides.

Graphical Solution of Trusses

When the external forces acting upon a truss are all in the same plane and may be assumed to act at the joints of the structure, it is often convenient to make use of graphical constructions to determine the stresses in the members. A series of stress polygons may be constructed for the forces acting at the different joints, using the methods shown on p. 204, but a combination diagram, using what is known as "Bow's Notation," greatly simplifies the work.

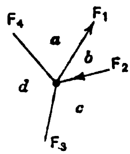

FIG. 13.

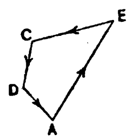

FIG. 14.

The forces F_1, F_2, F_3 and F_4 (Fig. 13) are all in the same plane and form a system in equilibrium. Their lines of action all pass through the same point (*o*). Letters are so placed as to bring each force between two letters, these letters being usually read in a right-handed or clockwise direction around the joint. F_1, F_2, F_3 and F_4 will then be designated *ab*, *bc*, *cd*, and *da*, respectively. A stress polygon (Fig. 14) is then drawn for the forces. Assume that the magnitudes, lines of action and directions of F_1 and F_2 are known and that the lines of action only of F_3 and F_4 are known. The forces must be taken in order and the letters must be so placed that when the forces are read right-handed about the point *o* (Fig. 13) the sequence of the letters (in Fig. 14) will indicate the direction in which the forces act upon point *o*. The manner of using Bow's notation is illustrated by the following problem.

Bow's Notation Applied to a Truss. The truss shown in Fig. 15 is loaded with a uniformly distributed dead load which may be considered to be concentrated at the joints as shown. First plot the polygon of external forces *ABCDEFGA* (Fig. 16). As the forces all act vertically, the sides of the polygon fall in the straight line *AF*. The supporting forces *GA* and *FG* are equal in this case, each being one-half the total load, so that no special construction for their determination is necessary. Start at any joint in the truss where there are not more than two unknown forces, *e.g.*, at the left end of the truss. The stress polygon for this joint is *ABHGA*. Reading the letters in a right-handed direction about the joint, the stress in the upper chord member is *BH*. This sequence of letters in the stress polygon indicates that this member acts downward and to the left on the joint, and therefore is in compression. The stress in the lower chord member is *HG*, and this sequence of letters indicates that this member acts to the right on the joint and therefore is in tension.

At the joint in the middle of the upper chord there are now two unknown stresses. Draw the stress polygon *HBCKH* for the second joint. The stress *HB* is of the same magnitude as for the lower joint but acts in the opposite direction. The stress in the member *kh* is *KH* and is therefore compression.

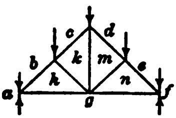

FIG. 15.

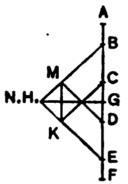

FIG. 16.

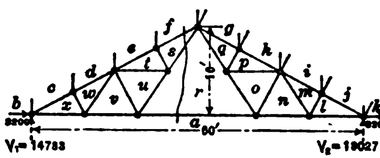

FIG. 17.

Problem. The truss shown in Fig. 17 is loaded with a dead load of 21,760 lb. uniformly distributed over the upper chord, together with a wind load of 13,600 lb. on the right side. Both ends of the truss are fixed and the horizontal components of the supporting forces are assumed to be equal. The supporting forces may be determined graphically by first assuming a roller under one end of the truss, or by the funicular polygon construction (see p. 201). They are often calculated and the polygon of external forces plotted from the results of the calculation. This is a desirable method, as it offers a check on this most important part of the graphical work.

The horizontal component of the wind load is $(16/34)13{,}600 = 6400$ lb. The *H* component of each supporting force is therefore $6400/2 = 3200$ lb. The vertical component of the wind load is $(30/34)13{,}600 = 12{,}000$ lb. Taking moments about the right end of the truss, $(21{,}760 \times 30) + (13{,}600 \times 17) = 60V_1 \quad \therefore V_1 = 14{,}733$; $V_2 = 21{,}760 + 12{,}000 - 14{,}733 = 19{,}027$.

The polygon of external forces can now be constructed, as in Fig. 18. The dotted part of the diagram is the combination of the dead and wind loads, assuming that they are each concentrated. The dotted line *BK* is the resultant of these loads. The supporting forces *KA* and *AB* are determined by plotting to scale their horizontal and vertical components as calculated. The polygon of external forces for the truss is *BCDEFGHIJKAB*, and must check with the polygon shown dotted. The forces *GH*, *HI*, *IJ*, and *JK* are the resultants of the forces acting at the joints on the right side of the truss.

When supporting forces are to be determined the loads *may* be concentrated at the lines of action of their resultants, but when internal stresses are to be determined the loads *must* be distributed at the various joints. Start with some joint of the truss where there are only two unknown forces and draw the stress diagram, Fig. 18. The magnitudes of the stresses in the different members are determined directly from the lengths of the corresponding lines and the scale used in the construction of the diagram. The nature of the stress (tension or compression) is determined by the use of Bow's notation.

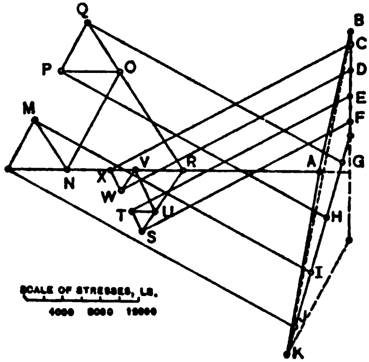

FIG. 18.

A difficulty often arises that is illustrated by the truss of Fig. 17. It is impossible by the usual graphical procedure to complete the stress diagram, as it will be found that, after obtaining the stresses in the members meeting at the left end and at the next joint on both upper and lower chords, no joint with less than three unknown forces is available. To overcome this difficulty, it is necessary to calculate some unknown stress, place it in the diagram and proceed with the graphical solution.

The stress which should be calculated in this case is that in the middle member of the lower chord. Taking moments about a point at the middle of the upper chord, $16RA = (14{,}733 \times 30) - (3200 \times 16) - [2720(22\frac{1}{2} + 15 + 7\frac{1}{2})] - (1360 \times 30) = 227{,}600$ $\therefore RA = 14{,}225$ (tension). Place this stress in the diagram and proceed.

FRICTION

BY

COEFFICIENTS OF FRICTION

Friction of Rest

If one body be pressed against another by a force P, as in Fig. 1, the first body will not move provided the angle a_0 included between the line of action of the force and a normal to the surfaces in contact does not exceed a certain value which depends upon the nature of the surfaces. The supporting force R acting through the second body has the same magnitude and line of action as the force P. In Fig. 1, R is resolved into two components: a force N normal to the surfaces in contact, and a force F_r parallel to the surfaces in contact. From the above statement it follows that

$$F_r \leq N \tan a_0 \leq Nf_0,$$

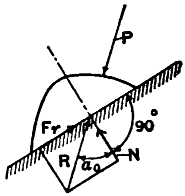

FIG. 1.

where $f_0 = \tan a_0$ is called the **coefficient of friction of rest** (or of static friction) and a_0 is the **angle of friction of rest** (or angle of repose). Values of the coefficients of friction of rest for various materials are given in Table 1.

Table 1. Angles of Repose and Coefficients of Friction of Building Materials

(Rankine's "Applied Mechanics")

Materials	a_0 deg.	$f = \tan a_0$	$\frac{1}{\tan a_0}$
Dry masonry and brickwork	31 to 35	0.6 to 0.7	1.67 to 1.4
Masonry and brickwork with damp mortar	36½	0.74	1.35
Timber on stone	22	about 0.4	2.5
Iron on stone	35 to 16⅔	0.7 to 0.3	1.43 to 3.3
Timber on timber	26½ to 11⅓	0.5 to 0.2	2.0 to 5.0
Timber on metals	31 to 11⅓	0.6 to 0.2	1.67 to 5
Metals on metals	14 to 8½	0.25 to 0.15	4.0 to 6.67
Masonry on dry clay	27	0.51	1.96
Masonry on moist clay	18¼	0.33	3.0
Earth on earth	14 to 45	0.25 to 1.0	4.0 to 1.0
Earth on earth, dry sand, clay, and mixed earth.	21 to 37	0.38 to 0.75	2.63 to 1.33
Earth on earth, damp clay	45	1.0	1.0
Earth on earth, wet clay	17	0.31	3.23
Earth on earth, shingle and gravel	39 to 48	0.81	1.23 to 0.9

Sliding Friction

If the applied force P of Fig. 1, which may be either a single force (*e.g.*, that due to its weight) or the resultant of several forces, makes an angle with the normal to the surfaces in contact exceeding the angle of friction of rest a_0, the frictional resistance F_r will no longer prevent the body from sliding. If a body sliding upon another is acted upon by a force N normal to the surfaces in contact, then a force acting in a direction opposing the motion is being overcome. This force is the **frictional resistance** F.

If the bodies have a common surface of contact, the relative motion is sliding and the resistance is that of sliding friction; if the bodies meet in line contact instead of surface contact, then the relative motion with reference to the line of contact may be either sliding or rolling. Rolling motion is opposed by rolling friction, see p. 236.

The value of the frictional resistance F is commonly expressed in terms of N, as $F = fN$, where f is the **coefficient of sliding friction.** The coefficient of sliding friction f varies with the materials, the character of the surfaces in contact, the unit pressure, the velocity of relative sliding and the temperature. It is less than the coefficient of friction of rest, f_0, except for very low velocities.

Table 2. Coefficients of Sliding Friction

(Condensed from the tables of Morin and from other sources. From Rankine's "Applied Mechanics")

Surfaces	α_0, deg.	f	$1/f$
Wood on wood, dry	14 to 26½	0.25 to 0.5	4.0 to 2.0
Wood on wood, soapy	11½	0.2	5.0
Metals on oak, dry	26½ to 31	0.5 to 0.6	2.0 to 1.67
Metals on oak, wet	13½ to 14½	0.24 to 0.26	4.17 to 3.85
Metals on oak, soapy	11½	0.2	5.0
Metals on elm, dry	11½ to 14	0.2 to 0.25	5.0 to 4.0
Hemp on oak, dry	28	0.53	1.89
Hemp on oak, wet	18½	0.33	3.0
Leather on oak	15 to 19½	0.27 to 0.38	3.7 to 2.86
Leather on metals, dry	29½	0.56	1.79
Leather on metals, wet	20	0.36	2.78
Leather on metals, greasy	13	0.23	4.35
Leather on metals, oily	8½	0.15	6.67
Metals on metals, dry	8½ to 11½	0.15 to 0.2	6.67 to 5.0
Metals on metals, wet	16½	0.3	3.33
Smooth surfaces, occasionally greased	4 to 4½	0.07 to 0.08	14.3 to 12.5
Smooth surfaces, continually greased	3	0.05	20.0
Do., best results	1¾ to 2	0.03 to 0.036	33.3 to 27.6

Table 3. Coefficients of Sliding Friction According to Rennie

(The surfaces were greased and then wiped so that the surfaces in contact were only slightly greasy)

Surface pressure, lb. per sq. in.	Wrought iron on wrought iron	Cast iron on wrought iron	Steel on cast iron	Brass on cast iron	Surface pressure, lb. per sq. in.	Wrought iron on wrought iron	Cast iron on wrought iron	Steel on cast iron	Brass on cast iron
	Values of f					Value of f			
125	0.14	0.17	0.17	0.16	485	0.40	0.37	0.36	0.22
186	0.25	0.28	0.30	0.23	523	0.41	0.37	0.36	0.22
224	0.27	0.29	0.33	0.22	560	Abraded.	0.37	0.36	0.23
260	0.29	0.32	0.34	0.21	600	Abraded.	0.37	0.36	0.23

373	0.35	0.35	0.35	0.21	710	Abraded.	0.43	Abraded.	0.23
390	0.38	0.36	0.35	0.21	784	Abraded.	Abraded.	Abraded.	0 23
448	0.40	0.37	0.35	0.21	820	Abraded.	Abraded.	Abraded.	0 27

Table 4. Coefficients of Friction for Dry or Slightly Lubricated Surfaces*

(Kimball and Barr, "Elements of Machine Design," 1st ed.)

Materials:	Values of f
Wood on wood, static or at very low velocity	0.3 to 0.5
Wood on metals, static or at very low velocity	0.2 to 0.6
Leather on metals, static or at very low velocity	0.3 to 0.6
Leather on wood, static or at very low velocity	0.3 to 0.5
Metal on metal, static or at very low velocity	0.3
Cast iron on steel, vel. = 440 ft. per min.	0.32
Cast iron on steel, vel. = 2640 ft. per min.	0.2
Cast iron on steel, vel. = 5280 ft. per min.	0.06

* The above values of f must be looked upon as approximate average values only, and should be used with judgment because of variations which come with slight changes of conditions. There are no experimental data giving the decrease in the value of f at high speeds for combinations such as wood or leather on metals. The data for cast iron on steel will, however, serve as a rough guide to what may be expected to occur. In designing brake shoes or other friction machinery where great velocities are involved, allowance must be made for the decrease in the value of the coefficient.

Friction Between Well-lubricated Surfaces. The following five laws (see Alford, "Bearings," p. 19) are based upon the laws of Goodman and the results of Lasche's experiments (see also p. 239):

1. The coefficient of friction for well-lubricated surfaces is practically independent of the materials composing the bearings and journals, but is dependent upon the nature of the lubricant.

2. The coefficient of friction for well-lubricated surfaces is from 1/6 to 1/10 that for unlubricated or scantily lubricated surfaces.

3. The coefficient of friction for moderate pressures and speeds varies approximately inversely as the normal pressure; *i.e.*, the frictional resistance per unit area is a constant, assuming the speed constant. The total frictional resistance varies as the area.

4. The coefficient of friction for well-lubricated surfaces for a given pressure is very high for low rubbing velocities, but decreases rapidly as the velocity increases. For velocities from 100 to 500 ft. per min. it decreases approximately as the square roots of the velocities; for velocities from 500 to 1600 ft. per min. it decreases as the fifth roots of the velocities; above 1600 ft. per min. the coefficient is practically independent of the velocity. (This law does not hold for all bearings; for example, in simple sleeve bearings the coefficient may vary directly as the speed for high speeds if the temperature is kept constant.)

5. The coefficient of friction varies approximately inversely as the temperature up to a point just before abrasion occurs. (This law, however, does not hold good for imperfect lubrication, as Tower's experiments attest.)

With good lubrication and high speeds the coefficient of friction is proportional to the viscosity of the oil and to the speed, and is inversely proportional to the pressure and the thickness of the oil film. At constant temperature the thickness of the oil film is inversely proportional to the square root of the pressure.

Frictional Resistance of Compound Sliding. A body sliding across another may be deflected from its direction of motion by any force; the force resisting motion will then alter its direction so that its component in the direction of the deflecting force equals the latter. A closely fitting plug gage can be freely moved through the ring gage if rotated while pushed axially, whereas the resistance to axial movement alone is very great.

Coefficients of Sliding Friction for Special Cases

Wrought-iron Tires on Dry Wrought-iron Rails (Poirée). Based on tests of cars weighing from 7500 to 18,500 lb.:

Speed, miles per hour	10.3	16.4	19.7	32	44.7	49
Values of f	0.209	0.206	0.171	0.145	0.136	0.112

Steel Tires on Steel Rails (Galton):

Speed, miles per hour	Start	6.8	13.5	27.3	40.9	54.4	60
Values of f	0.242	0.088	0.072	0.07	0.057	0.038	0.027

Cast-iron Brake Shoes on Steel Tires (Galton and Westinghouse):

Avg. speed, miles per hour	10	20	30	40	50	60
Value of f:						
First 3 seconds	0.320	0.205	0.184	0.134	0.100	0.062
5 to 7 seconds	0.209	0.175	0.111	0.100	0.070	0.054
12 to 16 seconds		0.128	0.098	0.080	0.056	0.048

For a uniform speed of v miles per hour, Wichert's tests gave values of the sliding friction between cast-steel brake blocks and steel tires of $f = B(1 + 0.018v)/(1 + 0.097v)$, in which $B = 0.45$ for dry surfaces and 0.25 for wet surfaces. If a train is to be brought to rest from an initial speed v, then an average coefficient of friction f_1 may be assumed for the entire braking period. The following values have been calculated from the formula for various speeds. The values for f_1 are for the unfavorable condition of wet rails.

Speed, miles per hr.	0	6.2	12.4	18.6	24.9	31.1	37.3	43.5	49.8	56.0
Dry surfaces, $f =$	0.450	0.313	0.250	0.215	0.192	0.176	0.164	0.154	0.146	0.141
Wet surfaces, $f =$	0.250	0.174	0.139	0.119	0.107	0.098	0.091	0.086	0.082	0.078
Average value, $f_1 =$		0.201	0.164	0.142	0.128	0.117	0.109	0.103	0.098	0.090

The specifications of the Master Car Builders' Association require that brake shoes upon cast-iron wheels in effecting a stop from an initial velocity of 40 miles per hour shall show a mean coefficient of friction of not less than 0.22 (0.16) where the pressure on the brake shoes is 2808 lb. (6840 lb.) For shoes on steel-tired wheels with an initial velocity of 65 miles per hour the mean coefficient of friction shall be not less than 0.125 (0.11) where the pressure on the shoe is 6840 lb. (12,000 lb.). No limitation is placed on the rise in the coefficient at the end of the stop.

Brakes. According to L. Klein, f is practically constant for velocities from 200 to 4000 ft. per min. and for pressures from 7 to 142 lb. per sq. in. The following values of f are for wood on lengthwise fiber, brake blocks carefully machined:

	Beech	Oak	Poplar	Elm	Willow
Cast iron	0.29–0.37	0.30–0.34	0.35–0.40	0.36–0.37	0.46–0.47
Wrought iron	0.54	0.51–0.40	0.65–0.60	0.60–0.49	0.63–0.60

The higher values apply for cast iron when the brake wheel is cleaned with gasoline, the lower when it is only wiped clean; the reverse holds for wrought iron.

Hydraulic Hoists. According to H. Lang, for bronze or lignum vitæ sliding surfaces on bronze, f is constant for slow, reversing motion and for pressures of from 30 to 1500 lb. per sq. in. For surfaces continuously lubricated, $f = 0.06$; for surfaces wet with water through numerous slots, 0.10; for surfaces running dry and creaking, up to 0.30.

Stuffing Boxes packed with hemp, cotton or leather: f is constant for hydraulic pressures between 15 and 750 lb. per sq. in. For **hemp or cotton packing**, loose or woven, soaked in hot tallow, smooth piston, box not set up too tightly so that the packing is still elastic, usual dimensions—even after months of use, $f = 0.06$ to 0.11 (see also *Am. Mach.* Feb. 3, 1898). When the packing is rendered difficult by unfavorable conditions, $f =$ up to 0.25. For well-made **leather packing rings** of soft leather $f = 0.03$ to 0.07; if of hard, stiff tanned leather, 0.10 to 0.13; under unfavorable conditions such as rough piston, dirty water, etc., up to 0.20. The coefficient of friction is found to be inversely as the diameter of the cylinder; the depth of the leather does not influence friction.

Stuffing Boxes of Steam Engines. Experiments made by C. H. Benjamin (*Trans. A. S. M. E.*, vol. 21, p. 292) with an engine having a 6 × 13-in. cylinder and 2-in. piston rod, using soft rubber, asbestos and graphite packings, braided flax packings lubricated with graphite and paraffin, and square duck packings without lubrication, showed that the power loss varies almost directly with the steam pressure for the harder packings while it is practically constant for the soft kinds. Oiling the rod will greatly reduce the friction with any packing. The friction loss may be made to assume serious proportions by injudiciously tightening the stud nuts. The loss occasioned by the 2-in. rod at a speed of 140 ft. per min. varied between 0.036 h.p. and 0.4 h.p. at 50 lb. steam pressure, with a safe average value for the softer classes of packing of 0.07 h.p.

Grindstones. The coefficient of friction between coarse-grained sandstone and cast iron is $f = 0.21$ to 0.24; for steel, 0.29; for wrought iron, 0.41 to 0.46, according as the stone is freshly trued or dull; for fine-grained sandstone (wet grinding) $f = 0.72$ for cast iron, 0.94 for steel, and 1.0 for wrought iron.

Vehicles on Roads (wheels with iron tires). Values of f:

Smooth granite flags	0.006	Macadam, dust covered	0.028
Avg. street railway tracks	0.006–0.008	Poor stone pavement	0.033
Good asphalt	0.010	Macadam, mud covered, rutted	0.035
Very good stone pavement	0.015	Dirt road, very good	0.045
Macadam in good condition	0.016	Macadam of very poor quality	0.050
Good wood block pavement	0.018	Dirt roads, good to poor	0.08–0.16
Good stone pavement	0.020	Loose sand	0.15–0.30
Macadam in good condition	0.023		

For values of f for **rubber tires**, see p. 1191.

The **resistance of ordinary vehicles on roads** and pavements varies widely according to the type and condition of the vehicle and of the road. The range of values commonly accepted is as follows:

Kind of Road or Pavement	Net Resistance, lb. per ton	Kind of Road or Pavement	Net Resistance, lb. per ton
Asphalt	30 to 70	Plank roads	30 to 50
Brick	15 to 40	Sand roads, ordinary condition	100 to 200
Cobblestones	50 to 100	Stone block	30 to 80
Earth roads, ordinary condition	50 to 200	Wood block, rectangular	30 to 50
Gravel roads	50 to 100	Wood block, cylindrical	40 to 80
Macadam	20 to 100		

Sleds. For **unshod wooden runners** on smooth wood or stone surfaces, $f = 0.07$ (0.15) when tallow (dry soap) is used as a lubricant (= 0.38 when not lubricated); on snow and ice, $f = 0.035$. For **runners with metal shoes** on snow and ice, $f = 0.02$.

Rolling Friction

If a cylinder rolls without sliding upon a flat horizontal surface and carries a load L acting normally to the flat surface, Fig. 2, the rotation about the line of support is due to a couple whose moment is $M = Lf_r$. f_r, which is the arm of the friction couple and is called the **coefficient of friction of rolling motion,** is dependent upon the hardness of the materials and smoothness of the surfaces, and has the following values: For lignum vitæ on lignum vitæ, $f_r = 0.0185$ in.; for elm on lignum vitæ, $f_r = 0.0319$ in.; for iron on iron (or steel on steel), $f_r = 0.0197$ in.

There is a scarcity of data on rolling friction, and its laws have not been definitely established. For railroad tracks, Thurston gives $f_r = 0.003$ ft. (ordinary construction) to 0.001 ft. (best possible construction). For iron on iron, Tredgold gives $f_r = 0.002$ ft.

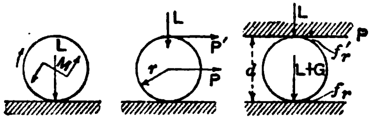

FIG. 2. FIG. 3. FIG. 4.

If the force P which causes rolling acts horizontally through the center of the cylinder (Fig. 3), then $P \times r = M = Lf_r$. If a force P' acts horizontally at the top of the cylinder (Fig. 3), then $P' \times 2r = M = Lf_r$. If a load L be moved on a roller (Fig. 4), and if f'_r and f_r are the respective coefficients of rolling friction and G is the weight of the roller, then $Pd = M = Lf'_r + (L + G)f_r$.

A cylinder of radius r will start to roll down an inclined plane when the angle a the plane makes with the horizontal is such that $\tan a = f_r/r$; whence $f_r = r \tan a$.

FRICTION OF MACHINE ELEMENTS

Work of Friction—Efficiency. In a simple machine or assemblage of two elements, the work done by an applied force P acting through the distance p is measured by the product Pp. The useful work done is less, and is measured by the product Ll of the resistance L by the distance l through which it acts. The **efficiency** e of the machine is the ratio of the useful work performed to the total work received, or $e = Ll/Pp$. The **work expended in friction,** W_f, is the difference between the total work received and the useful work, or $W_f = Pp - Ll$. The **lost-work** ratio $= V = W_f/Ll$, and $e = 1/(1 + V)$.

If a machine consist of a train of mechanisms having the respective efficiencies $e_1, e_2, e_3 \ldots\ldots e_n$, the combined efficiency of the machine is equal to the product of these efficiencies.

Efficiencies of Machines and Machine Elements. The following values for machine elements are from "Elements of Machine Design," by Kimball and Barr. Those for machines are from Goodman's "Mechanics Applied to Engineering." The quantities given are percentage efficiencies.

Common bearing (singly)	96–98	Belting	96–98
Do., long lines of shafting	95	Pin-connected chains (bicycle)	95–97
Roller bearings	98	High-grade transmission chains	97–99
Ball bearings	99	Weston pulley block (½ ton)	20–25
Spur gear, including bearings:		Epicycloidal pulley block	40–45
Cast teeth	93	1-ton steam hoist or windlass	50–70
Cut teeth	96	Hydraulic windlass	60–80
Bevel gear, including bearings:		Hydraulic jack	80–90
Cast teeth	92	Cranes (steam)	60–70
Cut teeth	95	Overhead traveling cranes	30–50
Worm gear: varies with thread angle	..	Locomotives (drawbar h.p./i.h.p.)	65–75

The efficiencies given for single bearings represent average values; the loss in a shaft bearing is not necessarily connected with the power transmitted and may be due chiefly to the load on the shaft.

Thurston found the **friction of a steam engine** to be constant at all outputs and to have the following approximate percentage distribution: main bearings, 35–47; piston and rod, 21–33; crank pin, 5–7; cross head and wrist pin, 4–5; valve and rod, 2.5 (balanced), 22 (unbalanced); eccentric strap, 4–5; link and eccentric, 9.

Wedges

Sliding in V Guides. If a wedge-shaped slide having an angle $2b$ is pressed into a V guide by a force P, Fig. 5, the pressure normal to the wedge faces will be $N = P/\sin b$, and the frictional force opposing motion along the axis of the wedge is $F = fN = fP/\sin b = f'P$, where $f' = f/\sin b$ is the coefficient of friction for V guides. In these formulæ the fact that the elasticity of the materials permits an advance of the wedge into the guide under the load P, has been neglected. If it be taken into account, then $F = fP/(\sin b + f \cos b)$. The efficiency for V guides is $e = 0.88$ to 0.90.

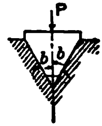

FIG. 5.

Taper Keys. In Fig. 6, if the key be moved in the direction of the force P, the force H must be overcome. The supporting pressures K_1, K_2, and K_3, together with the required force P may be obtained by drawing the force polygon, Fig. 7. The friction angles of these faces are a_1, a_2 and a_3, respectively. In Fig. 7 draw AB parallel to H in Fig. 6, and lay it off to scale to represent H. From the point A draw AC parallel to K_1, that is, making the angle $b + a_1$ with AB; from the other extremity of AB draw BC parallel to K_2 in Fig. 6. AC and CB then give the magnitudes of K_1 and K_2 respectively. Now through C draw CD parallel to K_3 to its intersection with AD which has been drawn through A parallel to P. The magnitudes of K_3 and P are then given by the lengths of CD and DA.

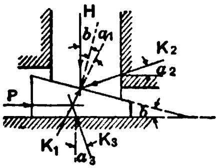

FIG. 6.

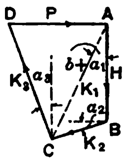

FIG. 7.

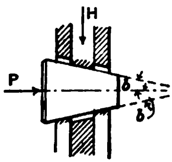

FIG. 8.

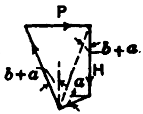

FIG. 9.

By calculation, $K_1/H = \cos a_2/\cos (b + a_1 + a_2)$.

$$P/K_1 = \sin (b + a_1 + a_3)/\cos a_3.$$

$$P/H = \cos a_2 \sin (b + a_1 + a_3)/\cos a_3 \cos (b + a_1 + a_2).$$

If $a_1 = a_2 = a_3 = a$, then $P = H \tan (b + 2a)$, and efficiency $e = \tan b/\tan (b + 2a)$. Force required to loosen the key $= P_1 = H \tan (2a - b)$. In order for the key not to slide out when force P is removed, it is necessary that $b < 2a < (a_1 + a_3)$.

The forces acting upon the taper key of Fig. 8 may be found in a similar way (see Fig. 9).

$$P = 2H \cos a \sin (b + a)/\cos (b + 2a)$$
$$P = 2H \tan (b + a)/[1 - \tan a \tan (b + a)]$$
$$= 2H \tan (b + a) \text{ approximately.}$$

The force to loosen the key is $P_1 = 2H \tan (a - b)$ approximately, and the efficiency $e = \tan b/\tan (b + a)$. The key will be self-locking when $b < a$, or, more generally, when $2b < (a_1 + a_2)$.

Journals and Bearings

The usual methods of calculating journal friction assume a fixed coefficient of friction and a definite distribution of pressure dependent upon whether the bearings are new or well-worn. The actual results may differ considerably. Calculations should be limited to cylindrical journals and flat thrust or step bearings, as only upon these have tests supplying sufficient data been made.

Friction of Journal Bearings. If P = total load on journal in lb., l = journal length in in., and $2r$ = journal diam. in in., then $p = P/2rl$ = mean normal pressure in lb. per sq. in. of the projected area of the journal. Also, if f_1 be the **coefficient of journal friction,** the **moment of journal friction** for a cylindrical journal is $M = f_1Pr$ in in.-lb. The **work expended in friction** at a speed of n r.p.m. is $W_f = 2\pi Mn = 6.283\, f_1Prn$ in.-lb. per min. For the **conical bearing,** Fig. 10, the mean radius $r_m = (r + R)/2$ is to be used.

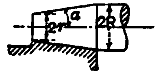

FIG. 10.

Journal friction may be **determined graphically** by assuming that the journal reaction does not pass through the journal axis but is tangent to a circle called the journal friction circle, whose radius is $f_1 \times r$.

Values of the Coefficient of Journal Friction, f_1. The value of f_1 is dependent upon the journal load, the circumferential speed of the journal, the temperature, the lubricant used and the design of the bearing. Due to the unavoidable inaccuracies of manufacture, it is higher for new journals than for those that have worn to a bearing. The experiments of Thurston, Tower, Stribeck, Lasche, Heimann, Kimball, Moore and others, lead to the following conclusions for well-lubricated journals:

1. For solid bearings that permit an uninterrupted distribution of pressure around the shaft, the total friction (or $f_1 \times P$) is independent of the load, as the coefficient of journal friction f_1 varies inversely as the unit pressure on the journal. In the case of bearings with surface interruptions and therefore without a continuous distribution of the pressure around the shaft, this law does not apply. Here the friction (with equal pressure) increases with the size of the friction surface.

2. The coefficient of friction of rest is independent of the pressure. The coefficient of friction of motion decreases with increasing velocity, more rapidly under low than under high pressures. After reaching a minimum value, which is approximately the same for all permissible pressures, the coefficient of friction then increases, increasing more rapidly for the lower pressures. At a velocity of about 2000 ft. per min. a point is reached beyond which the coefficient of friction seems to be independent of velocity. See Fig. 11.

3. With a temperature rise within the limits 32 to 104 deg. fahr., f_1 varies approximately inversely with the temperature above 32 deg. fahr.

4. The total friction ($= f_1P$) is approximately inversely proportional to the thickness of the oil film, that is, to the journal clearance.

Influence of the Method of Lubrication. Tower found the following values of f_1 for a journal of steel running in a bronze bearing 4 in. in diam. and 6 in. long, at a circumferential velocity of 160 ft. per min., and lubricated with rape-seed oil.

With an oil bath and p = 260 lb. per sq. in., f_1 = 0.00139.
With wick lubrication and p = 240 lb. per sq. in., f_1 = 0.00980.
With pad lubrication and p = 270 lb. per sq. in., f_1 = 0.00900.

Values of f_1 for Various Oils as determined by the German National

Bureau of Tests by means of the Martens oil-testing machine (having a steel journal 4 in. in diam. × 2¾ in. long), are given in Table 5.

Professor Kingsbury, from tests of a bearing 1⅜ in. diameter, 2 in. long, 120 deg. contact and with bath lubrication, gives the following average **coefficients of friction for sperm oil** under a pressure of 340 lb. per sq. in. at a temperature of 90 deg. fahr. (*Trans. A. S. M. E.*, vol. 24, p. 149): At 42 ft. per min., 0.000906; at 64 ft. per min., 0.001153; at 101 ft. per min., 0.00151. He also found in tests of a **journal lubricated by air** only, that $f_1 = 0.00075$ (*Jour. Am. Soc. Naval Engrs.*).

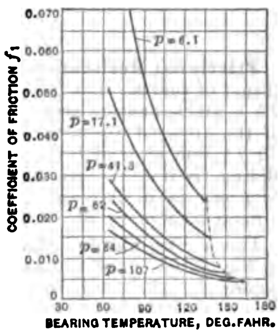

Fig. 12.—Influence of Bearing Temperature on the Coefficient of Journal Friction.

Table 9 gives results of **tests on large shaft bearings** (Kingsbury, *Trans. A. S. M. E.*, 1905, vol. 27, p. 431). In these, a horizontal shaft was supported in two 9 × 30-in. end bearings; a third bearing (15 × 40 in.), midway between the other two, was pressed upward against the shaft by a weighted lever, subjecting the shaft to a pressure of from 25 to 50 tons. The shaft was driven by an electric motor. The journals were flooded with paraffin oil for the lower pressures and heavy machine oil for the higher pressures. The values for the friction h.p. and f_1 in the table are for the three bearings.

Table 9. Tests of Large Shaft Bearings (Kingsbury)

Pressure		Velocity		Friction	
tons	lb. per sq. in.	r.p.m.	ft. per min.	h.p.	f_1
25.0	83	309	1215	12.6	0.0045
25.0	83	506	1990	21.7	0.0048
25.0	83	180	708	6.43	0.0040

33.6	112	454	1785	16.0	0.0029
42.3	141	480	1890	17.9	0.0024
47.0	157	946	3720	41.9	0.0025
47.0	157	1243	4900	47.8	0.0022
50.5	168	1286	5050	52.3	0.0022

For **approximate calculations** where it is preferred to err on the safe side, the coefficient of friction may be assumed at 0.06 for lubrication by rape-seed oil, mineral grease, mineral oil or their compounds for accurately machined journals running in bronze bearings. With machine oil, in common practice, it is often not more than 0.006 and sometimes as low as 0.003; under the very best conditions it may be as low as 0.0006. Where the lubrication is poor and in the open, as for rope drives, turntables, transfer tables, etc., take f_1 = 0.08 to 0.10.

With very **low velocities and high pressures** the coefficient for well-lubricated bearings approaches that for greasy or unlubricated surfaces, a minimum value for which may be taken as 0.15. Tests of new, well-fitted bearings have given values of 0.30 and more. These values should be used in estimating the starting moments for heavy machinery. **For** purposes of **design of ordinary machinery** with pressures from 50 to 500 lb. and velocities from 50 to 500 ft. per min., a fair average range of the coefficient of friction is from 0.02 to 0.008. In extraordinary cases, with perfect lubrication and moderate velocity, the coefficient may be taken as low as 0.001.

Thrust Bearings

Frictional Resistance. Step bearings or pivots are used to resist the end thrust of shafts. Let L = total load in lb. in the direction of the shaft axis, dA = an elementary area of the thrust-bearing surface in sq. in., y = distance of the area dA from its axis of revolution, in in., p = pressure on dA due to load L, in lb. per sq. in., and f = coefficient of sliding friction. Then, **moment of thrust friction** = M = $fp \int y dA$ in in.-lb.; and the **work expended in friction** per min. at n r.p.m. = W_f = $2\pi Mn$ in in.-lb.

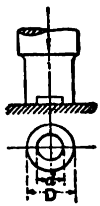

Fig. 13.

For a **ring-shaped flat step bearing** such as that shown in Fig. 13 (or a **collar bearing**), $M = \frac{1}{3}fL(D^3 - d^3)/(D^2 - d^2)$, where D and d are in in. For a **flat circular step bearing**, $d = 0$, and $M = \frac{1}{3}fLD$.

For a **conical pivot bearing,** $M = \frac{1}{3}fLD/\sin a$, where D = diam. of shaft in in. and a = the half angle of the cone or the angle of the slope with the axis. For a **truncated conical pivot bearing,** $M = \frac{1}{3}fL(D^3 - d^3)/(D^2 - d^2) \sin a$, where d = smaller diam. of the frustum in in.

For a **hemispherical step bearing** (end of shaft rounded to a hemisphere of diam. D), $M = \frac{1}{3}fLD$.

For **Schiele's "anti-friction" pivot bearing** (Fig. 14), $M = \frac{1}{2}fLD$. The outline of this bearing is in the form of a tractrix (see p. 155), but the term "anti-friction" applied to it is a misnomer, because its friction is much greater than that of a flat step bearing of the same diameter. It maintains its shape as it wears and is self-adjusting, but it is now seldom used.

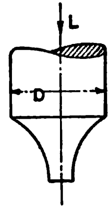

FIG. 14.

A nearly **frictionless step bearing** may be obtained by floating the bearing upon mercury. (See *Engg.*, July 14, 1893, p. 41.)

Values of the Coefficient of Friction f. The general laws of journal friction apply in the case of thrust bearings. The coefficient of friction decreases directly with the fluidity of the lubricant, *i.e.*, decreasing the more slowly the greater the pressure. The **influence of pressure and temperature** upon the coefficient of friction for step bearings as determined by Woodbury is given in Table 10. The ring-shaped flat steel pivot tested was 2.28 in. in outside diam. and 1.43 in. in inside diam. Speed, 300 r.p.m.; lubricant, paraffin oil.

Table 10. Influence of Pressure and Temperature on the Coefficients of Friction of Step Bearings (Woodbury)

Pressure per sq. in., lb.	Temperature, deg. fahr.				
	60	70	80	90	100
1	0.34	0.27	0.21	0.17	0.14
5	0.09	0.074	0.0620	0.052	0.044
10	0.055	0.047	0.040	0.035	0.030
15	0.044	0.038	0.033	0.028	0.026
20	0.038	0.033	0.029	0.026	0.023
25	0.034	0.030	0.027	0.024	0.021
30	0.031	0.027	0.025	0.022	0.020
35	0.029	0.026	0.023	0.021	0.019
40	0.027	0.024	0.022	0.020	0.018

The **influence of pressure and velocity** is shown by the following results of tests by Tower of a flat steel step 3 in. in diam. running on a manganese-bronze bearing and thoroughly lubricated with mineral oil; pressure range, 20 to 160 lb. per sq. in. (at higher pressures seizing occurred):

Speed, r.p.m.		50	128	194	290	353
Range of values of f	from	0.0181	0.0053	0.0051	0.0044	0.0053
	to	0.0221	0.0113	0.0102	0.0178	0.0167

On account of the difficulty in properly lubricating a step bearing it is not easy to assign a definite value to f. Experiments show that 0.01 is a safe average value for ordinary machine design.

Ball Bearings

Frictional Resistance. Let L = total load on a ball race, lb., S = sum of all the individual ball loads, lb.; b = angle between the supporting normals of two adjacent balls; d = ball diam., in.; r = radius of shaft, in.; D_0 = diam. of the circle passing through the ball centers, in. $= 2r + d$; B = number of balls in the race; f_r = the coefficient of rolling friction; f_i = coefficient of friction for ball bearings (referred to the radius of the journal) $= Sf_rD_0/Lrd$, and N = r.p.m. Then, according to Stribeck (see Fig. 15), the friction torque $M = Sf_rD_0/d = f_iLr$ in in.-lb.; the friction work $W_f = 2\pi NM =$

$2\pi NSf_rD_0/d$ in in.-lb. per min.; $S = L_0 + 2L_1 + 2L_2 + \ldots\ldots 2L_n$; $L_1 = L_0 \cos^{5/2} b$; $L_2 = L_0 \cos^{5/2} 2b$; etc.; $L = L_0 (1 + 2\cos^{5/2} b + 2\cos^{5/2} 2b + \ldots\ldots 2\cos^{5/2} nb)$. When the number of balls in a race $B = 10$ to 20, the greatest load on any one ball $= L_0 = 5L/B$ (approx.) and $S = 1.2L$ (approx.); also, $f_r = f_i r/1.2(D_0/d)$. The frictional work W_f decreases with a decrease in the ratio D_0/d, and is therefore lower the smaller the number of balls the race contains.

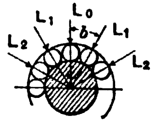

FIG. 15.

Coefficient of Friction of Ball Bearings. Within wide limits f_i is independent of the speed of rotation and the temperature; it decreases, however, with an increase in the load. Stribeck's investigations show that the value of f_i is materially influenced by the design of the bearing. For a bearing like that shown in Fig. 16, having $r = 1\frac{3}{4}$ in., $D_0 = 4$ in. and $d = \frac{7}{8}$ in. (races of steel, carefully ground, ball tracks with radius of curvature $= \frac{2}{3} \times$ ball diam., this design being best for heavy loads), the following values of f_i were found:

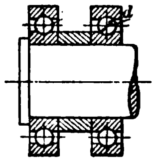

FIG. 16.

Load L, lb.	838	1874	2425	3483	4520	6614	10800
f_i at 65 r.p.m.	0.0033	0.0020	0.0017	0.0016	0.0015	0.0015	......
f_i at 385 r.p.m.	0.0035	0.0021	0.0018	0.0016	0.0015	0.0013	......
f_i at 780 r.p.m.	0.0037	0.0022	0.0019	0.0017	0.0015	0.0013	0.0011

The following values of f_i and f_1 give an idea of the **comparative friction of ball bearings and plain bearings** in large sizes:

Ball bearings, plain cylindrical races, 2-point bearing: $f_i = 0.0012$ to 0.0018; ball thrust bearings, flat races, 2-point bearing: $f_i = 0.0008$ to 0.0012; ball thrust bearings, 1 flat, 1 V-race, 3-point bearing: f_i (mean) $= 0.0018$; ball thrust bearings, 2 V-races, 4-point bearing: $f_i = 0.0055$ (all by Goodman).

Cylindrical gun-metal bearing: with bath lubrication, $f_1 = 0.001$; with ordinary lubrication, $f_1 = 0.01$ (Tower).

Gun-metal step or collar bearings, well lubricated, $f_1 = 0.03$ (Tower).

Roller Bearings

Let L = total load on a bearing, lb., l = length of roller, in., d = diam. of roller, in., B = number of rollers, $D_0 = 2r + d$ = diam. of the cylinder passing through the roller axes, in., $p = 5L/Bld$ = maximum load per sq. in. of projected area of one roller, lb. Then, according to Stribeck, using the same notation as for ball bearings (p. 243), $M = 1.2Lf_rD_0/d = f_iLr$ in in.-lb., and maximum load on one roller for $B = 10$ to 20 is $L_0 = 5L/B$.

Coefficients of Friction for Roller Bearings. In roller bearings the friction of motion is practically independent of the speed and differs but slightly from the friction of rest. It follows, therefore, that the starting resistance is low. The **coefficient of rolling friction** f_r decreases with increasing load and also with increasing temperature. Tests of roller bearings of various designs have shown that

for p =	43	71	103	142	213
f_r (in.) =	0.0018	0.0013	0.0011	0.0009	0.0007

The **coefficient of friction of roller bearings** $= f_i = 1.2D_0f_r/rd$.

The following values of f_i, which are stated to be good averages for an ordinary roller bearing, are given by Goodman in "Mechanics Applied to Engineering:"

Total load, lb.	2000	4000	6000	8000	10,000
At 40 r.p.m.:					
Value of f_t	0.0131	0.0094	0.0082	0.0076	0.0072
End thrust, lb.	82	147	212	276	340
At 400 r.p.m.:					
Values of f_t	0.0053	0.0035	0.0029	0.0026	0.0024
End thrust, lb.	51	89	128	166	205

The end thrust is the force required to prevent the bearing traveling along the shaft.

C. H. Benjamin (*Machinery*, Oct., 1905) gives the following **comparative values of the coefficient of friction of a plain cylindrical bearing and** two types of **roller bearings,** running at a speed of 560 ft. per min.:

Diam. of journal, in.	Hyatt roller bearing. Max.	Min.	Avg.	McKeel roller bearing. Max.	Min.	Avg.	Plain babbitted bearing. Max.	Min.	Avg.
$1\frac{15}{16}$	0.032	0.012	0.018	0.033	0.017	0.022	0.074	0.029	0.043
$2\frac{3}{16}$	0.019	0.011	0.014	...	...	...	0.088	0.078	0.082
$2\frac{7}{16}$	0.042	0.025	0.032	0.028	0.015	0.021	0.114	0.083	0.096
$2\frac{15}{16}$	0.029	0.022	0.025	0.039	0.019	0.027	0.125	0.089	0.107

According to Henry Hess, the **coefficient of friction of** a well-made annular **ball bearing** may be taken as 0.001 to 0.002, **and** that of a good **roller bearing** from 0.0035 to 0.014.

For further discussions on ball and roller bearings see translation and amplifications of the work of Professor Stribeck by Henry Hess (*Trans. A. S. M. E.*, vol. 29, pp. 367–472); "Ball Bearings," by Henry Hess (*Trans. A. S. M. E.*, vol. 27, p. 431, and vol. 31, p. 923); *Engg.*, Apr. 12, 1901, Dec. 26, 1902, and Feb. 20, 1903; *Am. Mach.*, Mar. 4, 1909.

Screws

Screws with Square Threads (Fig. 17). Let r = mean radius of the thread = ½ (radius at root + outside radius), and l = pitch (or lead of a single-threaded screw), both in in.; b = angle of inclination of thread to a line at right angles to the axis of screw ($\tan b = l/2\pi r$); and f = coefficient of sliding friction = $\tan a$ (see p. 232). Then, for a screw in uniform motion (friction of the root and outside surfaces being neglected) there is required a force P acting at right angles to the axis at the distance r. $P = L \tan (b \pm a) = L(l \pm 2\pi rf)/(2\pi r \mp fl)$, where the upper signs are for motion in a direction opposed to that of L and the lower for motion in the same direction as that of L. When $b \leq a$, the screw will not "overhaul" (or move under the action of the load L).

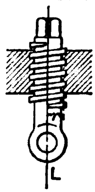

FIG. 17.

The **efficiency** for motion opposed to direction in which L acts $= e = \tan b/\tan (b + a)$; for motion in the same direction in which L acts, $e = \tan (b - a)/\tan b$.

The value of e is a maximum when b = 45 deg. − ½a; for example, e_{max} = 0.81 for b = 42 deg. and f = 0.1. Since e increases rapidly for values of b up to 20 deg., this angle is generally not exceeded; for b = 20 deg., and f_1 = 0.10, e = 0.74. In presses, where the mechanical advantage is required to be great, b is taken down to 3 deg., for which value e = 0.34.

Kingsbury found the following values of f for square-threaded screws from experiments with screws 1.426 in. in outside diam., and of 0.33 in. pitch, running slowly in loose-fitting cast-iron, steel, brass and wrought-iron nuts. The axial thrust on screw varied up to 14,000 lb. (= 14,000 lb per sq. in. of projected bearing surface of thread). No marked difference was noted at different pressures or with different metals.

	Max.	Min.	Avg.
Lard oil	0.25	0.09	0.11
Heavy mineral machinery oil	0.19	0.11	0.14
Heavy oil and graphite	0.15	0.03	0.07

Screws with V Threads. Let c = half the angle between the faces of a thread. Then, using the same notation as for square-threaded screws, for a screw in motion (neglecting friction of root and outside surfaces),

$$P = L\,[\tan b \pm f \cos b\sqrt{1 + \tan^2 b + \tan^2 c}]/(1 \mp f \sin b\sqrt{1 + \tan^2 b + \tan^2 c})$$

As b compared with c is usually small, $\sqrt{1 + \tan^2 b + \tan^2 c} = 1/\cos c$, approximately If then $f \cos b/\cos c$ be placed equal to $\tan a'$, $P = L \tan (b \pm a')$. The upper sign is for axial motion of the screw opposed to the direction of the load L, while the lower sign is for motion in the opposite direction. The screw will not overhaul when $b \overline{\gtrless} a'$, the value of a' corresponding to that for the angle of friction of rest.

The efficiencies are, $e = \tan b/\tan (b + a')$, for motion opposed to L, and $e = \tan (b - a')/\tan b$, for motion with L. The efficiency of a V thread is lower than that of a square thread, since $a' > a$. e is a maximum for $c = 0$.

Example: Assume b = 2 deg. 10 min.; c = 27 deg. 30 min.; $f = \tan a = 0.16$; also a = 9 deg. 5 min. 30 sec. Then $0.16 \times \cos 2°10'/\cos 27°30' = 0.180$. Also, $a' = 10°10'$, and $P = L \tan (b + a') = L \tan 12° 20' = 0.219\,L$; $e = \tan 2°10'/\tan 12° 20' = 0.173$. For a square thread, $P = L \tan, (b + a) = 0.199\,L$; $e = 0.190$. Both of these threads are self-locking, *i.e.*, they will not overhaul.

For a **V-threaded screw and nut,** let D = outside diam. of thread; d = diam. at root of thread—both in in.; and m = width across the flats of nut, in in. Then $r = (D+d)/4$; $\tan b = 2l/\pi(D+d)$; $\tan a' = f \cos b/\cos c$; and r_0 = mean radius of the nut seat $= (D + m)/4 = 1.4r$ (approx.).

To tighten up the nut a turning moment M is required: $M = Pr + Lr_0f' = [\tan(a' + b) + 1.4f']Lr$. **To loosen,** $M = [\tan (a' - b) + 1.4f']Lr$. In these equations f' is the coefficient of friction between the nut and its seat.

Example. For a screw with a U. S. standard thread, let D = ¾ in.; then d = 0.62 in., l = 0.10 in., $2c$ = 60 deg., r = 0.342 in., $\tan b$ = 0.04656, and b = 2 deg. 40 min. 3 sec. Taking $f = f' = 0.41$, a' = 25 deg. 18 min. 36 sec. Tightening the nut on the bolt requires a moment of M = [tan 27 deg. 58 min. 39 sec. + $(1.4 \times 0.41)]Lr = 1.105\,Lr = 0.3779L$ in.-lb. Loosening the nut will require a moment of M = [tan 22 deg. 38 min. 33 sec. + $(1.4 \times 0.41)]Lr = 0.9911Lr = 0.3390L$ in.-lb.

Kingsbury, from tests on U. S. standard bolts, finds efficiencies for tightening up nuts from 0.06 to 0.12, depending upon the roughness of the contact surfaces and the character of the lubrication.

Toothed Gearing

Spur Gears. DETERMINATION OF THE LOST-WORK RATIO V. If two teeth are in contact at E, Fig. 18, and ES be the tooth pressure normal to the teeth, M_1 and M_2 the two gear centers, then the lost-work ratio (or ratio of frictional work to useful work) for the instantaneous position may be derived graphically as follows: At a distance f draw a line parallel to ES. The two radii M_1E and M_2E (projected) will determine a length AB on this parallel, which, measured to the same scale as f, gives the value of the lost-work ratio V. (f is the coefficient of sliding friction.)

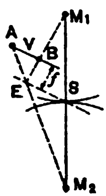

FIG. 18.

For the usual tooth profiles, V is approximately proportional to the lengths of the arcs of contact, q, measured on each side of the center line M_1M_2. As long as only one tooth is in contact, an average value of V for an arc of contact q is therefore $\frac{1}{2} V_1$, if V_1 is the value of V at the end of the arc of contact q_1. If the arcs of contact on both sides of the center line are equal, then this value may be taken as the average lost-work ratio V_m of the pair of gears. If the arcs of contact on the two sides of the center line are unequal, say q_1 and q_2, and the values V_1 and V_2 are those at the ends of the arcs of contact, then, according to Grashof, the average value is $V_m = (V_1q_1 + V_2q_2)/2(q_1 + q_2)$.

Let t_1 and t_2 be the number of teeth in a pair of gears, p = the circular pitch of the teeth, $r_1 = q_1/p$, $r_2 = q_2/p$, and $r = r_1 + r_2$ = arc through which the teeth are in contact; then

$$V = \pi f\left(\frac{1}{t_1} \pm \frac{1}{t_2}\right)\frac{r_1^2 + r_2^2}{r_1 + r_2} = \pi f\left(\frac{1}{t_1} \pm \frac{1}{t_2}\right)\frac{r}{2} \text{ (approx).}$$

the + sign being for external gears, and the − sign for internal gears. Considering that for an arc of contact r there are alternately 1 and 2 teeth in contact, then, more accurately,

$$V = \pi f\left(\frac{1}{t_1} \pm \frac{1}{t_2}\right)(r_1^2 + r_2^2 - r_1 - r_2 + 1)$$

or, approximately,

$$V = \pi f\left(\frac{1}{t_1} \pm \frac{1}{t_2}\right)\left(\frac{r^2}{2} - r + 1\right) = \pi f\left(\frac{1}{t_1} \pm \frac{1}{t_2}\right)u.$$

f ranges from 0.1 to 0.3 according to the material and the surface conditions of the teeth; for well-cut gears that have worn to a good bearing this value is smaller, while for rough teeth it will be higher. The average value $f = 0.16$ gives $\pi f = 0.5$, and

for r = 1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0
u = 0.5	0.505	0.520	0.545	0.58	0.625	0.68	0.745	0.82	0.905	1.0

For the usual proportions of cycloidal and involute teeth, r_1 and r_2 are dependent on the numbers of teeth t_1 and t_2, as follows:

Cycloidal	t_1 =	7	10	15	20	30	40	50	∞
	r_1 =	0.58	0.60	0.64	0.66	0.68	0.69	0.71	0.75
Involute	t_1 =	20	25	30	40	50	60	∞	
	r_1 =	0.84	0.90	0.92	0.97	0.99	1.02	1.24	

In the **graphical determination of the friction losses** for a pair of gears, the loss by tooth friction may be found by representing the line of action of the tooth pressure not on a line passing through the point of contact S of the two-pitch circles, but through a point on the center line that is nearer the center of the driven gear by an amount $E = fup/2$. The total efficiency of a pair of gears with machine-molded teeth, including the journal losses, is 0.92 to 0.95.

Bevel Gears. The formulæ for spur gears apply if $(1/t_1) + (1/t_2)$ be replaced by $\sqrt{(1/t_1^2) + (1/t_2^2) + 2 \cos b/t_1t_2}$, where b = angle included between the axes of the two shafts.

Helical Gears. In these, in addition to the tooth friction proper there is the usually much greater friction due to the transverse sliding of the teeth on each other. Let c and c_1 be the angles of inclination of the two helical gears, then the lost-work ratio due to this sliding is $V_s = [\sin c_1 \sin (c + a)/\sin c \sin (c_1 - a)] - 1$. For the special case of the **worm** with $c_1 = 90° - c$,

$$V_s = [\tan (c + a)/\tan c] - 1 = [(1 + 2\pi r f/p)/(1 - pf/2\pi r)] - 1,$$

in which p = lead or pitch of worm thread, r = mean worm radius, and f = $\tan a$ = coefficient of friction for sliding. In this case the tooth friction loss is $\pi fu/t$, t being the number of teeth in the worm wheel; for u, see spur gears. For values of f see Table 3; note also the remarks on p. 234 concerning the dependence of f on certain conditions.

Stribeck gives the following values of f (at 140 deg. fahr.) for a single-threaded cast-iron worm and gear (worn to bearing) for various speeds and pressures between the teeth (Worm: outside diam., 3¾ in.; root diam., 2⅜ in. Wheel: pitch diam., 9.46 in.; number of teeth, 30; width of face, 3 in.; pitch of teeth, 1 in.); v = speed at pitch circle, ft. per min.; P = pressure in lb.:

v =	100	200	300	400	600	800
P =	1100	1100	1100	880	550	352
f =	0.060	0.051	0.047	0.040	0.030	0.025

Friction Gearing

For values of f between driving wheels of millboard, leather, wood, and various fiber boards and driven wheels of cast iron and other metals, see "Machine Elements," p. 735.

Tension Elements

Frictional Resistance. In Fig. 19 let T and t be the tensions with which a rope, belt, chain or brake band is strained over a drum, pulley or sheave, and let the rope or belt be on the point of slipping from t toward T by reason of the difference of tension $T - t$. Then $T - t$ = circumferential force P transferred by friction, must be equal to the frictional resistance W of the belt, rope or band on the drum or pulley. Also, let $b = 2\pi b°/360°$ = angle subtending the arc of contact between the drum and tension element, measured in radians. Then, disregarding centrifugal forces,

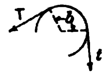

FIG. 19.

$$T = te^{fb} \text{ and } P = (e^{fb} - 1)T/e^{fb} = (e^{fb} - 1)t = W$$

where e = base of the Napierian system of logarithms = 2.718+.

Table 11. Values of e^{fb}

e^{π} = 23.1407. $\log e^{\pi}$ = 1.3643764.

f is the coefficient of friction of repose (f_0) when there is no slip of the belt or band on the drum, and the coefficient of sliding friction (f) when slip takes place. In addition to the values given below, see p. 233.

Average values of f_0 for belts, ropes and brake bands are as follows: For leather belt on slightly greasy wood pulley 0.47. For leather belt on cast-iron pulley, very greasy, 0.12; slightly greasy, 0.28; moist, 0.38. For hemp rope on cast-iron drum, 0.25; on wooden drum, 0.40; on rough wood, 0.50; on polished wood, 0.33. For iron brake bands on cast-iron pulleys, 0.18.

Lost Work Due to the Stiffness of Tension Elements. Let d = the rope diam., the diam. of the chain stock or the diam. of the pin in link chains, and R = the radius of the pitch circle in which the tension element travels, both in in. The internal frictional rigidity of the tension element causes a shortening at the driving end T of the lever arm R an amount h_1 in inches, and at the following end a lengthening of the lever arm R an amount = h_2 in. Then, for simultaneous winding on and off, $T(R - h_1) = t(R + h_2)$. Approximately, $h_1 = h_2 = h$, whence $h_1 + h_2 = 2h$ (approx.) and $T = [1 + (2h/R)]t$. If the tension element is only wound on the drum, $h_1 = 0$ and $T = [1 + (h/R)]t$.

For **chains** the coefficient of friction between the link faces or pivots is f = 0.2 to 0.3; and when d = the diam. of the link pin, $h = fd/2$.

For **hemp ropes** $h = 0.03d^2$ to $0.09d^2$ according to the construction, material and condition of the rope. In the absence of reliable values for **wire ropes,** those for chains may be tentatively used.

The **elastic rigidity** of the material, *i.e.*, the work performed in changing the shape of the tension element, is not a factor in simultaneous winding on and off, since the lever arm R is increased equally at the points of winding on and off; the work expended in bending the tension element as it is wound on is recovered as it straightens out in unwinding. But if there is only winding on, then the lost work due to the bending is to be taken into account.

Lost Work Due to Creeping. Creeping is due to the elastic elongation of the tension element and must not be confused with the **slip** due to insufficient frictional grip on the pulley or drum.

Owing to a change in tension from the winding-on to the winding-off end, the length of the tension element varies in such a way that the driving pulley winds on a greater length than it winds off, the reverse being true for the driven pulley. This causes a loss of relative velocity which is equal to the lost-work ratio V. Assuming a uniform distribution of the tension over each cross-section of the tension element, there results for the entire drive system, *i.e.*, for the driving plus the driven pulley, $V = k(T - t)/A = kP/A$, where P is in lb., A = area of cross-section of element in sq. in., and $k = 1/E$, E being the modulus of elasticity of the tension element in lb. per sq. in. Since P is transmitted at the inner face of the tension element (belt), the tension (and therefore the elongation) is materially greater on the side of the belt in contact with the pulley than Tk/A, also $V > kP/A$. It is further to be considered that k decreases with increasing tension, thus reducing the value of V.

Bach recognizes the lack of uniform tension distribution and the variation in k by the use of an empirical constant m, thus: $V = mkP/A = mP/AE = mp/E$, where $p = P/A$. He gives the following values of m, p, E and V.

	m	p, lb. per sq. in.	E, lb. per sq. in.	$V = mp/E$, per cent.
Leather belt, new.....	2.00	140	17,800	1.6
Leather belt, used.....	2.00	140	32,000	0.9
Hemp rope*..........	1.25	137	107,000	0.16
Wire rope, new*......	1.50	4300	10,000,000	0.065

* p and E are based on the actual cross-section of the strands and wires, *i.e.*, for hemp rope, $A = 0.66\pi d^2/4$, and for wire rope $A = 0.42\pi d^2/4$, where d = diam. of rope in inches.

Efficiency of Rope and Chain Sheaves, at low speeds, including journal friction (180-deg. contact):

For fixed sheaves, chain and wire rope, e = 0.94 to 0.96.
For floating sheaves, chain and wire rope, e = 0.97.
Hemp rope sheaves:

Rope diam., in.	5/8	1	1 1/2	1 3/4	2
Fixed sheaves: e =	0.95–0.96	0.91–0.96	0.89–0.93	0.84–0.92	0.85–0.91

General Properties of Liquids

A **liquid** is a substance that **has a definite volume,** but whose particles move relatively to each other so readily that, when unconfined laterally, the action of gravity causes it to flow and seek the lowest possible level. Hence a liquid **conforms to the shape of the containing vessel** or reservoir and, when at rest, presents a level upper surface unless restrained by the rigidity of the walls of a completely filled container.

When two or more liquids that do not mix (*e.g.*, water, oil and mercury) are contained in the same vessel, the heaviest liquid occupies the lowest position and the surfaces of division between the liquids are level. (But see p. 283 for capillarity, cohesion, adhesion and surface tension as affecting glass column gages.) In any continuous body of liquid at rest, the pressures at all points in a horizontal plane are equal. For a body of liquid moving at a uniform rate in a straight line, the above-stated principles are also true, but they are subject to modification for motion in a curved path or for accelerated motion other than vertical.

Compressibility and Elasticity of Liquids. A pressure of 1 lb. per sq. in. compresses liquids in volume as follows: Water, 1 part in about 300,000; mercury, 1 part in about 4,700,000; ether, 1 part in about 120,000. For water in an iron pipe this corresponds to a compression of 2 in. per mile length for a pressure of 10 lb. per sq. in. Because of this small compressibility, **liquids are** said to be **practically incompressible.** Liquids are perfectly elastic, *i.e.*, they regain their former volume upon removal of the pressure. As a consequence of the small compressibility and decided elasticity of liquids, pressure waves, exactly analogous to sound waves in air, are transmitted through liquids with high velocities—for water, over four times as fast as sound in air.

HYDROSTATICS

Liquid Pressure may mean either **total pressure** or **intensity of pressure.**

Gage pressure is the pressure indicated by a gage, and shows pressure above atmospheric pressure. **Absolute pressure** commonly means **intensity of pressure referred to vacuum as zero.** Pressures less than atmospheric are always referred to by some distinct phrase, *e.g.*, "10 lb. **suction,**" "20 in. (mercury) **vacuum,**" "5 lb. per sq. in. **absolute** pressure."

Pressure Head. Liquid pressure is often caused by the weight of the overlying liquid, and all liquid pressures can be thought of as being so caused. Special names are given to this real or imaginary height, as **"pressure head," "static head,"** or, simply, **"head."**

General Considerations Regarding Liquid Pressure

1. Pressure head is the height to the real or imaginary free liquid surface corresponding to the pressure of the liquid.

2. In any continuous body of liquid at rest, the **intensity of pressure** increases directly with the depth of the liquid. $p = hw$, or $h = p/w$, where p is the increase of pressure per unit area, h the increase of depth (or head) and w the weight per unit volume of the liquid. This law is true whether the liquid has a free upper surface open to the atmosphere or is confined and subjected to mechanical, gaseous or other pressure.

To find

Pressure of water in lb. per sq. ft., multiply head in ft. by 62.4.

Pressure of water in lb. per sq. in., multiply head in ft. by 0.433. (See Conversion Scales, Fig. 1.)

Vacuum head of water in ft., multiply "in. of mercury" by 1.13.

Vacuum pressure in lb. per sq. in., multiply "in. of mercury" by 0.49.

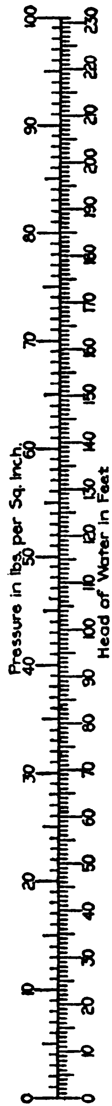

FIG. 1.—Conversion Scale for Water. Head in Feet to Pressure in Lb. per Sq. In.

Hydrostatic Paradox. In the cases shown in Fig. 2 the **intensity of pressure** in lb. per sq. in. is the same at the bottoms of the variously shaped liquid containers. But the total liquid pressures against the various bottoms are proportional to the areas of the bottoms. The amount of liquid or its total weight makes no difference in either the intensity of pressure or the total pressure as long as the head, h, is the same. The fact that the total liquid pressure (bursting pressure) against the bottom may be many times greater or less than the total weight of the liquid, is termed the **hydrostatic paradox.**

3. Liquid pressure is exerted with equal intensity in all directions.

4. **Liquid pressure acts perpendicularly to surfaces** in contact with the liquid. For curved surfaces the pressure at any point acts in the direction of the normal to the surface at that point.

5. **The total liquid pressure against a submerged plane area** equals the product of the average intensity of pressure by the area, *i.e.*, the product of the intensity of pressure at the center of gravity of the area by the area, or, as often stated, it equals the weight of a liquid column with a base equal to the area and height equal to the head on the center of gravity of the area. For a vertical **rectangular** plane extending to surface of liquid, with depth h and width b, the formula becomes: Total pressure $= P = \frac{1}{2}wbh^2$, where w is the weight of a unit volume of liquid. See **special calculating scale** for total pressures of water against vertical planes 1 ft. wide and 1 to 100 ft. deep, Fig. 3.

6. **The component in any direction** of the total liquid pressure on any submerged plane surface equals the product of the area of the projection of the surface on a plane perpendicular to the direction by the intensity of pressure at the center of gravity of the surface. For curved or non-planar surfaces, the principle may be applied to small portions of the surface, each regarded as plane, and the summation taken. Such cases, however, as **hollowed-out pump plungers and dished tank ends** have the same total pressures in the direction of the axis of the cylinder or tank as if the plunger or end were plane, *i.e.*, $P = Ap$, where A is the cross-sectional area of tank and p the average pressure. For submerged and floating bodies, see Buoyancy and Flotation, p. 253.

7. The **center of pressure** of a plane area subject to liquid pressure, *i.e.*, the point where the application of a single support will balance the liquid pressure, is located by the formula:

$$x_{c.p.} = \text{Moment of inertia of area/Area} \times x_{c.g.}$$

where $x_{c.p.}$ is the distance in the plane from the water surface to the center of pressure, $x_{c.g.}$ is the corresponding distance to the center of gravity of the area, and the moment of inertia is referred to line where the plane cuts the water surface. In Fig. 4, the point G represents the center of gravity of the area and point C the center of pressure. C is always below G, but with relatively small areas submerged under large heads they are very close together and for most purposes may be considered coincident. For common shapes, calling the distance to the upper edge s_1 and to the lower edge s_2 (see Fig. 4), the values of $x_{c.p.}$ are:

Rectangle, $\frac{2(s_2^3 - s_1^3)}{3(s_2^2 - s_1^2)}$; Triangle, vertex up, $\frac{1}{2}\frac{3s_2^2 + 2s_1s_2 + s_1^2}{2s_2 + s_1}$; Triangle, vertex down, $\frac{1}{2}\frac{3s_1^2 + 2s_1s_2 + s_2^2}{2s_1 + s_2}$; Circle, $x_{c.g.} + \frac{1}{4}\frac{r^2}{x_{c.g.}}$. If the upper edge is at the surface, the above formulæ become:

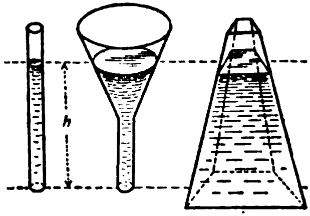

FIG. 2.

Rectangle, $2s_2/3$; Triangle: vertex up, $3s_2/4$; vertex down, $s_2/2$; Circle, $5r/4$.

The maximum bending moment on a vertical rectangular beam subjected throughout its full length to liquid pressure, supported at top and bottom, and with the top support at the surface, occurs 0.09 s_2 above the center of pressure or $\frac{1}{12}$ the span below the middle.

Example. Required the total pressure against a vertical gate 3 ft. wide and 5 ft. high at the bottom of a tank 12 ft. deep; also the position of the center of pressure.

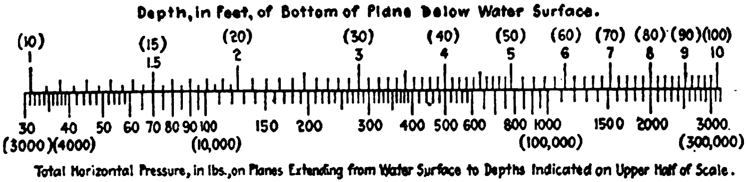

FIG. 3.

The center of gravity of the gate face is $(7 + \frac{5}{2} =)9\frac{1}{2}$ ft. below the surface, and according to (5), total pressure against gate $= 9\frac{1}{2} \times 62.4 \times (5 \times 3) = 8892$, say, 8900 lb. The total pressure scale, Fig. 3, gives 4500 and 1530 lb. respectively for depths of 12 and 7 ft. The difference, 2970 lb., is the pressure per ft. of width, or 8910 lb. total. The center of pressure [according to (7), for a submerged rectangle] is $\frac{2}{3}(12^3 - 7^3)/(12^2 - 7^2) = 9.72$ ft., or only 0.22 ft. below the center of gravity. Graphically, the depth of the center of pressure is the same as that of the center of gravity of the trapezoid forming the bottom 5 ft. of the "triangle of pressures."

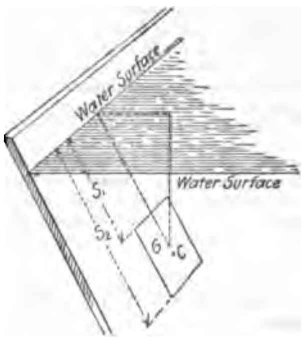

FIG. 4.

Buoyancy and Flotation. The total **upward pressure** of a liquid against a floating or a submerged body is the same as if the portion of the body below the surface were replaced by the liquid. In the latter case there would be simply a mass of liquid at rest, *i.e.*, with the upward pressure just **equal to the weight of** the liquid volume in question, which is the **volume displaced** by the floating or submerged body. Obviously, for a floating body, this weight and upward pressure equals the weight of the body. Hence, for any floating body, $P_u = W = Vw$, where P_u is the total upward pressure, W the weight of the body, V the volume of the displaced liquid (= "the displacement"), and w the weight of a unit volume of the liquid.

The **draft or depth of flotation** may be calculated when the weight, size and shape of the floating body are known, for in all cases $W = Vw$.

The **center of buoyancy** is at the center of gravity of the displaced volume of liquid. It shifts its position, both vertically and sidewise, as the floating body tips. The total upward pressure of the liquid may be regarded as concentrated through the center of buoyancy, about which it balances.

Stability, or tendency to float upright, demands that, when the floating body is tipped, the vertical through the new center of buoyancy shall pass above the center of gravity of the body. When it does so pass, both the weight and buoyancy tend to right the floating body. When it passes below the center of gravity, both the weight and buoyancy act to overturn it. It is not necessary for stability that the center of gravity be below the center of buoyancy. In ships it is usually above. The point where the vertical through the new center of buoyancy cuts the original vertical (now inclined), through the center of gravity, is called the **metacenter.** If, then, the metacenter is above the center of gravity, there is stability; if below, instability. The further above, the greater the stability.

Example. (Float control of a mechanism.) It is desired to obtain a force of 100 lb. from a float when the water surface rises or falls 1 in. Required to find size of float necessary. From $P_w = Vw$, $100 = Vw$ = water-line area $\times$ $1/12$ $\times$ 62.4, or area = 19.25 sq. ft., calling for, *e.g.*, a circular float 4.95 ft. in diam.

For submerged bodies, the "weight in water" (or other liquid) = ($W - V_w$), where V_w is the "loss of weight." The so-called "loss of weight" is not a real loss, but only apparent by reason of the buoyant force of the liquid. Thus, a block of granite weighing 170 lb. per cu. ft. can be supported under water by an upward force of (170 − 62.4 =) 107.6 lb. per cu. ft. of granite. The difference, 62.4 lb. per cu. ft., is borne by the water, and whatever supports the water supports the difference also. Thus, when a ship moves into a drydock and displaces water from the dock, the bottom of the dock is not relieved of any weight at all.

The Hydrometer. A floating body rides higher in a heavy liquid than in a light one. The density and specific gravity, therefore, may be found by noting the depth to which a specially prepared float sinks. Such a device is called a **hydrometer.** The most common type is made of glass, consisting of a graduated stem above a hollow bulb, below which is a smaller bulb containing mercury to make the whole instrument float upright. By properly proportioning the weight and volume any desired degree of sensitiveness may be obtained. Hydrometers to suit various needs are obtainable in the market. The scale is graduated to read either specific gravity (referred to water) directly or according to some arbitrary scale. Of the latter the most widely used is the **Baumé scale.** (See p. 85 for equivalents.) **Twaddell's hydrometer** is used in England for liquids denser than water. See p. 84 for several special hydrometer scales. Fahrenheit's and Nicholson's hydrometers are arranged so that weights may be added to sink them to a standard mark on the stem. For details see text-books on physics. For precise calculations the temperature of the liquid should be measured and corrections made to the hydrometer indications. Nearly all liquids expand and contract much more than water for equal temperature changes near 60 deg. fahr.; see p. 293.

Determination of Specific Gravity and Volume of Solids by Immersion. By weighing an insoluble solid heavier than water in air and then in water, the specific gravity referred to water may be readily found, the specific gravity being (weight in air)/(loss of weight). Also, the volume of the solid = (loss of weight)/(weight of unit volume of water). The method is at once a convenient field method and one of precision when weights are accurately measured.

THE FLOW OF LIQUIDS

General Considerations Regarding Flow

Steady, Unsteady, Uniform and Non-uniform Flows Defined. Flow is called **steady** when conditions in the stream (*i.e.*, in any cross-section of the flowing liquid) remain unchanged, especially the quantity flowing per second, the velocity and the size of the stream. If, also, the size and shape of the stream remain nearly constant from point to point along the course, the flow is called **uniform.** If the size of the stream and the velocity change from point to point along the course, even though the flow be steady, it is called **non-uniform.**

Examples of **steady uniform flow** are the common flows **in pipes, hose, canals and rivers.** This sort of flow is seen to be associated with long conduits, and is controlled by the laws of fluid friction. **Pressure and head** are consumed (hence **"lost"**) in forcing the liquid along against the resistances caused by the portions of the conduit in contact with the liquid.

Steady non-uniform flow is exemplified by the flow **through orifices, nozzles, Venturi meters,** revolving water **turbines, weirs,** etc. It is seen to be associated with cases of changing velocity, where flow starts from a nearly quiet body of liquid or where a flowing stream changes its size and its velocity. For these cases **pressure and head** are not consumed and lost (except to a small extent), but are **converted into moving energy.**

Unsteady Flow proceeds **in waves,** pronounced pulsations **or surges,** or under rapidly changing conditions, *e.g.*, breaking ocean waves, pressure and velocity surges in a pipe line supplying a hydraulic ram, etc. No flow is steady or uniform when started. A short time elapses, of necessity, before steady conditions can be established. No ordinary flow is ever perfectly steady, there always being some pulsations and tremblings in velocity and pressure. The flow through a long pipe line carrying the discharge from a good double-acting plunger or piston pump with air chambers in good order is considered practically steady as far as flow calculations are concerned, although a pressure gage shows fluctuations of several per cent.

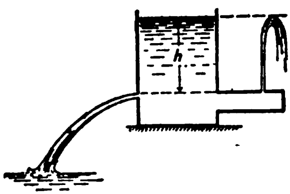

Fig. 5.

Interrelations of Heads. Potential, Pressure and Velocity Heads. When water spouts through an orifice in the side of a tank (Fig. 5), the jet has a velocity $V = \sqrt{2gh}$, nearly, where h is the head at the level of the orifice in the body of water well away from the orifice, and g is the acceleration constant of gravity. As a result of liquid friction at the orifice the actual velocity is 1 to 2 per cent. less than that given by the above formula. A jet issues in any direction according to the same law. If issuing nearly vertically, as in Fig. 5, the jet will rise nearly to the height of h ft. above the orifice. For great heights the friction of the air and the breaking-up of the jet reduce the height considerably. See p. 277. For a liquid flowing with a velocity V, the name **velocity head** is given to the quantity $V^2/2g$, which corresponds to the static or pressure head h that could cause or could be caused by the velocity V.

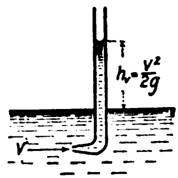

Fig. 6.

Fig. 6 shows the water surface of an open stream flowing with velocity V, and against the current of which is directed the opening of a **Pitot tube.** The water rises in the tube to a height of h ft. above the surface of the stream, such that $h = V^2/2g$ or $V = \sqrt{2gh}$; *i.e.*, the Pitot tube indicates the velocity head of the flowing water. If a tube of this sort is inserted in a pipe with water flowing under pressure, see Fig. 7, the water rises to a height h_v above the height in an open water column attached to a hole in the wall of the pipe; *i.e.*, the Pitot tube shows the sum of the pressure head and the velocity head of the water at the point of the tube, demonstrating that both sorts of head co-exist. The **Venturi meter** also illustrates the relation between pressure and velocity heads. This device (Fig. 8) consists of a conical, nozzle-like reducer followed by a more gradual enlargement to the original size, which is that of the pipe line in which the meter is laid. At 1, 2, and 3 the pressure heads in the pipe are shown as they appear when measured by open water columns. Experiment shows that h_2 is less than h_1 by very nearly the difference in velocity heads $[(V_2^2/2g) - (V_1^2/2g)]$, and that at 3, where the velocity is again V_1, the pressure head is nearly h_1 again, the diminution being accounted for by loss due to friction of the flowing water.

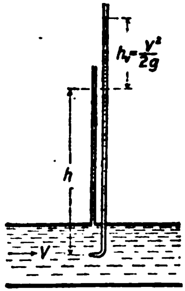

FIG. 7.—Pitot Tube.

If the pressure in the pipe is changed, but the rate of flow kept the same, *e.g.*, by manipulating valves to the left of 1 and right of 3, all the pressure heads rise or fall equal amounts, *i.e.*, the **differences in heads remain unchanged.** If the pipe is not level, Fig. 9, allowance is made as follows: All points are referred to any convenient reference level, *O-O*. The difference in level of the tops of the open water columns is $H_1 - H_2 = (h_1 + Z_1) - (h_2 + Z_2)$, where Z_1 and Z_2 are the heights of 1 and 2 above the datum level, and are called the **potential heads** of these points. With no flow, water would stand at the same level in columns 1, 2 and 3, for both the level and sloping pipes. Hence the differences $h_1 - h_2$ in Fig. 8, and $H_1 - H_2$, in Fig. 9, are due solely to the flow of the water. It is to be noted that the difference in pressure heads of the water in the pipe is $h_1 - h_2$ in both Figs. 8 and 9, but in Fig. 9 this difference is due partly to the hydrostatic effect of the difference of level. Consequently it is seen that a difference in pressure heads at two points along a stream (the velocity being different at these two points) may be due not only to a difference of velocity heads, but also in part to a difference in potential heads according to the hydrostatic law. Hence,

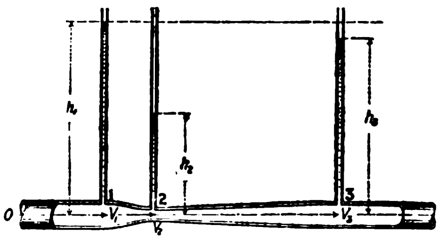

FIG. 8.—Venturi Meter.

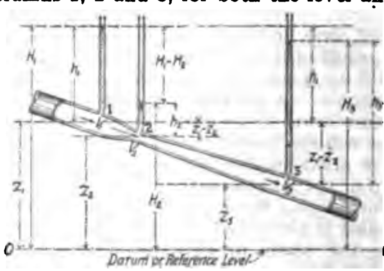

FIG. 9.

$$(h_1 + Z_1) - (h_2 + Z_2) = (V_2^2/2g) - (V_1^2/2g),$$
$$\text{that is, } h_1 + Z_1 + (V_1^2/2g) = h_2 + Z_2 + (V_2^2/2g)$$

This formula is the mathematical expression of **Bernoulli's Theorem.**

To summarize:

1. The **total head** present in a mass of flowing liquid is made up of potential head, pressure head and velocity head, mutually convertible, each into the other's form.

2. **Bernoulli's Theorem.** The total head in a particle of a continuous mass of flowing liquid at any one point in its stream line (*i.e.*, the path along which the liquid flows) is equal to the total head at any other position of its stream line, *provided* that there is no loss between the two positions due to friction, the giving up of work, etc., and no gain due to the application of outside work.

Flow Through Orifices

Flow of Water Through Orifices. The general law of flow is $V = \sqrt{2gh}$, in which V is the velocity of the jet at its smallest section near or in the plane of the opening, h is the head referred to the level of the center of the stream cross-section where the filaments of the issuing jet first become parallel.

The Standard Orifice for measuring or regulating purposes is the **sharp-edged orifice,** also called "orifice in thin plate." The jet contracts in size (Fig. 10*a*) just after coming through the opening of such an orifice. The area of the cross-section of the jet, at a distance out from the opening about one-half its diameter, is about 0.62 of the area of the opening. The average velocity past this contracted section is about 0.98 to 0.99 of $\sqrt{2gh}$. Hence, calling A the area of the opening, the **discharge of a standard sharp-edged orifice** is $Q = 0.61A\sqrt{2gh}$, Q being in cu. ft. per sec. when A is in sq. ft., h in ft. and g in ft. per sec. per sec. The value 0.62 is called the **contraction coefficient;** 0.98 to 0.99 is the **velocity coefficient,** and their product, or 0.61, is the **discharge coefficient.**

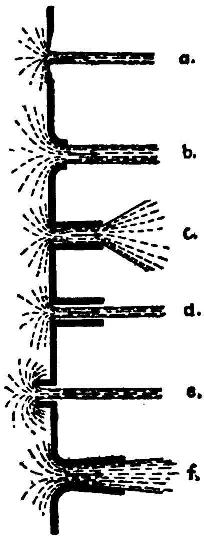

FIG. 10.—Types of Orifices.

For Values of $\sqrt{2gh}$ for any head, see Velocity Head Scale, Fig. 11, also Conversion Scales (cu. ft. per sec. to gal. per min. and per 24 hr.), Fig. 12.

Example. For a circular sharp-edged orifice, 1 in. in diam., under 50 ft. head, Q = 0.189 cu. ft. per sec. = 85 gal. per min.

Large Orifices with Low Heads, *e.g.*, sluice gates (see also Submergence). Unless the orifice is in a horizontal plane, *e.g.*, in the bottom of a tank, the top may be so much nearer the surface of the liquid than the bottom that the head at the level of center of orifice does not correspond to the real average velocity of all the water flowing out, but to more than the average, *i.e.*, the actual discharge is less than that shown by the formula. (For theoretical principle, see Weirs, p. 263.) When the head above the center is equal to the vertical dimension of the orifice, the discharge is only about 1 per cent. less, and when the head is twice the vertical dimension the diminution is

negligible, except for the most precise sort of investigations, for which a special calibration should be made to determine the exact coefficient. For lower heads, if h_c represents the head above the center and O the height of opening, Table 1 gives the percentage reduction in discharge and the corrected discharge coefficient for circular and rectangular orifices. The value of the coefficient, however, is not certain within from 1 to 3 per cent. without special calibration of the particular orifice.

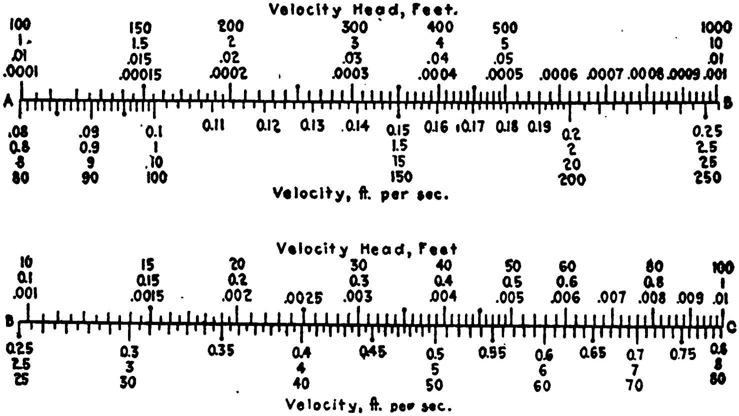

FIG. 11.—Velocity-Velocity Head Conversion Scale.

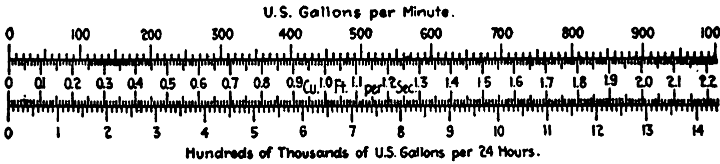

FIG. 12.—Conversion Scale. Cu. Ft. per Sec. to Gal. per Min. and per 24 Hr.

Table 1. Corrections for Rectangular and Circular Orifices

$\frac{h_c}{O}$	Rectangular Orifices: Reduction in discharge, per cent.	Rectangular Orifices: Corrected coefficient of discharge	$\frac{h_c}{O}$	Circular Orifices: Reduction in discharge, per cent.	Circular Orifices: Corrected coefficient of discharge
0.50	5.7	0.575	0.50	4.0	0.585
0.62	3.2	0.590	0.55	3.2	0 590
0.87	1.6	0.600	0.73	1.6	0.600
1.00	1.1	0.603	1.00	0.8	0.605

Hamilton Smith's Coefficients. Relying chiefly on his own precise experiments of 1885 and earlier, and on those of Poncelet and Lesbros, 1827–1835, Smith published tables of coefficients for sharp-edged orifices with square and round openings. The accompanying diagram, Fig. 13, shows the range and variations with head and diameter of these coefficients. The writer has found corresponding variations with small circular sharp-edged orifices ½ to 1 in. in diameter. It will be noted that there is little change in the coefficient for heads above 2 ft. and diameters greater than ½ in.

Variously Shaped Orifices. Typical shapes are shown in Fig. 10. (*a*) is a **sharp-edged orifice**; (*b*) is a **rounded-approach orifice**; (*c*) is a **short pipe** or **orifice in thick wall** (length = 2.5 to 3 × diam.), flowing full; (*d*) is a short pipe flowing like a sharp-edged orifice (see below); (*e*) is a **re-entrant short pipe**, or a **Borda mouthpiece** (when length < diam.); (*f*) is a **Venturi orifice**.

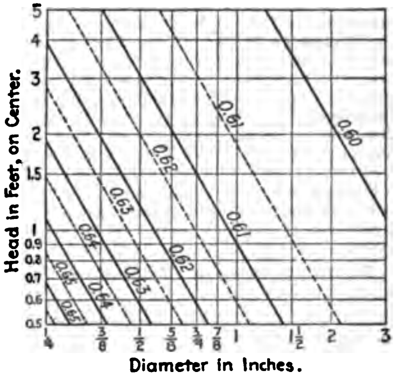

FIG. 13.—Coefficients for Sharp-edged Orifices. (Hamilton Smith.)

For (*b*), when the curve is not too abrupt and there is a short length (= ¼ to ½ diam.) of uniform bore where the jet issues, there is no contraction and the coefficients of discharge and of velocity are equal. The value for an average good, smooth, rounded orifice is 0.97; for the very best, 0.99; for one "well rounded and smooth" but with poor curvature, causing contraction and cross currents, the coefficient may be as low as 0.90.

For (*c*), at low heads, the tube flows full at the downstream end and the discharge is "broomy," *i.e.*, agitated and divergent, while at high heads, above 40 to 50 ft., the jet jumps free at the upstream corner as from a sharp-edged orifice, as shown in Fig. 10(*d*). If the jet is once made to jump free by a high head, the head may be lowered to only a few times the orifice diameter without bringing back the "broomy" flow condition. For "broomy" flow, the discharge coefficient is about 0.82; for clear flow it is 0.61, as for the sharp-edge. If the interior of the tube is greasy, the broomy flow will not occur, even at a low head. Obviously, this is an uncertain measuring device unless conditions are known.

For (*e*), when the length is 2.5 to 3 times the diameter, the above statements for (*c*) and (*d*) apply. The discharge coefficient is about 0.72 for "broomy" and 0.53 for clear discharge. For Borda's mouthpiece the coefficient is 0.53.

For (*f*), if the divergence angle is not greater than 7½ deg. nor the length more than 10 nor less than 5 times the smallest diameter, the tube will flow full, and the velocity through the narrow "throat" will be greater than $\sqrt{2gh}$, because the pressure is less than atmospheric at that point, causing a suction and making the effective head greater than h. Values of the discharge coefficient as high as 1.55 have been found by experiment. For the downstream end of the tube, the coefficient is always less than 1. With high heads the jet may jump free and discharge as (*b*).

Rounding or beveling the sharp upstream edge, even slightly, increases the discharge of an orifice. Placing a sharp-edged orifice close to a side wall or a corner "suppresses" the contraction and increases the discharge. For each side of a rectangular orifice on which contraction is suppressed, the discharge is increased about 3 per cent.

Attainable Precision in estimating the flow through a well-made sharp-edged or rounded-approach orifice depends on several factors. The orifice should be located at least 3 diameters away from any side wall and should be screened from the eddying effects of in-rushing water. If the head is low, guide vanes may be necessary to prevent whirlpools or vortices that obstruct the discharge. The size of the opening must be accurately measured. An error or uncertainty of a small percentage in the diameter makes twice that error in the discharging area; and a small percentage change in the head affects the discharge by half that percentage. **With accurate measurements** made with a knowledge of the various effects above mentioned, the engineer may feel assured that the **discharge will be within 3 per cent. of the calculated value.** By calibrating an orifice under the exact conditions of use, a future precision of 0.5 per cent. may be assured. Such an accuracy is seldom necessary except for precise testing or investigation. For an assured **precision within 1 per cent.**, maintenance of the orifice in "sharp-edge" condition is essential. A very slight dulling of the edge increases the discharge as much as 1 to 2 per cent. As to the effects of a little corrosion, the nature and extent of the change in the coefficient depend on those of the defect. If a corroded edge is tuberculated, the discharge is decreased. If the rust accumulation is brushed or washed off, the effect is the same as dulling the edge. Published tables that give **coefficients to three places**, *e.g.*, 0.615, **are deceptive,** in that they suggest a precision of 1 in 600, when 1 in 60 would be nearer to the accuracy expected by an experienced engineer for routine cases.

Submergence, or Discharge Under Water (*e.g.*, headgates). The coefficients already given apply in this case, but the value of h in the formula is the difference in water levels upstream and downstream from the opening. In the case of headgates there is liable to be uncertainty as to the effective area of the opening and of the amount of contraction. An uncertainty of from 5 to 10 per cent. is to be expected.

Several openings side by side (*e.g.*, headgates, intake screens and baffles) cause an increase in the discharge, if submerged on the downstream side. For openings close together increases of from 5 to 10 per cent. have been measured. Hence the engineer is somewhat safeguarded in his calculations by this fact. Results of a series of experiments on 4-ft.-square openings and tubes with differences of water levels of only a few inches, and with various lengths and entrance conditions, are given in *Bulletin* No. 216, Univ. of Wis., and in *Eng. News*, Jan. 9, 1908.

Velocity of Approach. If, some distance upstream from the orifice, there is a high velocity of approach due to a small approach channel or passageway or due to peculiar flow conditions, this **velocity head,** $V^2/2g$, should be added to the static head to obtain h for the formula. The percentage effect is seldom large unless the channel is so small as to interfere with the flow by reducing contraction, etc., and then, of course, there will be considerable uncertainty. (See Nozzles.)

The Miner's Inch. In some of the western states, water for mining and irrigation is sold by the **Miner's Inch,** which is the quantity of water that will flow through 1 sq. in. of an opening in a plank under a head of (usually) 6 in. The arrangement of the opening (from 1 to 4 in. high), the thickness of the plank (from 1 to 3 in.), the datum level for the measurement of the head (the top, center, or bottom of opening), as well as the head itself (from 3 to 9 in.), are largely matters of local custom and of state law. In Cal. and Mont., 40; in Col., 38.4; and in Ariz., Idaho, Nev. and Utah, 50 miner's inches = 1 cu. ft. per sec. In some old deeds in the eastern states water rights were sold by **inches,** but this commonly meant the discharge through 1 sq. in. of some portion of an old-fashioned water wheel under the head at the particular power site, and, of course, is an extremely variable unit, the subject of many controversies in courts.

Oils, if not too tarry or viscous, **and mercury have** been found to have practically **the same coefficients as water.**

Time Required to Empty Tanks through Orifices. An open tank whose cross-sectional area is uniform throughout its depth (*i.e.*, a vertical cylindrical or prismatic tank) will empty itself through an orifice, if there is no inflow, in just twice the time required to discharge the same amount of water under the initial head. For other shapes of reservoirs, the time may be computed by dividing the volume into five to ten horizontal layers and computing the time for each layer to discharge under the average head for that layer.

Nozzles. Fig. 14 shows typical forms of nozzles. The **orifice formula,** modified to include velocity of approach, **applies to** the flow from **nozzles.**

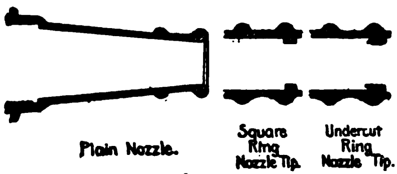

FIG. 14.—Types of Nozzles.

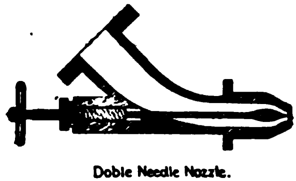

FIG. 15.

Ring and needle nozzles (Figs. 14 and 15) cause contraction of the jet, the amount depending on the shape. A plain conical nozzle (called a **smooth nozzle**) causes no contraction. The velocity coefficient of a **good nozzle is** from 0.97 to 0.99, and this is also the discharge coefficient for smooth nozzles. A **square-ring nozzle** is really a sharp-edged orifice with high velocity of approach. The discharge coefficient depends on the proportion of the area taken up by the ring (see curve in Fig. 16, determined by J. R. Freeman from his experiments). The use of ring and undercut-ring nozzles arose from the mistaken notion that a better fire stream could be thrown from these than from a smooth nozzle. **Undercut-ring nozzles** have discharge coefficients of from 0.58 to 0.72, varying as for square-ring nozzles. The discharge coefficient of a well-finished **Doble needle nozzle** (Fig. 15) referred to the smallest area of passageway (surface of frustum of cone) between needle and nozzle proper, is from about 0.82 to 0.95, depending on the "opening" or position of the "needle." When nearly closed the coefficient is lowest; it is highest at about a ¾-open or full-load operating position, for which the curves are especially designed.

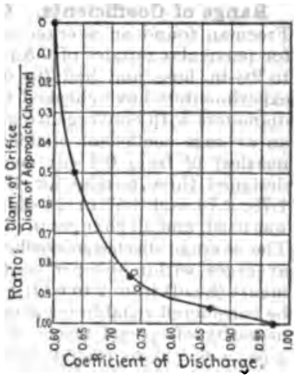

FIG. 16.—Discharge Coefficients for Square-ring Nozzles.

The **nozzle formula** is:

$$Q = CA_2\sqrt{\frac{1}{1-(A_2/A_1)^2}}\sqrt{2gh} = CA_2\sqrt{\frac{1}{1-(d_2/d_1)^4}}\sqrt{2gh}$$

where A_1 and A_2 are the cross-sectional areas at the base of the nozzle (*i.e.*, where the pressure head is measured) and at the discharge tip, respectively, and d_1 and d_2 the corresponding diameters. C is the discharge coefficient and h is the pressure head in the pipe or hose just upstream from the convergence, referred to the level of the center of the discharge tip. (For ordinary purposes, h is usually measured by a spring steam gage, or, more precisely, by an open water-column gage for low heads and a mercury gage for high heads. See p. 284.) h is sometimes called the **gage pressure head,** and $[h + (V_1^2/2g)]$ the **theoretical or total head.**

Effect of Neglecting the Velocity of Approach. The value of the expression $\sqrt{\frac{1}{1-(d_2/d_1)^4}}$, or its equal, $\sqrt{\frac{1}{1-(A_2/A_1)^2}}$, which corrects for the velocity of approach, is as follows for the range of probable values of d_2/d_1:

Table 2. Correction Factors for Nozzles

$\frac{d_2}{d_1}$	$\sqrt{\frac{1}{1-(d_2/d_1)^4}}$	$\frac{d_2}{d_1}$	$\sqrt{\frac{1}{1-(d_2/d_1)^4}}$
0.1	1.00005	0.5	1.033
0.2	1.0008	0.6	1.072
0.25	1.002	0.67	1.116
0.3	1.004	0.7	1.147
0.33	1.006	0.75	1.210
0.4	1.013	0.8	1.301

The correction factor is seen to be practically unity for any ratio d_2/d_1 less than 0.3, and therefore for such nozzles the following simpler formula may be used: $Q = CA_2\sqrt{2gh}$.

Range of Coefficients. Certainty. For smooth fire-hose nozzles, J. R. Freeman found an average coefficient of 0.977, with variations in averages for particular nozzles of 0.5 per cent. each way. The nozzles were attached to 2½-in. hose and had tip diameters of from ¾ to 1⅜ in. Several other experimenters have checked this value closely. For 1¾-, 2- and 2½-in. tip diameters with convergence angles of from 10 to 15 deg., Mr. Freeman found an average coefficient of 0.995, with a variation (in averages for individual nozzles) of from 0.4 per cent. above to 0.8 per cent. below. The writer designed three nozzles for 4-, 6- and 8-in. pipes, the tips being respectively 1.78, 2.74 and 3.57 in. in diameter; a common convergence angle of 25 deg. was used, and all changes in direction were made by easy curves of 9 in. radius. The average discharge coefficient was found to be 0.986, with variations in averages within 0.3 per cent. and extreme variations in individual experiments (heads from 2 to 60 ft.) of about 1 per cent. **A coefficient of 0.98** may be considered reliable for good, smooth nozzles within 1½ per cent., without necessity of special tests. The writer tested, as a nozzle on a 6-in. W. I. pipe, a 6 × 3-in. rusted, riveted-steel reducer, 24 in. long, with projecting flat rivet heads at both ends and along a longitudinal seam. The discharge coefficient was 0.91 under heads of from 2 to 50 ft., allowance being made for rivet heads reducing the tip area. This may be taken as the low limit for an **extra rough conical nozzle.** In case of such a nozzle the coefficient 0.91 means that 17.2 per cent. of the head is "lost," *i.e.*, used up in overcoming friction.

Fire-extinguishing Nozzle Streams: Range and Capacity. See p. 276.

The Venturi Meter. This device was invented by Clemens Herschel in 1887, and named after Venturi, who observed the principle in 1791. The general formula of this useful flow meter is discussed on p. 256. Referring to Fig. 9, the practical formula connecting the measured difference of pressure heads, $H_1 - H_2$, with the mean velocity of flow in the pipe line, is

$$V_1 = C\sqrt{\frac{1}{(d_1/d_2)^4 - 1}}\sqrt{2g(H_1 - H_2)}$$

The value of the coefficient C has usually been taken as 0.97. It appears from recent tests that a value of 0.98 may be safely assumed for the Venturi meters now on the market. Very precise tests made by the writer on new 12-in. meters, with throat diameters (d_2) of 4, 5 and 6 in., showed an average coefficient of 0.99 for throat velocities from 5 to 60 ft. per sec. The departure from the average value was mostly less than 0.5 per cent., and only in a few cases as much as 1 per cent. Precise tests on large Venturi meters after being in service for several years are lacking.

The **nominal size** of a Venturi meter is that of the pipe line in which it is to be placed. The throat diameter usually is made some size between 0.25 and 0.50 of the upstream diameter, depending on the rate of flow to be expected and on the pressure in the line. The throat velocity with the low rates of flow should be great enough so that the difference of pressure heads (often called **the Venturi difference**) will cause a measurable indication on the register or gage, but should not be so great as to cause the throat pressure to drop below atmospheric, lest there be trouble with air leaking into the gage and register connections. The upstream convergence angle of a Venturi meter may be from 25 to 30 deg., but the downstream divergence angle should not be greater than 7½ deg. The pressure connections usually are made to **ring piezometers**, consisting of circumferential passageways communicating to the interior of the meter by four or more small holes equally spaced around the pipe. The object is to assure the obtaining of the average pressure by avoiding dependence on a single piezometer hole subject to possible local disturbances. The ring piezometers are cast as part of the meter tube. The meters are usually made of cast iron and in several sections, bolted together. The throat is bronze-lined, very accurately bored to size and very smoothly finished. Venturi meters have been made of concrete and wood staves, the throats being lathe-finished bronze castings.

The **loss of head** caused by the presence of a Venturi meter in a pipe line, *i.e.*, $H_1 - H_3$, Fig. 9, is from $\frac{1}{6}$ to $\frac{1}{10}$ of the "Venturi difference" $H_1 - H_2$. Expressed in terms of the equivalent additional length (L) of pipe line of diameter d_1, *i.e.*, for same loss of head with same quantity flowing, V_1 being about from 2 to 5 ft. per sec., Venturi meters give: for ratio $d_2/d_1 = 0.5$, $L = 80d_1$; for $d_2/d_1 = 0.4$, $L = 170d_1$; for $d_2/d_1 = \frac{1}{3}$, $L = 430d_1$, and for $d_2/d_1 = 0.25$, $L = 1300d_1$. Improper angles of convergence and divergence cause higher losses.

FLOW OVER DAMS AND WEIRS

Weirs. A weir is a **bulkhead or dam** over which water flows, or a **notch** in the top of such a structure through which water flows. An orifice becomes a weir if the water surface upstream falls below its top edge. The velocity of approach is sometimes considerable, as for a low dam in a river at flood time, or it may be practically negligible, as for a small notch in the side of a large tank.

The theoretical discharge over a weir of width l is $Q = \frac{2}{3}lh\sqrt{2gh}$. This is two-thirds of the theoretical discharge through a rectangular orifice l ft. long and h ft. high under a head h. Actually, for a sharp-crested weir, contraction occurs at the crest. The under surface of the falling sheet of water rises as it leaves the sharp crest, just as for an orifice. The discharge coefficient is about 0.62, *i.e.*, $Q = 0.62\ (\frac{2}{3}lh\sqrt{2gh})$. This formula, for which the product of the constants $= 3.33$, may be expressed as $Q = 3.33lh^{3/2}$, and as such is known as the **Francis formula** for sharp-crested weirs. Q is in cu. ft. per sec., and l and h are in ft. (See Weir Discharge Scale, Fig. 17.)

Accuracy of Francis Formula. This formula is very widely used by engineers. It is **reliable within from 1 to 3 per cent. for heads above 0.3 ft.**, provided that (1) the weir bulkhead has a vertical upstream face and occupies the full width of the channel, (2) the crest is level, (3) the channel of approach is deep (*i.e.*, the weir bulkhead is high, so that the velocity of approach is small—see below for corrections), (4) there is free access of the air to the space below the falling sheet of water (*i.e.*, between it and the downstream face of the weir), (5) the head is measured a distance upstream from the weir of at least 4 times the head, (6) the side walls extend downstream from the weir (above the crest level) to prevent a lateral spreading as the water passes over the crest, and (7) due precautions in measuring are taken.

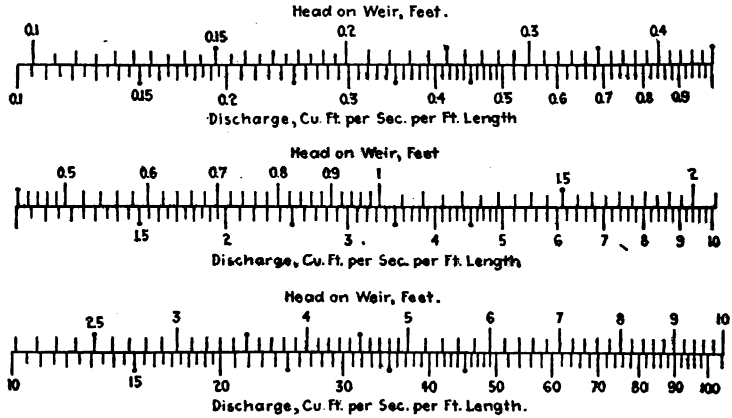

FIG. 17.—Weir Discharge Scale. Francis Formula.

For very low heads Francis formula results for discharge must be increased 3 per cent. when $h = 0.2$ ft., and 7 per cent. when $h = 0.1$ ft.

By a **sharp crest** is meant one with a sharp upstream corner from which the water springs. The crest itself may be of considerable thickness (but see under broad, flat crests below), and is frequently made of a steel plate or angle planed off and sometimes beveled on the downstream side to give a top flat portion from $\frac{1}{16}$ to $\frac{1}{8}$ in. wide.

Effects of Errors or Uncertainties. A small percentage error in head causes $1\frac{1}{2}$ times that error in discharge. Conversely, the allowable percentage error in head is $\frac{2}{3}$ that in discharge. Considerable errors in the measured head may be made by careless methods of referencing the crest level to the head gage scale, and by assuming that a non-level crest is level without knowing the average level. The mean level of the water surface must be measured, not the crests of the small waves or surges existing in all flowing water.

For a **rectangular notch** with vertical sharp-edged ends, contraction occurs at the ends as well as at the crest, and the discharge is reduced approximately as though the length of the weir were decreased by 0.1 h for each end contraction. Hence, the **Francis formula for a sharp-crested weir with two end contractions** is

$$Q = 3.33\,(l - 0.2h)h^{\frac{3}{2}}$$

This formula must not be used unless l is at least 2 times h. (See Narrow Rectangular Notches below.)

Cippoletti Trapezoidal Weir. Cippoletti found that a trapezoidal notch with end slopes 1 horizontal to 4 vertical (Fig. 18) just compensated for the reduction due to end contraction in a rectangular notch of the same crest length, and, accordingly, the simple Francis formula, $Q = 3.33lh^{3/2}$, may be used for such a trapezoidal notch. The crest length l must be at least 2 times h, and the crest should be 2 or 3 times h above the bottom of the channel of approach to avoid a velocity-of-approach correction (see Narrow Trapezoidal Notches below). The Cippoletti weir has become popular in the western states for measuring irrigation water.

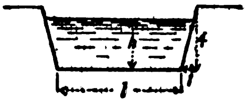

FIG. 18.—Cippoletti Weir.

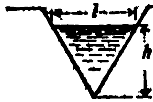

FIG. 19.—Triangular Notch Weir.

Triangular Notch. There are certain advantages in the triangular notch for measuring discharges that vary from a moderate maximum to a very small minimum, *e.g.*, 1 gal. per min., and where about the same degree of precision is desired whether the discharge is high or low. The formula for a sharp-edged notch (Fig. 19) is $Q = C(\frac{4}{15} lh\sqrt{2gh})$, where l is the width of the notch a distance h above the vertex, and C is a coefficient with a value of from 0.57 to 0.60, based on experiments with heads up to 3 ft. and vertex angles of 28, 60, 90 and 120 deg. The coefficient 0.57 was found for the 60- and 90-deg. weirs, and 0.60 for the 28- and 120-deg. weirs. Prof. Thomson found for 90 deg., 0.60, and for 127 deg., 0.62, heads 0.2 to 0.8 ft. Hence the discharge through a triangular notch (for which $l = 2h \tan \frac{\text{notch angle}}{2}$) is from 38 to 40 per cent. of that given by the discharge scale (Fig. 17).

Very precise experiments on 90-deg. V notches, with heads up to 10 in., have been made by James Barr (London *Engineering*, Apr. 8 and 15, and Oct. 28, 1910). With smooth upstream face and wide and deep tank, the coefficients at the same heads on several weirs were found constant within ½ of 1 per cent. for heads ranging from 3 to 10 in., and within 1 per cent. for heads as low as 1½ in. The tests show noticeable changes in discharge due to variations in roughness of upstream face of the notch plate. A surface like coarse emery increases the discharge over that for smooth brass some 2 per cent. (for a head of 0.3 ft.). It was found also that the tank upstream from the notch should be seven to eight times the head in width and three to four times the head in depth below the vertex to avoid, respectively, increases and decreases up to 1 to 2 per cent. in discharge with narrow and shallow tanks. As above, $Q = C(\frac{4}{15} lh\sqrt{2gh})$. For a 90 deg. notch $l = 2h$ and $Q = C(\frac{8}{15}\sqrt{2g})h^{5/2} = Kh^{5/2}$. With sharp-edged notches in smooth brass plates the formula $K = (0.2907 + 0.028/\sqrt{h})$, proposed by T. P. Strickland, applies. This is for Q in cu. ft. per min. and h in in. For Q in cu. ft. per sec. and h in ft., $K = (2.42 + 0.067/\sqrt{h})$ and $C = (0.565 + 0.016/\sqrt{h})$.

Narrow Rectangular and Trapezoidal Sharp-edged Notches with Crest Length Less than 2 Times h. Experiments on narrow rectangular notches beyond the applicability of the Francis formula, covering heads up to 3 ft. and widths down to 2.7 in., have shown that the formula $Q = 0.56\,(\frac{2}{3} lh\sqrt{2gh})$, *i.e.*, $Q = 3.00\,lh^{3/2}$, is reliable when h is as great as or greater than l. Hence for such cases we may take 90 per cent. of the discharge given by Fig. 17. For notches with l between h and $2h$ the coefficient increases and merges into values given by the Francis formula for two end contractions. For narrow trapezoidal notches the discharge may be expressed as the sum of that through a central rectangle and two triangles at the ends (see above formulæ). A discharge coefficient of from 0.58 to 0.60 has been found to apply.

The inverted notch, with discharge proportional to head, allows very simple regulating and recording devices to be used with it. It is constructed with curved sides such that the width of notch above the straight level crest decreases just enough to keep the discharge proportional to the head. The rate of flow is given by the formula, $Q = C \times 1.57\sqrt{2g}(l\sqrt{h})h$, where Q is in cu. ft. per sec., l and h are notch width and head, respectively, in ft. With $C = 0.60$, this becomes $Q = 7.55(l\sqrt{h})h$. The product $l\sqrt{h}$ is constant, and this gives the relation for the curves of the sides. Starting with some desired or convenient head for a value of the discharge, say near the probable maximum to be expected, the value of the notch width at that height above the crest is calculated from the above formula for Q. These values of width and head give the constant value $l\sqrt{h}$. It is not necessary to continue the side curves of the notch closer to the crest than about 1/32 to 1/8 in. (depending on the range of heads); they may terminate in short verticals to the crest. The ratio of the discharge shut off by reason of such an abrupt termination of the curves to the full opening discharge (if it could be secured) is $0.64\sqrt{h_1/h}$, where h_1 is the height of the end verticals and h is the head of water. For values of $h/h_1 = 400$, 100, 25 and 10, respectively, the percentage reductions in discharge are 3, 6, 13 and 20. Unless the notch curves are accurately constructed, large errors in estimated discharge are to be expected. For results of tests see *Eng. News*, Nov. 25, 1915.

Velocity-of-approach Effects have been variously expressed in the formulæ adopted by different engineers. Probably the simplest one, and yet one entirely adequate for our present knowledge, is a modification of the

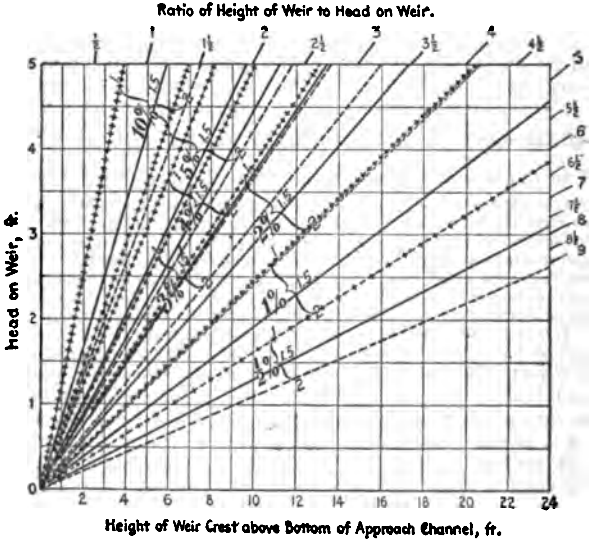

FIG. 20.—Correction Chart for Velocity of Approach at Weirs.

Francis formula, viz.: $Q = 3.33\, l[h + a\,(V^2/2g)]^{3/2}$, in which V is the mean velocity of approach (*i.e.*, $V = Q/A$, where A is the cross-sectional area of the stream in the approach channel upstream from the weir), and a is a factor dependent on the ratio of the head to the height of the crest above the bottom, and also on the distribution of velocities in the approach channel (see below).

For practical purposes a **diagram**, Fig. 20, has been prepared by the writer. This gives the percentage by which results from the Francis formula ($Q = 3.33\ lh^{3/2}$; see Discharge Scale, Fig. 17), are to be increased. The proper percentage may be read off directly when the height of weir crest and the head are known, for values of the factor a of 1.00, 1.50 and 2.00, and for intermediate values by interpolation. For assistance in selecting the proper value for a, a short discussion is given herewith, but it may be stated (see diagram) that when the height of crest above the bottom of the approach channel exceeds 4 times the head, the correction will be about 1 per cent. or less, practically negligible in many cases in view of other uncertainties. A 3 per cent. addition to the discharge corresponds to a ratio of height to head of about 2½ or 3. Only in cases where the head is about as great as the height does the correction reach 10 per cent.

For very low weirs with high heads, the value of the factor a approaches 1.00, while for deep channels with conditions causing high surface velocities upstream from the weir, the value of a is as high as 2.00 or even higher. Most cases lie between these extremes. Basin found average values of a to be 2.21, 1.70, 1.56 and 1.38 for weirs of heights 2.47, 1.64, 1.16 and 0.79 ft., respectively, the heads ranging from 0.3 to 1.4 ft. For **Bazin's formula** the results from the lowest weir were ignored and the value 1.67 used for a, but the velocity of approach is most important for low weirs. **Fteley and Stearns** found values of 1.59, 1.78 and 1.66 for weir heights of 0.50, 1.00 and 1.70 ft., heads from 0.23 to 0.92 ft. They used the value 1.50 for a in their formula, but this employs 3.31 instead of the Francis' 3.33, *i.e.*, for the main coefficient. Based on additional experiments, Fteley and Stearns used 2.05 for a for weirs with two end contractions. The writer's experimental experience covers cases where the value of a is as low as 1.15 and as high as 2.82, the former value for high heads over a low weir, *e.g.*, a 2-ft. head over a weir 1 ft. high, and the latter value for a case of high surface velocity and very low bottom velocity with heads up to 4 ft. over a weir 10 ft. high, as well as many intermediate cases.

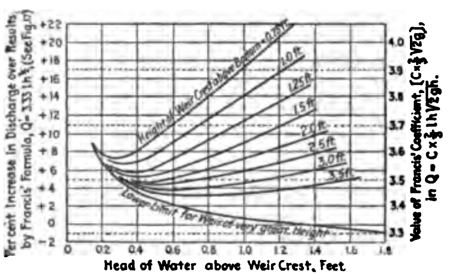

FIG. 21.—Results of Bazin's Experiments on Flow over Sharp-crested Weirs, Expressed in Terms of Francis's Coefficient.

The Fteley and Stearns Formula for sharp-crested weirs without end contractions is $Q = 3.31l[h + 1.5(V^2/2g)]^{3/2} + 0.007l$. For weirs with end contractions they recommended the factor 2.05 instead of 1.5. The units are ft. and cu. ft. per sec. They experimented with weirs from 5 to 19 ft. long (see *ante* for range of heights and heads). The formula is seen to be nearly the same as the modified Francis formula given above. **Hamilton Smith** suggested as average values for the velocity-of-approach multiplier, 1⅓ for weirs without end contraction and 1.4 for weirs with end contraction.

Bazin's Formula for sharp-crested weirs without end contraction is

$$Q = mlh\sqrt{2gh}, \text{ where } m = \left(0.405 + \frac{0.0098}{h}\right)\left[1 + 0.55\left(\frac{h}{p+h}\right)^2\right]$$

This formula eliminates the necessity of a separate velocity-of-approach correction by introducing the height of weir crest above the bottom of the approach channel, p. On this account it has been used to a considerable extent by engineers (see remarks above on the range of Bazin's experiments, etc.). The diagram, Fig. 21, shows the range of the experiments and the results in terms of the Francis coefficient so that discharge computations may be made in connection with the Francis weir discharge diagram, Fig. 17, without the necessity of using a table of Bazin's coefficient, m. It will be seen from the diagram, Fig. 21, that Bazin's formula gives higher discharges for very low heads and lower discharges for heads above 1.3 ft. (for a weir of great height) than does Francis's formula. For the low heads, from 0.1 to 0.3 ft., it is undoubtedly very near to the truth, as numerous recent measurements by several experimenters have shown, thus checking Bazin, Fteley and Stearns, Hamilton Smith and others. The so-called Bazin formula is only an approximation to his precise experimental data. Fig. 21 is prepared from his data, and, excepting the lower limit line, fairly represents Bazin's experiments.

Recommendations for the use of the diagram (Fig. 20) in connection with Francis's formula (see Discharge Scale, Fig. 17): Choose values of the velocity of approach factor a as follows: For cases where the head is greater than the height of crest, 1.00 to 1.3; for intermediate cases, 1.5; for cases where high surface and low bottom velocities prevail upstream from the weir, 2.00 or more. In important work the distribution of velocities should be measured by current meter or Pitot tube (see pp. 282 and 285). In this way one can approximate to the ratio of the mean velocity head for the water above the crest level to that for the full depth of channel. The value of this ratio may be taken as the value of a, with the assurance that the result will be, at least, on a basis firmer than if a compromise formula (*e.g.*, Fteley and Stearns's, Bazin's or Hamilton Smith's) is used for an extreme case. But refinement is unnecessary in a correction that amounts to only a small percentage of the total discharge. Thus, with a 2-ft. head over a weir 3 ft. high, the percentage additions to the Francis formula results are bout 4.5 per cent. for $a = 1.0$, and about 7.5 per cent. for $a = 1.5$. For this ase 6 per cent. would be chosen. The diagram and scale (Figs. 20 and 17) ive results accurate enough for weir measurements.

Flow of Water over Dams varies from about 20 per cent. less to 20 er cent. more than for a sharp crest of the same length and with the same head. For **broad, flat-crested dams,** the flat top wider than the head, the coefficient 2.64, instead of Francis's 3.33, applies, or, with sufficient accuracy, the discharge is 80 per cent. of that given by the Francis formula. If the upstream corner is rounded, the discharge may be greater. **Dams with steeply sloping upstream faces** (about 1 to 1) may have coefficients nearly as high as 4, as will also a thin vertical **bulkhead with a rounded upstream corner** (radius = 2 to 8 in. = thickness of bulkhead). **A very gradually sloping approach,** *e.g.*, 5 horizontal to 1 vertical, or a **rounding crest of large radius** introduces an appreciable friction effect, and the discharge may be no greater than for a sharp-crested weir. Non-vertical upstream faces on sharp-crested dams increase the discharge if inclined downstream and decrease it if inclined upstream, the coefficient being 3.10 for a 1 to 1 upstream and 3.73 for a 2 horiz. to 1 vert. downstream inclination, coefficients for intermediate inclinations being between these values. **If air is not allowed free access under the falling sheet** of water at the crest, the **discharge over** any **narrow-top weir** or dam **is increased,** but is also made less certain due to the tendency of the partial vacuum so formed to break at intervals and cause pulsating flow.

Submerged Weirs and Dams, where the water surface downstream from the dam is at a higher level than the crest, do not show much reduction in discharge, as compared with the unsubmerged condition, until the downstream head, or backwater, is nearly one-half the upstream head above the crest. This is especially true for broad-crested dams, whether flat or rounded or with easy upstream sloping faces, since in these cases there is a considerable surface drop to the water and a decided increase in velocity even before the water leaves the crest. This condition remains practically unchanged with submergence until the downstream backwater head is over half the upstream head, *i.e.*, high enough to smother the flow.

For experimental results on weirs, see "Weir Experiments, Coefficients and Formulas," by R. E. Horton (U. S. Geol. Survey W. S. & I. Paper No. 200).

Flow in Pipes

Flow of Water in Pipes. (See also Pitot Tube, p. 285, and Very Small Tubes, p. 275.) In any pipe or conduit through which water is flowing there is a continuous **loss of head.** This loss of head, also called **friction head,** limits the discharge that a certain reservoir head or pump pressure can cause through a pipe line. Fig. 22 shows a portion of a pipe line in which water is being forced uphill from A toward B. With no flow, *i.e.*, only standing water pressure, the head at B would be h ft. less than at A. But, owing to the flow, there is loss of head and the head at B is $(h + h_f)$ ft. less than at A, where h_f designates the friction loss of head. **The amount of loss of head depends on** (1) the velocity of the water; (2) the roughness of the interior surface of the conduit; (3) the diameter or size of the pipe or conduit; and (4) the length of the conduit. The pressure available at the end of a long pipe and the amount of flow depend largely on the last three items. The pressure of the water in the pipe has no effect, by itself, on the loss of head. For any particular pipe, experimental measurements indicate a law, $h_f = mV^n$, where h_f is the loss of head, V the mean velocity of the water and m and n are constants for a particular pipe of a particular roughness. The loss of head is found to vary directly with the length, and, for simplicity, h_f usually represents the loss of head per 100 or 1000 ft. of length. The value of n depends on the roughness of the interior surface of the pipe and varies from about 1.75 for very smooth pipes to about 2.00 for very rough pipes (see Very Small Tubes, p. 275). The value of m depends on both the diameter and the roughness.

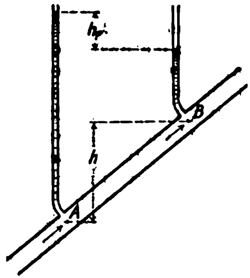

FIG. 22.

In arriving at a reasonably reliable formula for the ordinary pipes of engineering practice, there is considerable difficulty, chiefly for the following reasons: (1) There exists no standard of roughness; (2) the degree of roughness of a pipe's interior surface does not remain constant in service. The **experimental data do not indicate precise coefficients** but show a rather wide range of values from which the investigator must select limits and averages according to his judgment.

In one case a few months' rusting of a 4-in. wrought-iron pipe increased the friction 20 per cent. In another, incrustations due to 17 years' service increased the friction of a 48-in. cast-iron pipe 70 per cent. An unlined linen hose causes over twice the resistance of a high-grade rubber-lined hose. One year's growth of slime in a large aqueduct increased the friction 20 per cent. In these cases the discharges were reduced about half as much as the above-stated percentages for the same head.

Attainable Precision. A pipe, when new, may possibly discharge from 1 to 10 per cent., more or less, than did some other pipe line apparently exactly like it. This difference in performance may be expected to change appreciably after water has been flowing and standing in the pipes for several months, and quite pronouncedly after several years, especially with different waters and in different climates. Nevertheless, data are available that serve to indicate approximately how much such service effects as "a slight layer of rust," "a thin deposit of lime," "a growth of slime," "considerable tuberculation," "heavy incrustation," etc., may be expected to reduce the discharge through a pipe line or increase the loss of head if the same discharge is maintained. The formulæ and diagrams given herewith make due allowances for such of these effects as are stated with them.

Pipe-flow Diagrams. The diagrams in Figs. 23 and 24 give any two of the four quantities: discharge, velocity, diameter and loss of head, when the other two are known or assumed. Any point on the diagram corresponds to the intersection of four lines representing values of these quantities, as indicated. Fig. 23 is for general designing purposes for **average cast-iron and wrought-iron** (not riveted) **pipes in fair interior condition** (not tuberculated). It is based on the formula $h_f = 0.38\, V^{1.86}/d^{1.25}$,* in which h_f is the loss of head in ft. per 1000 ft. of length, V the velocity in ft. per sec. and d the diameter in ft.

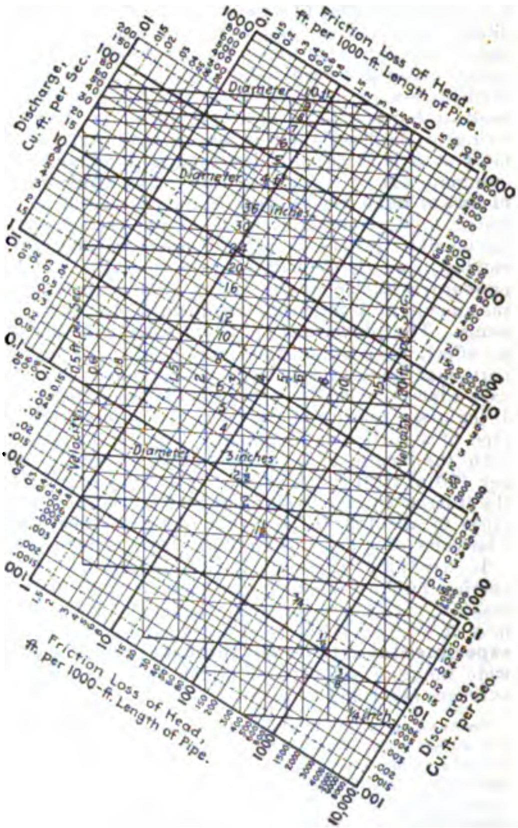

Fig. 23.—Pipe-flow Diagram for Cast-iron and Wrought-iron Pipes in Fair Interior Condition.

Reliability of Diagrams. The diagram probably will not give too high a discharge or velocity for a given friction head and should be within 10 per cent. for a pipe 5 years in service, excepting for very corrosive or highly mineralized waters, and assuming a sufficient velocity to prevent mud deposits. It may be taken as safe for cases where rapid growth of demand or other conditions would probably call for new or additional pipes within about 10 years. To safely assure discharges as great as calculated and friction heads not higher than calculated at the end of some 10 years of service, the diagram in Fig. 24 should be used. For new pipes (not riveted) Fig. 23 will give too low discharges and too high friction heads, *i.e.*, the results are on the safe side. These statements are based on many comparisons with actual experimental measurements covering a wide range of diameters and conditions. The diagram in Fig. 24 is for riveted and rough pipes (see p. 269).

* *Eng. Rec.*, Sept. 3, 1904, p. 281, and *Trans. Am. Soc. C. E.*, vol. 51, 1903, p. 308.

To show how results from these formulæ and diagrams compare with those from the Chézy formula (p. 273), Table 3 gives values of the Chézy coefficient *C* that will produce the same results.

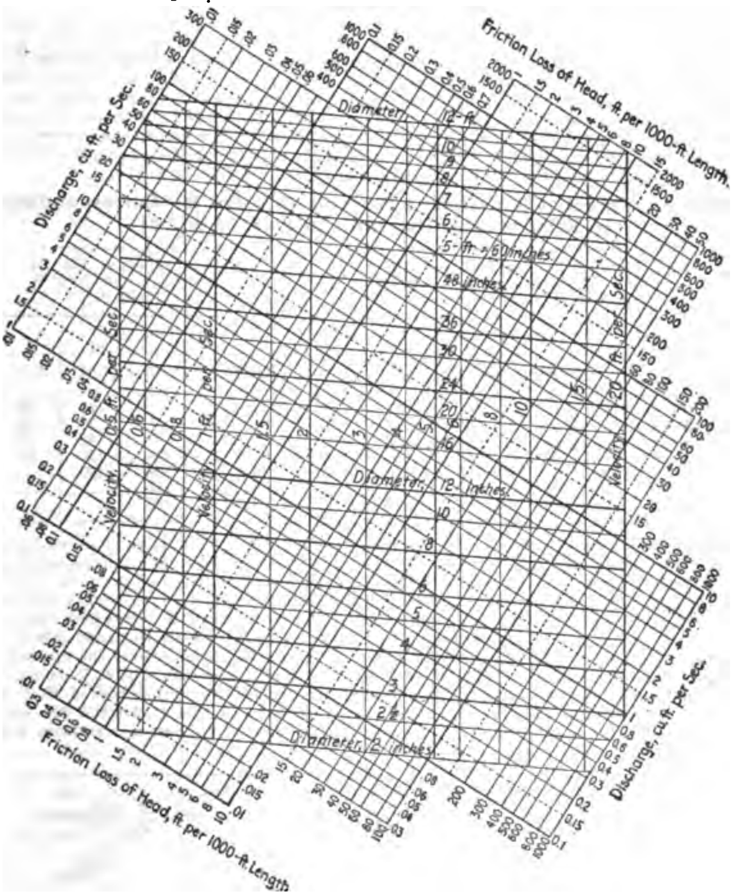

Fig. 24.—Pipe-flow Diagram for Riveted and Rough Pipes, *e.g.*, Cast-iron and Wrought-iron Pipes After 10 Years of Service.

Plain Pipe Problem. A reservoir is to be supplied by a pump through a wrought- or cast-iron pipe line 2800 ft. long containing several elbows, tees, etc., and making the total equivalent length (see p. 275) 3000 ft. The difference of elevation is 100 ft. and the rate of pumping is to be 200 gal. per min. What size of pipe should be laid, and for what working pressure should the pump be specified? Solution: 200 gal. per min. = 0.446 cu. ft. per sec. (see Conversion Scale, Fig. 12). Fig. 23 shows lines for pipes from

$2\frac{1}{2}$ to 12 in. in diam. crossing this discharge value, and the corresponding friction losses of head range from 320 ft. to 0.14 ft. per 1000 ft. of length. The problem, then, is to select a pipe large enough to avoid great friction but not so large as to cause too great a first cost. The friction head for an 8-in. pipe, for $Q = 0.446$ cu. ft. per sec., is seen to be 1 ft. per 1000 ft., or a total of 3 ft. for the 3000 ft. of pipe line. A 6-in. pipe causes about $(4 \times 3 =)$ 12 ft. total loss; a 5-in. pipe $(10 \times 3 =)$ 30 ft.; a 4-in. pipe, $(30 \times 3 =)$ 90 ft., etc. **The pump must force water against a head of 100 ft. plus the friction loss of head.** It would be unwise to use smaller than a 6-in. pipe on account of the large loss of head and consequent wasted work by the pump (see Most Economical Diameter, p. 274). It is seen that, for a given discharge, the loss of head changes much for a small change in diameter. Approximately, h_f varies inversely as d^5 for a given Q; for example, doubling the diameter reduces the loss of head to about $\frac{1}{32}$. See Useful Relations, p. 273, and Percentage Effects, p. 274.

Table 3. Values of C in Chézy's Formula ($V = C\sqrt{Rs}$) Corresponding to Results from Diagrams in Figs. 23 and 24

Value of d in ft.	Formula for diagram, Fig. 23: $h_f = 1000s = 0.38\, v^{1.86}/d^{1.25}$, or $V = 174\, R^{0.67} s^{0.54}$ — Values of s				Formula for diagram, Fig. 24: $h_f = 1000s = 0.50 v^{1.95}/d^{1.25}$ or $V = 117\, R^{0.64} s^{0.51}$ — Values of s

Compound Pipe Problem. A pipe line is to be made up of sections of several different diameters, the same Q flowing through all. Required to find the discharge Q for assumed diameters and lengths. Solution: Find such portions of the total available head for each pipe as correspond to equal values of Q. Approximate results may be quickly obtained by noting that, for a fixed Q, h_f varies nearly as l/d^5, where l is the length of pipe of a certain diameter. Thus, if the total available friction head is 80 ft., and there are 3000 ft. of 12-in. pipe and 2000 ft. of 8-in. pipe, the ratio of the two friction heads is $(3000/12^5) \div (2000/8^5) = \frac{3}{2} \div (\frac{12}{8})^5 = 0.198$, or, say, $\frac{1}{5}$, i.e., $\frac{1}{5}$ as much loss of head in the 12-in. pipe as in the 8-in. pipe. Hence, the friction head of 80 ft. is divided into 13.3 ft. and 66.7 ft., or, per 1000 ft., into 4.4 and 33.4 ft. for the 12- and 8-in. pipes, respectively. Fig. 23 shows that $Q = 2.8$ cu. ft. per sec. satisfies the friction requirements of both pipes.

Branching Pipe Problem. It is sometimes necessary to design several branching pipes, fed by a single pipe, to discharge certain definite quantities. Such problems are readily solved by trial, using the diagrams. The pressure head where the branching occurs is assumed (or else the loss of head to the branching), and then for the corresponding friction heads the discharges for the several branches are found from the diagrams. The sum of these discharges must, of course, equal the discharge of the main pipe. If it does not, a second trial is made. In Fig. 25 the reservoir A is to supply reservoirs C and D, respectively 10 and 30 ft. lower than A. A–B = 4000 ft., B–C = 2000 ft., and B–D = 5000 ft. What sizes of pipes are necessary to supply 20 cu. ft. per sec. to C and 5 cu. ft per sec. to D? As a trial, assume 5 ft. loss from A to B, leaving 5 ft. for B–C and 25 ft. for B–D, or 2.5 and 5 ft. per 1000 ft., respectively. The discharge Q for A–B is $25 + 5 = 30$ cu. ft. per sec., and the assumed friction head is $\frac{5}{4} = 1.25$ ft. per 1000 ft. On the diagram the intersection of lines for 30 cu. ft. per sec. and 1.25 ft.

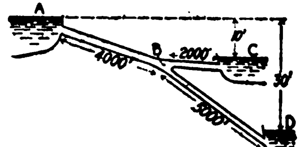

FIG. 25.

friction head gives a diam. of 38 in. Also, 20 cu. ft. per sec. and 2.5 ft. give a diam. of 28 in.; and 5 cu. ft. per sec. and 5 ft. give a diam. of 14 in. These are the desired sizes, but, of course, practically there would be valves located at the reservoirs to adjust the discharges to the needs from time to time, this being a matter for which the design of the pipe sizes does not provide. If it is desired to make the pipes in *A–B* and *B–C* of the same diameter, more loss of head must be allowed from *A* to *B*, say 8 ft. This gives about a 34-in. pipe for both *A–B* and *B–C*, and a 24-in. pipe from *B* to *D*. On the other hand, if it be planned to limit the diameter for *B–D* to 12 in., the loss of head in *B–D* for this diameter and the required discharge (5 cu. ft. per sec.) is first investigated. Fig. 23 shows that the loss of head would be ($12 \times 5 =$) 60 ft., and, since there is only a total head of 30 ft. available, a 12-in. pipe is not large enough for *B–D*.

Looping Pipe Problem. When a pipe branches into two or more pipes which again come together, or are cross-connected (Fig. 26), the arrangement is known as a "loop." In such a case, there is the same total loss of head for each branch, although the loss per 1000 ft. may be different because of different lengths. For example, for fire protection purposes it is desired to have available at *B* a supply of 2500 gal. per min. and 100 lb. per sq. in. hydrant pressure with water flowing. What pressure must be maintained at *A* with this volume flowing and this pressure maintained? Solution: To facilitate computation, note at once that, for a fixed h_f, Q varies nearly as $\sqrt{d^5/l}$. Hence, the ratio of the Q in the 10-in. pipe to that in the 8-in. pipe is about $\sqrt{10^5/1000} + \sqrt{8^5/1800} = \sqrt{1.25^5/0.55}$ = about 2.35. 2500 gal. per min. = 5.57 cu. ft. per sec. (see Conversion Scale, Fig. 12), and dividing this into two parts, one 2.35 times the other, gives 3.91 and 1.66 cu. ft. per sec. In Fig. 23, at the intersection of 3.91 cu. ft. per sec. and 10 in. diam., it is seen that $h_f = 19$ ft. per 1000 ft., and for 1.66 cu. ft. per sec. and an 8-in. pipe, that $h_f = 11$ ft. per 1000 ft., or 20 ft. for the 1800-ft. length. This is a close enough check, and the loss of head from *A* to *B* may therefore be taken as 20 ft., or ($20 \times 0.433 = 8.7$), say 9 lb. per sq. in. drop in pressure, *i.e.*, the pressure at *A* must be 109 lb. per sq. in. If the whole discharge flowed through the 10-in. pipe alone, the loss of head would be 36 ft., or 15.6 lb. per sq. in. drop in pressure (for losses in elbows, tees and hydrant and slight corrections to above, see p. 275).

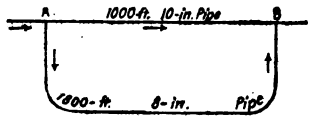

FIG. 26.

Approximate Pipe Formulæ. The well-known **Chézy formula** is $V = C\sqrt{Rs}$, and this is applicable to both pipes and open channels. V is the mean velocity (= discharge ÷ cross-sectional area = Q/A); C is a coefficient; R is the **hydraulic radius** (= cross-sectional area ÷ wetted perimeter = $d/4$ for a circular pipe); s is the **hydraulic slope** [= loss of head (or the surface fall, for open channels) in ft. per ft. of length]. The value of C usually ranges from about 50 to 150 (see Table 3). For offhand estimates, 100 is taken for moderate roughness.

The **Fanning formula** is $h_f = 4f(l/d)(V^2/2g)$ where h_f is the total loss of head, f a friction coefficient, l the length of the pipe and d its diameter, V the mean velocity, and g the acceleration constant of gravity. The value of f usually ranges between 0.004 and 0.010. For offhand estimates, 0.006 is taken for moderate roughness. The Chézy and Fanning formulæ are essentially the same, for $s = h_f/l$ and $R = d/4$, hence $C = \sqrt{2g/f}$ and $f = 2g/C^2$. They are usually accompanied by tables giving values of f and C, which are not constant but vary with V and d. The use of these formulæ, however, is being superseded by the use of those with a constant coefficient and odd decimal exponents.

Useful Relations. From the Fanning formula, $h_f = 4f(l/d)(V^2/2g)$, it is seen that h_f varies as $(l/d)V^2$ if f be assumed constant, which, for a moderate range of values, is approximately true. Introducing into this relation the discharge, Q ($= \pi d^2 V/4$), it is apparent that h_f varies as $(l/d^5)Q^2$. Also, Q varies as $d^{5/2}\sqrt{h_f/l}$, d varies as $Q^{2/5}/(h_f/l)^{1/5}$, and l varies as $h_f d^5/Q^2$. These relations enable one, at first trial, to make close estimates in cases where it is necessary to compare the (unknown) values of Q, h_f, d or l for two or more pipes in terms of the other (known or assumed) quantities.

Percentage Effects due to a change, uncertainty or error in any one factor: The above relations show that, for any pipe line under consideration, the other factors remaining the same, a small percentage change in available friction head causes ½ that per cent. change in the discharge Q, or corresponds to ⅕ that per cent. change in diam. (in opposite way). A small change in Q corresponds to twice that per cent. change in h_f, or ⅖ that in d; in d corresponds to 2½ times that per cent. change in Q, or an opposite change of 5 times that per cent. in h_f; in l corresponds to ⅕ that per cent. change in d, or an opposite change of ½ that per cent. in Q.

The considerable effect of small variations in diameter on the discharge and friction head are thus emphasized. To illustrate, if the diameters of two nominal 6-in. pipe lines are actually 5⅞ and 6⅛ in., a difference of 4 per cent., the discharge of the latter, with the same h_f, will be 10 per cent. more and the friction head, with the same Q, will be 20 per cent. less than the former, due solely to the difference in diameters. If the smaller diameter is in whole or part the result of rusting, tuberculation or incrustation, the increased roughness will still further decrease the discharge or increase the friction head if the same Q is forced through the pipe.

Siphons are arrangements of pipe or hose to cause liquids to flow from one level, *e.g.*, A in Fig. 27, to a lower level C, over an intermediate summit B. Before flow will start the pipe must be filled with the liquid, either by pumping from the end or by pouring in at the summit B. Valves are located, usually, at A and C. B cannot be more than 34 ft. above A (at sea level) *less* the friction head from A to B *less* the velocity head in the pipe. With this limitation calculations are made as for any pipe, the head being the difference in level between A and C. If the pressure at B is low, the dissolved air in the water is liberated and may accumulate in sufficient quantity to stop the flow, unless there is provision for removing it. A low summit, a high velocity and a small pipe tend to counteract the accumulation of air.

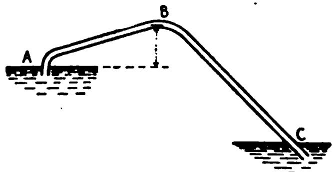

Fig. 27.—Siphon.

The Loss of Head Due to Curves, Elbows, Meters, Etc., may be expressed as equal to the loss in certain additional lengths of straight pipe. When these lengths are expressed in **pipe diameters** instead of in feet, it has been found that the value is nearly enough constant for a certain source of resistance so that a single average value may be used as sufficiently exact for designing purposes. Actually, these resistances are not entirely concentrated in the fitting itself. They create a disturbed, abnormal flow that does not return to normal until some distance downstream. The values given in Table 4 are for the total extra loss.

The Most Economical Diameter of a Pipe Line where pumping is required or where water power is to be delivered, *i.e.*, where it is desired to reduce the friction head as much as possible without increasing too much the diameter and thus the first cost, may be calculated by the following rule:

The sum of the annual value of the power lost by friction and the annual cost of the pipe line must be a minimum. The friction head for each of several diameters delivering the desired volume (in cu. ft. per sec.), may be found from the pipe diagrams, Figs. 23 and 24. The corresponding theoretical wasted h.p. is $Qh_f/8.8$. For pumps this should be increased 20 to 40 per cent., and for a water-power plant it should be reduced 20 per cent. because of the efficiency factor of the machinery. The **annual cost of the pipe line,** or rather that portion of it that would be different for different sizes of pipe, **includes interest** on the cost of pipe and construction **and depreciation.** Obviously, in deciding on the annual value of 1 h.p. and the per cent. annual depreciation in value of a pipe line, economic as well as engineering considerations must be taken into account. (See *Trans. Am. Soc. C. E.*, vol. 59, 1907, pp. 173–194.)

Table 4. Equivalent Resistances of Curves, Elbows, Meters, Etc., Expressed in Lengths of Straight Pipe

Nature of Resistance	Length of straight pipe to cause equal loss of head, expressed in pipe diameters
Square-edged entry. Upstream end of pipe flush with inside face of reservoir wall	20
Entry like Borda's mouthpiece (see Orifices)	40
Rounded entry or very large radius bends	None
90-deg. curves, smooth,* same inside diam. as pipe:	
Center-line radius = diam. of pipe	20
Center-line radius = 2 to 8 diams	10
90-deg. elbows, common screw end, short turn (experiments on ½- to 6-in. ells.)	30
Tees, common screw end, full size branch (experiments on 1- to 4-in. tees)	60
Square elbow (intersection of two cylinders)	50
Water meters †	
Disk, or wobble type	135 to 400
Rotary	400
Reciprocating piston	600
Turbine wheel type	200 to 300

For Venturi water meters, see p. 263, and for hydrants for fire hose, see p. 277.

† Different makes of meters and different sizes of the same make vary considerably.

Flow in Very Small Tubes follows a different law from that for ordinary-size pipes. The friction head varies as the velocity, and is very sensitive to the temperature of the water. The experiments of Poiseuille (1846), Hagen (1854), Reynolds (1883), Coker and Clement (1903), and Saph and Schoder (1903) on glass, brass and lead tubes with internal diameters ranging from 0.001 to 0.631 in. show an average value of about 500 for C in the formula $V = C(h_f/l)d^2(t + 10)/60$, where h_f and l are friction head and length, respectively, both expressed in same units, d the diam. in in., t the temperature of the water in deg. fahr., and V the velocity in ft. per sec. For the larger tubes this formula holds only at very low velocities, viz., the velocity must be less than about $V = 0.37/d^{0.85}$, V in ft. per sec., d in in. This gives roughly the "**critical velocity,**" above which the flow changes from "stream-line" to "eddy" motion and the friction head varies as a higher power of V. The critical velocities from above formula for various diameters are: 1 in., 0.37 ft. per sec.; ½ in., 0.66; ¼ in., 1.2; ⅛ in., 2.2; 1/16 in., 4.0; 1/32 in., 7.1.

Flow of Oil in Pipes. The resistance to the flow of oils lighter than about 30 deg. Baumé, sp. gr., 0.875) is not much different from that of water. The value 96 for C in the Chézy formula ($V = C\sqrt{Rs}$) is used in the oil fields in designing pipe lines for crude oil (42–43 deg. Baumé, sp. gr. 0.814 to 0.819). One per cent. is added for each 3 deg. Baumé, *i.e.*, lighter oils flow more easily. As pumping is universal, diagrams based on the more practical form of the formula, viz., $Q = 1.125\, d^{2.5}\sqrt{p/l}$, are used, in which

Q is expressed in bbl. (of 42 U. S. gal.) per hour and d in in.; p is the necessary pump pressure in lb. per sq. in. and l the length of line in miles. Friction increases with cold oils in winter and decreases in summer. Deposits of paraffin in the pipes conveying crude oil reduce the effective diameter and increase the friction. "Scrapers" are therefore driven through the pipes periodically to clean away the paraffin. Exceedingly viscous asphalt-base oils having a specific gravity of about 0.97 (14 deg. Baumé) may be pumped through a long line by using a "rifled" pipe and mixing 10 per cent. of water with the oil. (*Eng. News*, June 7, 1906, and *Eng. Rec.*, May 23, 1908.)

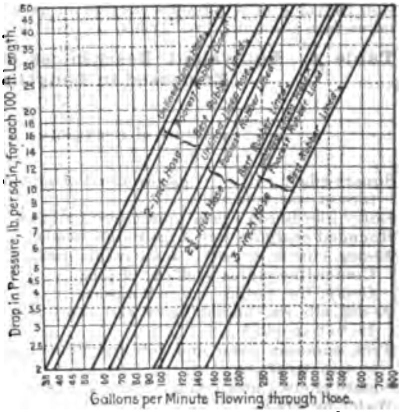

FIG. 28.—Loss of Pressure in 100 Ft. of Fire Hose at Various Rates of Flow.

Fire Hose and Fire-extinguishing Streams. The roughest sort of hose is the unlined linen or cotton woven, and the smoothest is the heavy rubber-lined hose with the fabric interstices so well filled with rubber that the inside remains smooth even under high pressures. A poor grade of rubber lining, or a poor fabric, or both, allow the rubber to be forced into the fabric, when under water pressure, and the interior of the hose may become nearly as rough as if there were no rubber lining at all. In purchasing what purports to be high-grade hose, it should be tested not only for strength to resist bursting but also for loss of head. The diagram in Fig. 28 shows the **loss of pressure** per 100 ft. of length for various rates of flow **in various grades of** 2-, 2½- and 3-in. internal diameter **hose.** Fig. 29 shows the **discharge from** various sizes of **smooth nozzles** for various pressures in the hose close to the nozzle. These diagrams are based on J. R. Freeman's experiments, *Trans. Am. Soc. C. E.*, 1889. Fig. 30 is a diagram showing the ranges, horizontal and vertical, of "good fire streams" and of "average of main body of stream," for various pressures in the hose line at nozzle, By **a good fire stream** is meant one that, at the range in question, has not broken into spray and that projects about three-fourths of the water through a 10-in. circle and nine-tenths of it through a 15-in. circle. The "main body of stream" and the "extreme drops" carry much farther, but the water is too much spread out to be able to penetrate a hot fire and reach the burning materials before evaporating. **A first-class fire stream** is one from a nozzle of at least 1¼ in. tip diameter with at least 40 lb. per sq. in. pressure in the hose

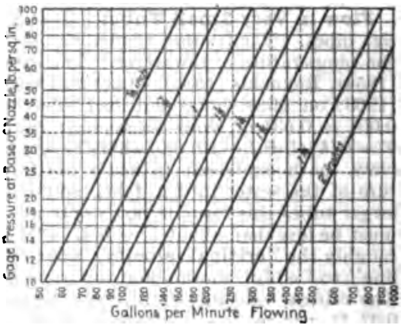

FIG. 29.—Discharge from Fire-hose Nozzles at Various Pressures.

close to the nozzle. For 1¼ in. and 40 lb. the discharge from a smooth nozzle is 240 gal. per min. Such a stream (see Figs. 29 and 30) will be effective as a good fire stream for a height of 60 ft. above the nozzle or for a horizontal distance of about 57 ft., the nozzle being pointed at angles above the horizontal of about 75 deg. and 32 deg., respectively, for farthest throw.

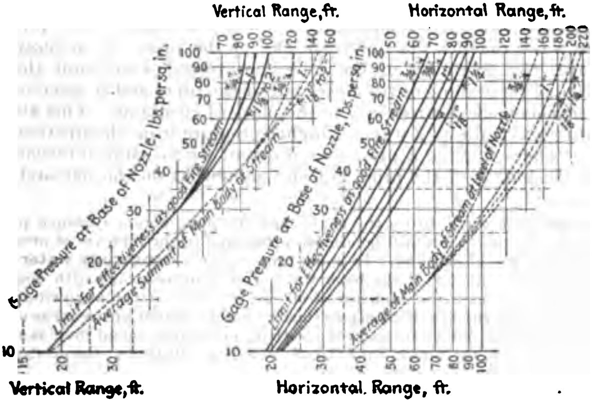

FIG. 30.—Vertical and Horizontal Ranges of Fire Streams.

Extra Losses of Pressure. With as many streams flowing as there are connections on the **hydrant**, the loss of pressure ranges from about 2 to 10 lb. per sq. in., but the total loss from street main to hose connection need not exceed 5 lb. with ample-size waterways in the pipe connections and a well-designed hydrant. **Projecting washers** at the hose couplings cause an extra loss of head; *e.g.*, a single washer 5/16 in. thick with a hole 2.28 in. in diam. used in a 2½ in. hose was found to cause an average loss of 0.56 lb. per sq. in., and a 2-in. washer caused a loss of 3.11 lb. per sq. in., the rate of flow being 240 gal. per min., or a velocity of about 16 ft. per sec. From this an idea may be gained of the resistance caused in small wrought-iron pipes by failure to remove **inside burrs** due to cutting off with wheel cutters. Failure to open fully hydrant valves causes much loss of pressure.

Practical Recommendations for Fire-protection Installations. Hydrants should be located at such intervals that not over 300 ft. of hose need be laid in any one line, and so that about ten first-class fire streams can be concentrated on any large building. The drop will amount to 14 lb. per sq. in. for each 100 ft. of the very best 2½-in. hose, and as high as 30 lb. for a rough quality hose (when 240 gal. per min. are flowing). A main pressure of 100 lb. per sq. in. during a fire is desirable, but, if the hose lines are rough and 500 ft. long, fire protection cannot be assured unless a pressure of 200 lb. is maintained at the hydrant. For important buildings the mains and laterals to hydrants should be at least 6 in. in diameter and as short as possible.

Water Hammer is the **shock produced by** the arrival of a **pressure wave** at an obstruction in a pipe line. The obstruction may be a closed end ("dead end"), the entrance to a smaller pipe, a partially closed valve, etc. The pressure wave may be caused by the operation of a reciprocating pump, by a pressure engine taking water intermittently from a main, by the sudden closure or partial closure of a valve or faucet, or, in general, by any sudden change of pressure at any point of a pipe line full of water. The **pressure wave** so caused **travels** through the water in the pipe at about four times the velocity of sound in air. In the case of a valve or water-wheel gate at the end of a long pipe line with flowing water suddenly closed, wholly or partly, there is a sudden increase of pressure at the place of checking due to the compression of the water suddenly arrested. This increase in pressure is considerable if the rate of checking the flow is rapid and the change of flow is large. The wave or surge of increased pressure travels upstream at high speed, *i.e.*, the flow is not changed instantly throughout the pipe length. When the wave reaches the upstream end of the pipe, *e.g.*, a reservoir or a larger main, the elasticity of the now compressed water and that of the distended pipe force some of the water out of the pipe, and a wave of reduced pressure travels back downstream to the place of checking. This abnormally low pressure wave allows a wave of higher pressure from the upstream end to follow it. There is thus a pressure vibration whose time interval depends chiefly on the length of the pipe, but also somewhat on the size and material of the pipe.

If a high-pressure wave, in its travel through the pipe, enters a branch pipe with a closed, or "dead," end, there will be almost a doubling in the increase of pressure when the wave strikes the closed end. In some pipe systems **dangerous water-hammer pressures** are built up, for, if the back wave from a branch pipe with dead end has access to another branch the high pressure may receive further augmentation. The intensity of the first pressure shock is practically as great farther upstream as at the place of checking. Because of friction and the elasticity of the pipe metal there is some dying away in intensity, but the notion that the effect is concentrated at the downstream end of the arrested column of water is incorrect.

The **intensity of** the **excess pressure** in the "hammer" wave depends on the amount of "extinguished" velocity. Thus, practically the same excess pressure is produced by suddenly reducing the velocity from 7 to 4 ft. per sec. as by entirely stopping a velocity of 3 ft. per sec. If the flow is not checked rapidly, so that the first pressure wave has time to travel upstream to the end and back again several times while the checking is in progress, the excess pressure is very much reduced. Hence, the wisdom of using slow-closing valves on long pipe lines. (See Relief Devices below.)

For **small pipes**, 2 to 6 in. in diameter, Joukovsky's experiments show an **increase of pressure** of about 60 lb. per sq. in. for each ft. per sec. of extinguished velocity. The speed of the pressure wave was found to be about 4200 ft. per sec. For a 24-in. cast-iron pipe the increase of pressure was about 45 lb. per sq. in. for each extinguished ft. per sec., and the speed of transmission about 3300 ft. per sec. These experiments agree well with theory, which gives the formulæ

$p = V\sqrt{Ew/g}$; $S = \sqrt{Eg/w}$, and also $p = V\sqrt{(w/g)\ (EE't)/(tE' + dE)}$; $S = \sqrt{(g/w)\ (EE't)/(tE' + dE)}$. [See Church's "Hydraulic Motors" (J. W. Wiley & Sons), and *Proc. Am. Water Works Assn.*, 1904.] In these formulæ p is the excess pressure intensity and S the speed of transmission of the pressure wave through the water in the pipe. The first two simpler formulæ consider the pipe as perfectly inelastic. The last two formulæ take into account the elasticity of the metal of the pipe. V is the extinguished velocity in ft. per sec., w the weight of 1 cu. ft. of water, $g = 32.2$, E the bulk modulus of elasticity of water = about 300,000 lb. per sq. in., E' the linear modulus of the pipe metal = about 30,000,000 lb. per sq. in. for steel, t the thickness of the pipe metal, and d internal diameter of the pipe. The same system of units should be used throughout. If the ft., lb., sec. system is used, the above values for E and E' must be multiplied by 144.

Relief Devices. Adequately proportioned **air chambers** on pumping mains and surge tanks on water-power supply pipes serve to **absorb** almost entirely the **shock of water hammer.** Relief or safety valves with adjustable springs are not so good for **water-hammer shocks, and are more likely to be out of order.**

Flow in Open Channels

Flow of Water in Open Channels. Open channels may include canals, flumes, rivers, etc., and also any closed conduit, *e.g.*, a large pipe or a tunnel, when it flows only partly full. For open channels, instead of a loss of pressure head in a unit of length, its equivalent, or the surface slope or surface fall of the stream, is taken. The flow in an open channel, if long and of uniform cross-section, tends to adjust itself to a steady uniform flow, so that the surface is parallel to the bottom.

Formulæ: Chézy, Kutter, Bazin. Because of the multitude of different shapes, the dimensions of the cross-section do not appear directly in the general formula, but indirectly in the **hydraulic radius,** or "hydraulic mean depth," R ($= A/w$, *i.e.*, cross-sectional area ÷ wetted perimeter). The **Chézy formula** ($V = C\sqrt{Rs}$) is known as the **Kutter formula** when for C is substituted an expression proposed by Ganguillet and Kutter and depending on the roughness of the channel, the slope and the hydraulic radius; and as the **Bazin formula** when another expression, proposed by Bazin, is used for C.

The Kutter expression for C is $\dfrac{41.6 + (0.0028/s) + (1.81/n)}{1 + [41.6 + (0.0028/s)]\,(n/\sqrt{R})}$ (ft., sec. units), in which n is the **Kutter coefficient of roughness.** The Bazin expression for C is $158/[1 + (N/\sqrt{R})]$, where N is the **Bazin coefficient of roughness.** (See *Eng. News*, Aug. 22, 1912, p. 351, for a comparison of these formulæ.).

Table 5. Values of Kutter's and Bazin's Coefficients of Roughness for Open Channels

	Coefficients Kutter's n	Coefficients Bazin's N
ARTIFICIAL CHANNELS OF UNIFORM CROSS-SECTION:		
Sides and bottom lined with well-planed timber evenly laid	0.009	
Neat cement plaster, smoothest pipes....................	0.010	0.11
Cement plaster (3 cement to 1 sand), smooth iron pipes....	0.011	
Unplaned timber evenly laid, ordinary iron pipes.........	0.012	
Ashlar masonry, best brickwork, well-laid new sewer pipe..	0.013	0.29
(This last value should be used for the previous categories, if in doubt as to the excellence of construction and the maintenance free from slime, rust or other growths and deposits.)		
Average brickwork, foul planks, foul iron pipes, ordinary sewer pipes..	0.015	
Good rubble masonry, concrete laid in rough forms, poor brickwork, heavily incrusted iron pipes..................	0.017	0.83
CHANNELS SUBJECT TO NON-UNIFORMITY OF CROSS-SECTION:		
Excellent clean canals in firm gravel, of fairly uniform section; rough rubble, "dry paving".........................	0.020	1.54
Ordinary earth canals and rivers in good order, free from large stones and heavy weeds.........................	0.025	2.35
Canals and rivers with many stones and weeds............	0.03 to 0.04	3.2

Degree of Roughness. Certainty. Open concrete, masonry, metal or timber flumes can be cleaned periodically, and the removal of slime, weeds, silt deposits, etc., considerably increases their capacity. (See *Eng. News*, Aug. 29, 1912, p. 416.) For earth channels this is not readily done and for pipes it is more difficult and expensive—often impracticable. Open flumes are subject to rapid ice formation in winter in northern latitudes, to upstream retarding wind action, and to very rapid vegetable growths in many localities. These cause a rapid drop in discharging capacity, and should be allowed for by increased cross-section or slope, or both. Channels in earth are also subject to loss of water by seepage, sometimes so considerable as to require special investigation. The state of uniformity of cross-section is as important as mere local roughness. A channel with frequent minute changes of cross-section must be regarded as a rough channel even if the sides and bottom are smooth in appearance.

Erosion. All canals should be designed to have velocities high enough to prevent silt deposits and to retard vegetable growths. Earth channels, however, must not have such high velocities as to scour loose the material of the sides and bottom. Roughly approximate values of eroding velocities, in ft. per sec., are: for clay, ⅓; fine sand, ½; medium sand, 1; coarse sand and fine gravel, 2; gravel, 2 to 4.

Table 6. Values of the Hydraulic Radius, R, for Various Cross-sections
(R = Cross-sectional Area ÷ Wetted Perimeter)

Form of Cross-section:	Value of R
Semi-circle[1]	$r/2$ or $d/4$
Square (depth = width = d)[1]	$d/3$
Half square (width = $2d$, depth = d)[1]	$d/2$
Trapezoidal Channels (bottom width = b; depth = d):	
Half regular hexagon, side slopes 60 deg[1]	$d/2$
Channel with 45 deg. side slopes	$(bd + d^2)/(b + 2.83d)$
Channel with side slopes 1½ hor. to 1 vert	$(bd + 1.5d^2)/(b + 3.61d)$
Channel with side slopes 2 hor. to 1 vert	$(bd + 2d^2)/(b + 4.48d)$
Wide, shallow stream[2]	d (approx.)

[1] Running full. [2] Hence the term "hydraulic mean depth," sometimes used for R.

The Open Channel Flow Diagrams prepared by Prof. I. P. Church* and by Karl R. Kennison† are very convenient for general use, rendering the use of the somewhat complicated formulæ quite simple. For the Kennison diagram, see Fig. 31.

Open Channel Problem. It is necessary to carry 150 cu. ft. of water per sec. in an unplaned timber flume whose width is to be twice the depth of water ($R = d/2$). What are the required dimensions for various slopes of the flume? Solution: For unplaned timber a value of $n = 0.013$ is safe. For assumed values of d = 3, 4, 5, and 6 ft., the cross-sectional areas of stream are 18, 32, 50 and 72 sq. ft. and the mean velocities for 150 cu. ft. per sec. are 8.3, 4.7, 3.0 and 2.1 ft. per sec., respectively. Noting in lower half of Fig. 31 the intersections of the lines for the corresponding values of R (1.5, 2, 2.5 and 3 ft.) with a line interpolated for $n = 0.013$, and looking vertically above for the values of the slopes at the desired velocities, they are found to be 2.9, 0.65, 0.20 and 0.08 ft. per 1000 ft. slope, respectively, for the above assumed sizes. If it is required to find the dimensions of a canal with some desired shape of cross-section for a given discharge and fixed slope, the procedure is to assume trial dimensions, calculate the mean velocity (= Q/area) and see if, on the diagram (at the proper n line vertically below the intersection of lines for assumed velocity and given slope) the value of R agrees closely with the R for the assumed dimensions. If not, new trials are made until there is close agreement.

Measurements of Flow in Open Channels. Where a weir or a dam does not exist, the velocity of flow is generally determined by the use of **floats** or by a **current meter**. **Headgates and water wheels**, considered as orifices, are sometimes used, and are fairly accurate if calibrated for various gate openings by weir, floats or current meter. **Calculation** based on open channel flow formulæ is **sometimes resorted to in** cases **such as extreme flood flows where only high-water marks are left,** in **backwater problems, etc.,** this method being practically the only one available.

* "Diagrams of Mean Velocity of Uniform Motion of Water in Open Channels," (11 diagrams covering the different degrees of roughness from $n = 0.009$ to 0.035), J. Wiley & Sons.

† "A New Kutter Formula Diagram," *Eng. News*, June 20, 1912. Published, 1913, by Karl R. Kennison, 815 Grosvenor Bldg., Providence, R. I., as "Diagrams, Kutter and Bazin Formulæ."

Floats. By observing the time required for floating objects in a stream to pass over a measured distance, a good estimate of the velocity of the water in the path of the float is obtainable. By properly distributing floats across the

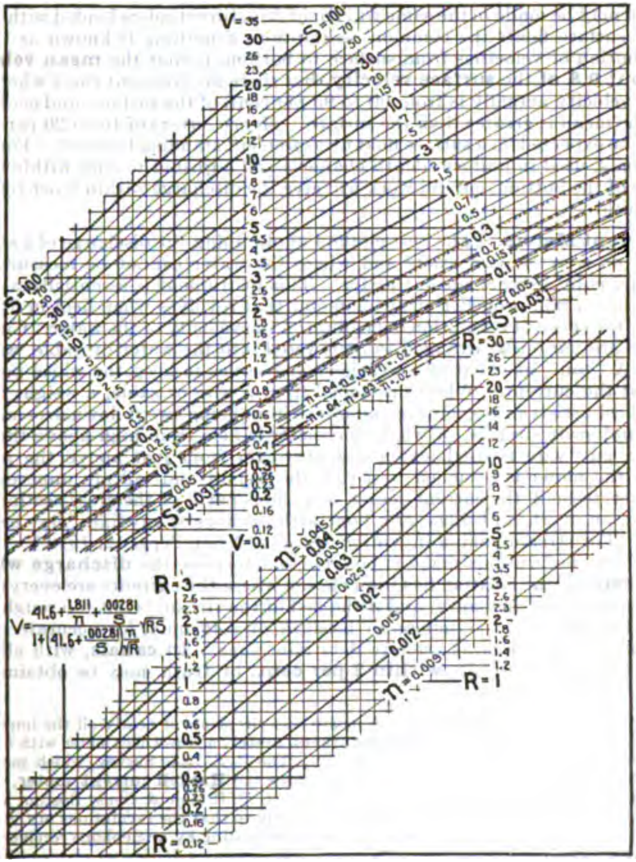

Fig. 31.—Kennison's Open Channel Flow Diagram for the Kutter Formula.
(The units are: *S*, ft. per 1000 ft.; *V*, ft. per sec.; *R*, ft.)

stream, a fair estimate of the total discharge is obtainable if the width and depths have been accurately measured. The use of float measurements is commonly restricted to **surface floats** for rough approximations in reconnaissance, checking other measurements, and in times of high floods when there is too much ice or débris to allow the use of a current meter, and to **rod float measurements** in channels of fairly uniform depth where current meters or weirs are not available. For the surface floats any small pieces of wood will serve for one or two measurements. For more systematic work use 2 × 2 × 12-in. wooden rods, weighted with iron or lead so they will float upright with an inch or so above water. Long rods reaching nearly to the bottom of the stream may be made in the same way, or of 2-in. tin cylinders loaded with sand.

For surface floats the common assumption, if nothing is known as to the distribution of velocities from surface to bottom, is that the **mean velocity is about 0.8 of** the **surface velocity,** but there are frequent cases where the mean velocity actually is from 90 to 95 per cent. of the surface, and occasionally the mean is greater than the surface. Hence, errors of 10 to 20 per cent. are to be expected on a surface float measurement standing by itself. For long rod floats, used in uniform-depth channels and adjusted to sink within a few inches of the bottom, careful work will give the discharge within 5 per cent. of the truth.

Current Meters. The best method of obtaining the discharge of a stream where no weir or dam exists and where the water cannot be measured by volume, is by using a current meter. This instrument is essentially a small wheel like a fan, propeller or anemometer that revolves when held in flowing water, the speed of revolution depending on the velocity of the water. Current meters are variously arranged to be lowered into the water by cable, wire or rod. A "tail" like that of a weather vane serves to keep the wheel pointed against the current. When suspended from a wire or cable, a weight below the wheel assists in preventing the meter from being swept downstream. In deep and swift streams, or where the meter is held from high above the surface, a guy wire is used, extending upstream from just above the meter. When the meter is attached to a rod, the weight and tail are unnecessary. In order to hold the current meter in various parts of the cross-section of a stream, an overhead bridge, or a boat with anchors or guy lines, may be utilized. (For stream gaging in winter, see *Eng. News*, Sept. 12, 1912.)

Careful observations make it possible to determine the **discharge within 5 per cent.** if the location has been chosen where the currents are everywhere fairly parallel to the banks, and if the bed of the stream is not too rough with large boulders, or too indefinite because of soft mud, for accurate depth measurements as well as velocity determinations. **In canals,** with all conditions favorable, results **within 2 per cent.** of truth may be obtained by experienced observers.

The U. S. Geological Survey, which makes measurements of nearly all the important streams in the country, uses the **Price current meter,** a cup-wheel meter with a vertical shaft (W. & L. E. Gurley, Troy, N. Y.). The U. S. Lake Survey, which measures the large rivers connecting the Great Lakes, uses the **Haskell current meter,** a propeller-type instrument having a horizontal shaft (E. S. Ritchie & Sons, Boston, Mass.). Both these current meters are arranged commonly so that the revolutions of the wheel operate a make-and-break in an electric circuit, indicating by a telephone receiver or by a counter register.

A very complete discussion of **stream measurements** is given in Hoyt and Grover's "River Discharge" (J. Wiley & Sons). A new method of **plotting and interpreting data** is given in *Eng. Rec.*, Aug. 3, 1912.

Pressure Due to Deviated Flow

Force or Pressure Due to Deviated Flow. Pressure of a Stream Against Stationary Solids. When a flowing liquid is turned from its course by a body such as a curved vane or a pipe bend, a pressure is exerted on that body. The total force exerted in any direction is equal to the mass of water being deviated, multiplied by the change of velocity in that direction. If the angle turned is B (see Figs. 32 and 33), the pressure or thrust in the direction before the turning is $P_x = (QwV/g)(1 - \cos B)$, where Q is the quantity flowing per sec., w the weight of unit volume of liquid, V the velocity of the liquid, and g the gravity acceleration constant. If A is the cross-section of the stream before turning, the equation may be written $P_x = 2Aw(1 - \cos B)V^2/2g$, thus introducing the velocity head in the flowing liquid. Taking Q in cu. ft. per sec. and V in ft. per sec. the formula becomes, for water, $P_x = 1.94\ QV(1 - \cos B)$. For $B = 90$ deg. and 180 deg., respectively (Figs. 35 and 36), it becomes $P_x = 1.94QV$ and $3.88QV$. The pressure in a direction at right angles to the original direction is $P_y = (QwV/g) \sin B$, or $2Aw \sin BV^2/2g$, or, for water and ft., lb., sec. units, $1.94QV \sin B$. With solids shaped as in Figs. 33 and 37, the components of the pressure in directions other than the original direction neutralize each other due to the divided stream. The **total resultant pressure** due to turning the water aside (P in Fig. 32) is $P = (QwV/g)\sqrt{2(1 - \cos B)}$ and its direction is 90 deg. from midway between the original and final directions of the flowing liquid, *i.e.*, angle C in Fig. 32 $= 90$ deg. $- \frac{1}{2}B$. If a stream impinges squarely against a wall, as in Fig. 34, the effect is the same as it would be in Fig. 33 with $B = 90$ deg.

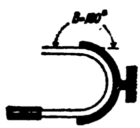

FIG. 36.

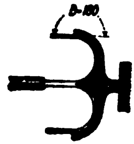

FIG. 37.

GAGES FOR MEASURING PRESSURES, VELOCITIES AND LEVELS

The Open Liquid Column (discussed on p. 256) furnishes the most direct means of measuring and indicating the pressure head or the height of water in tanks, standpipes, boilers, etc. (see Figs. 7 and 50). The arrangement of Fig. 38 may be used for measuring low gas or oil heads, using water instead of mercury.

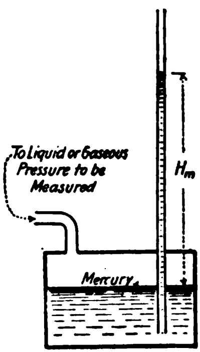

FIG. 38.—Open Liquid Column.

Capillary Attraction. Cohesion, Adhesion and Surface Tension. The exception to the otherwise general statement that the upper surface of a free body of liquid at rest is level, consists in the condition at the edges of the surface area, close to a bounding solid. If the liquid wets the solid (*e.g.*, water and clean glass), it is because there is a greater attraction between the liquid and the solid than between particles of the liquid, or adhesion is stronger than cohesion, and conditions are as shown by Fig. 39 (*a*). On the other hand, if the liquid does not wet the solid (*e.g.*, mercury and glass), cohesion is stronger than adhesion and conditions are as shown by (*b*) Fig. 39. The curved upper surface is called a **meniscus.**

If small-bore glass tubes are used in gages, the effects of capillarity will cause water to stand higher and mercury lower than with large glass tubes, and even with the large tubes there is a curved surface where the liquid touches the glass. For water, the extra height is about $0.046/d$ in., where d is the internal diameter of the tube in in. Thus, if a differential water-air gage (see below) has two glass columns nominally both ⅛ in. in internal diam., but actually one 0.01 in. larger and the other 0.01 in. smaller, the water will stand about 1/16 in. higher in the smaller tube than in the larger, when a common hydrostatic pressure would lead one to expect them to stand at exactly the same level. In experimental work this possible difficulty may usually be avoided by using larger glass tubes, say of ⅜ in. internal diam. **All readings should be taken at the level of the middle of the meniscus,** *i.e.*, the bottom of the curve for water and the top for mercury. These positions are away from the maximum effects of capillary attraction and are nearest to the proper level.

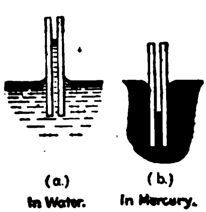

FIG. 39.—Capillary Attraction.

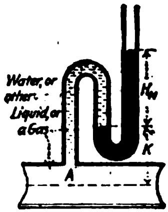

FIG. 40.—Open U-tube Gage.

The Open U-tube Gage (Fig. 40) is much used to measure air, gas and liquid pressures, either above or below atmospheric. Various liquids are used, *e.g.*, mercury, carbon bisulphide colored with iodine, water, kerosene, dilute alcohol, etc. **For gas, air or condenser pressures,** this arrangement will allow pressures ranging from vacuum to several atmospheres to be measured, using mercury; or, using water or kerosene, a more sensitive gage for gas-holder pressures, ventilating pressures, etc., is obtained.

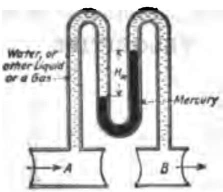

FIG. 41.

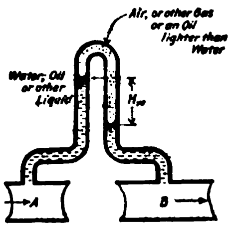

FIG. 42.

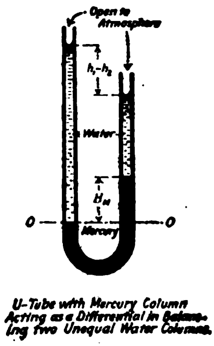

FIG. 43.

FIGS. 41–43.—Differential U-tube Gages.

The Differential U-tube Gage, shown in principle in Figs. 41 and 42, has both branches subject to liquid or gaseous pressures. **The principle of the indications** is shown by Fig. 43, where a liquid column acts as a differential in balancing unequal pressures (equivalent to unequal heads of some other liquid). For the arrangement shown in Figs. 41 and 43, $(h_1 - h_2) = H_M \times [(w_m/w_w) - 1]$, where $(h_1 - h_2)$ is the difference of pressure heads, H_M the gage difference, and (w_m/w_w) the ratio of the heaviness of the liquid in the U of the gage to that of the other liquid. For the case shown in Fig. 42,

$(h_1 - h_2) = Hw[1 - (w_o/w_w)]$, where w_o is the weight per unit volume of the lighter liquid (or of air in the gage, if no second liquid is used).

For mercury and water, $(h_1 - h_2) = 12.57\ H_M$
For carbon bisulphide and water, $(h_1 - h_2) = 0.26\ H_M$
For kerosene and water, $(h_1 - h_2) = 0.21\ H_W$

These ratios vary with the temperature of the liquids.

For gas pressures, unless the pressure is many atmospheres, the value $[(w_m/w_w) - 1]$ may be taken as practically equal to w_m/w_w; and **for the water-air differential gage** (Fig. 42), the value $[1 - (w_o/w_w)]$ may be taken practically equal to 1 in most cases. If the liquid pressure, however, is 100 lb. per sq. in. or over, the value of w_o/w_w will be about 0.01 or more, and the correction then becomes practically appreciable.

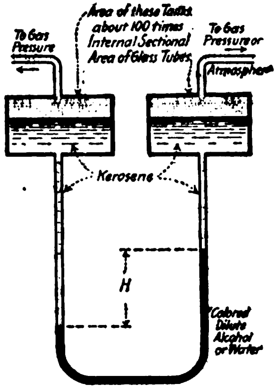

FIG. 44.—Sensitive Differential U-tube Gage.

An Extremely Sensitive Differential (or Open) U-tube Gage for gas pressures is shown in Fig. 44. One of the cisterns may be open to the atmosphere, thus making still another type of **multiplying open U-tube gage.** The heavier liquid may be either water or alcohol diluted with water to make its specific gravity only slightly greater than that of the lighter liquid (kerosene). The alcohol may be colored with an aniline dye that is insoluble in the kerosene. If the specific gravity of the dilute alcohol is 0.83 and that of the kerosene is 0.79, then the difference of gas pressures is $Hw\ (0.83 - 0.79) = 0.04Hw$, where w is the weight of a unit volume of water, *i.e.*, the gage shows a difference 25 times greater than a U-tube with water. A small correction may be necessary for the difference in level of the surfaces in the two cisterns, but by making the cisterns large this correction may be avoided. The glass columns should not be over 3/16 in. in internal diameter to avoid irregular meniscus.

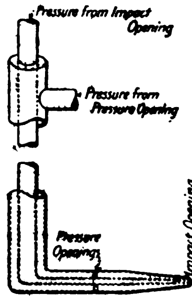

FIG. 45.—Pitot Tube.

The Pitot Tube. See p. 255 and Figs. 6 and 7. Fig. 45 shows one form of Pitot tube. The side "pressure" holes give the pressure head in the water. Such a tube is not readily adapted for insertion through a small hole in the wall of a pipe. Figs. 46 and 47 illustrate representative tubes of more compact type. Such tubes have coefficients less than 1 because of the suction effect at the pressure openings, due to the shape of the tube causing the flowing water to be swerved away from the openings instead of flowing perpendicularly past them as for the side openings of the tube in Fig. 45 or the wall opening in Fig. 7. For tubes as in Fig. 47, $V = 0.84\sqrt{2gh}$, *i.e.*, the indicated water column difference h is about $(1/0.84)^2$ or 42 per cent. greater than the h_v of Fig. 7. Very slight changes in the shape of a compact-type side-pressure-opening tube as in Fig. 46, or in the location of the pressure openings, cause a change in the coefficient of the tube. For Fig. 46, $V = 0.84$ to $0.88\sqrt{2gh}$, depending on location of side openings and shape of tube; for precise work such tubes should be rated. The use of a single-opening tube in connection with a "wall piezometer" (*i.e.*, either a single hole as Fig. 7, a pair of diametrically opposite holes, or a ring piezometer, see p. 263) that transmits only the pressure head of the water, affords the combination of the simplest and most easily constructed instrument with the greatest certainty of indications without necessity of special calibration in case the tube is constructed a little differently from some model. No coefficient is necessary, *i.e.*, $V = \sqrt{2gh}$, for a tube that has its impact opening projecting a little upstream from the body of the tube (see Fig. 48). The pressure holes in the pipe should be about 1 in. upstream from the impact point of the tube, so that the flow past them will be undisturbed by the presence of the tube in the pipe.

For abnormal flow in curved passages, or wherever a wall opening is subject to centrifugal action due to the flow not proceeding parallel to the wall, a two-opening tube is most convenient, as also where many tests in different pipes are to be made.

A sheath, or elongated stuffing box (Fig. 48), into which the point of the tube can be drawn back out of the pipe, is very convenient and is practically essential for high pressures where the flow in the pipe cannot be shut off. A corporation cock (½, ¾, 1 in. or larger, to suit the tube) may be permanently tapped into the pipe. The sheath should have a union coupling adapted for connection to the corporation cock. This gives a shut-off that allows a ready insertion of the tube at any future time. A ¼-in. tap and a gage cock are suitable for the pressure holes when a single-opening tube is used.

FIG. 46.

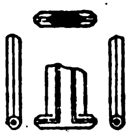

FIG. 47.

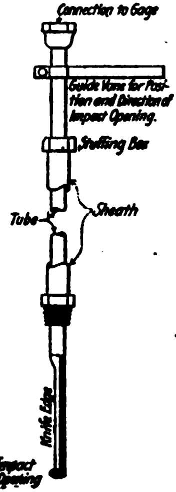

FIG. 48.

FIGS. 46–48.—Pitot Tubes for Insertion in Pipes.

Use of the Pitot Tube in Pipes. The distribution of velocities in the cross-section of a pipe with flowing water is affected by upstream disturbances and by the roughness of the pipe's interior surface. If some 50 diameters' length of straight pipe without tees, valves, etc., extends upstream from the place of measurement, normal distribution prevails. For this the velocity at the wall of the pipe is about one-half the center velocity, and the ratio of the mean velocity to the center velocity, (*the pipe coefficient*), averages about 0.83, the **velocity curve** being approximately a semi-ellipse with the points of mean velocity at about one-fourth the radius from the wall toward the center (see Fig. 49).

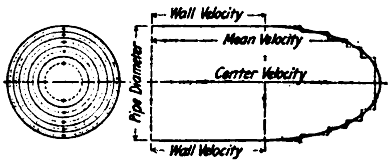

FIG. 49—Distribution of Velocities in a Pipe Cross-section by the 10-point Method.

Discharge Measurements. The Traverse. Various local effects cause departures from the above-stated normal conditions. If the mean velocity deduced from $0.83 \times V_{cen.}$ does not agree with that found at the normal mean velocity points within some 3 per cent., or if the greatest possible precision is required, a complete **traverse** should be made, *i.e.*, the velocity should be found at points distributed along the whole diameter. If this is done for various mean velocities and for two diameters perpendicular to each other, the ratio of mean to center velocities for the particular pipe and cross-section may be determined precisely, and thereafter observations with the Pitot tube set on the center only will suffice for accurate discharge measurements.

The 10-point Method of making a traverse consists in observing with the Pitot tube impact opening set on each of the intersections of a diameter with the circumferences of the odd numbered of 10 concentric circles dividing the cross-section into 10 equal areas. The inner wall of the pipe is the tenth circle (see Fig. 49). Since each point of observation controls one-tenth of the cross-sectional area, it is only necessary to add the calculated velocities and divide by 10 to obtain the mean velocity. The so-calculated mean velocity is theoretically only 0.30 per cent. too high and may be considered practically exact for most measurements. If 20 points are used, the error in summation is theoretically only 0.10 per cent. too high. (See *Proc. A. S. M. E.*, May, 1908, p. 517.)

The Float Gage consists of a hollow float of non-corrosive metal or other substance, either spherical or cylindrical with convex or conical top and bottom. A light, rigid stem extends vertically upward, having an index mark that is guided along the edge of a graduated scale or is attached to an automatic recording mechanism. For cases of **great range of levels**, a graduated tape attached to the float and passing over a pulley or system of pulleys, and with a suitable counterweight, makes a sensitive indicator. The tape need be marked only every foot, if it passes the edge of a fixed auxiliary scale with subdivisions.

For precise work the float should be confined against lateral movement by a vertical pipe with internal diameter ¼ or ½ in. larger than the float. **For the greatest accuracy**, where errors of 0.001 to 0.004 ft. are inadmissible, the float should be made at least 1 in. smaller than the pipe and should be loosely guided (at the stem or by rounded radial fins on the float itself) to keep it away from the pipe so as **to avoid capillary lifting.** To lessen oscillations due to surges and waves, the lower end of the float pipe is capped and one or more small openings are made near the bottom to allow equalization of levels inside and outside. The area of the openings may be some 1 to 3 per cent. of the float-pipe section. For standing liquids in open tanks or reservoirs the float pipe may be placed either inside or outside the container, as is most convenient. For flowing water in open channels it is placed outside the channel and communication is made by a small pipe, which must end perpendicularly to the inside wall of the channel and without projecting into the channel; *i.e.*, its end should be flush with the inside wall, so as to avoid suction effect (see Fig. 50).

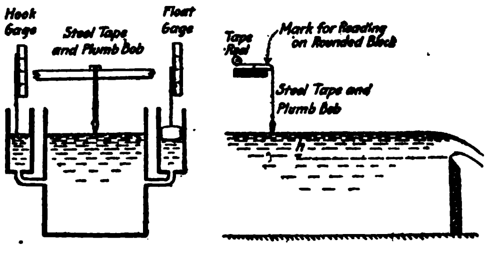

FIG. 50.—Hook, Plumb-bob and Float Gages.

The Hook Gage, Point Gage, Plumb-bob Gage (Fig. 50). These all are devices for locating the height of a liquid surface by observing its contact with the "point" attached to the movable graduated scale of the gage. The point gage has a sharpened point directed downward in place of the hook of the hook gage. For these gages the scale usually is engraved on a square brass rod. A steel or bronze tape is used for the **plumb-bob gage**. The "point" should not be a "needle point," but a conical point with a vertex angle of 90 to 120 deg., so as to produce a maximum of optical effect for slight variations from perfect contact of the point with the liquid surface. The use of a **stilling box**, such as the float pipe above described, is desirable especially for the hook gage (see Fig. 50).

In use, the **hook-gage** point is moved up from beneath until it just pierces the liquid surface. The **point gage** and **plumb-bob gage** are manipulated by lowering from above until a "bubble" shows contact with the liquid surface. If with flowing water or a large surface of a tank or reservoir, where there are waves or surges, and where a stilling box is not available, the gage should be set so that the average time durations during which the point is alternately submerged and exposed shall be as nearly equal as the observer can estimate. Even with a stilling box there may be surges of small amplitude, and several sets of observations may be necessary to assure a determination within 0.001 ft.

The **float gage** is the **best** of the gages mentioned **for sensitiveness and accuracy**. It automatically shows the small variations of water surface level. Whenever there is a perceptible vibration of the water surface, maximum and minimum readings should be taken, corresponding to the crests and roughts of the waves. The average will give the mean level.

THERMAL PROPERTIES OF BODIES

The Measurement of Temperature

Thermometers. The scale of the constant-volume **hydrogen thermometer** is taken as the standard temperature scale. Within the limits of ordinary use the scale of the mercury thermometer agrees closely with the standard scale, but above 500 deg. fahr. the divergence between the two scales may be appreciable.

The ordinary **mercury thermometer** may be used to about 600 deg. fahr.; this limit may be extended to 1000 deg. fahr. if the capillary tube above the mercury is filled with nitrogen or carbon dioxide under high pressure. The lower temperature limit for the mercury thermometer is -39 deg. fahr. For lower temperatures, alcohol, pentane or petroleum ether may be used as the thermometric substance. For stem exposure corrections, see "Temperature Measurements," p. 1670. Very high temperatures are measured by various forms of **pyrometers**. See pp. 1671–1674.

Thermometer Scales. Let F and C denote the readings on the Fahrenheit and Centigrade (or Celsius) scales, respectively, for the same temperature; then

$$C = \tfrac{5}{9}(F-32), \qquad F = \tfrac{9}{5}C + 32$$

Table 1 gives corresponding readings on the two scales.

Fixed Temperatures. The following fixed temperatures, adopted by the U. S. Bureau of Standards, are useful in the calibration of pyrometers:

	Deg. fahr.	Deg. cent.
Liquid tin solidifies at	449	232
Liquid lead solidifies at	621	327
Liquid zinc solidifies at	787	419.4
Liquid sulphur boils at	832.5	444.7
Liquid antimony solidifies at	1167	630.5
Liquid aluminum (97.7 per cent. pure) solidifies at	1216	658
Solid gold melts at	1947	1064
Liquid copper solidifies at	1983	1084
Solid nickel melts at	2615	1435
Solid palladium melts at	2815	1546
Solid platinum melts at	3187	1753

High Temperatures and Color. High temperatures may be judged approximately by color, though the estimate of an experienced observer is likely to be 100 deg. fahr. from the true value. The following table associating color and temperature of iron or steel is due to White and Taylor.

	Deg. fahr.		Deg. fahr.
Dark blood red, black red......	990	Orange, free scaling heat.........	1650
Dark red, blood red, low red....	1050	Light orange....................	1725
Dark cherry red...............	1175	Yellow..........................	1825
Medium cherry red............	1250	Light yellow....................	1975
Cherry, full red................	1375	White...........................	2200
Light cherry, light red.........	1550

Wood (beech)	0.016
Wood (pine)	0.028

rise of temperature of 1 deg. Denoting these coefficients by a' and a''', respectively,

$$a' = \frac{1}{l}\frac{dl}{dt} \qquad a''' = \frac{1}{V}\frac{dV}{dt}$$

in which l denotes length, V volume, and t temperature. For homogeneous solids $a''' = 3a'$, and the **coefficient of superficial expansion** $a'' = 2a'$.

The coefficients of expansion are in general dependent upon the temperature, but for ordinary ranges of temperature constant mean values may be taken. If lengths, areas, and volumes at 32 deg. fahr. (0 deg. cent.) be taken as standard, then these magnitudes at other temperatures t_1 and t_2 are related as follows:

$$\frac{l_1}{l_2} = \frac{1+a't_1}{1+a't_2} \qquad \frac{A_1}{A_2} = \frac{1+a''t_1}{1+a''t_2} \qquad \frac{V_1}{V_2} = \frac{1+a'''t_1}{1+a'''t_2}$$

Since for solids and liquids the expansion is small, the preceding formulæ for these bodies become approximately

$$l_2 - l_1 = a'l_1(t_2 - t_1). \quad A_2 - A_1 = a''A_1(t_2 - t_1). \quad V_2 - V_1 = a'''V_1(t_2 - t_1)$$

For certain metals the variation of the coefficient of expansion with temperature has been investigated by Holborn and Day and by Dittenberger. Denoting by l_0 the length at 32 deg. fahr., and by l the length at temperature t, the following relation is obtained.

$$l = l_0 \left[1 + a\left(\frac{t-32}{1000}\right) + b\left(\frac{t-32}{1000}\right)^2\right]$$

The following table gives values of the constants.

Metal	1000 a	1000 b	Temperature range, deg. fahr.
Aluminum	13.380	2.182	32–1130
Cast iron	5.441	1.747	32–1160
Ingot iron	6.375	1.636	32–1380
Malleable iron	6.503	1.622	32– 930
Ingot steel	6.212	1.623	32–1380
Copper	9.278	1.244	32–1160
Nickel	7.652	1.023	32–1830

The tensile or compressive **stress set up** in a prismatic bar by a **temperature change** of t deg. is $P = a'EAt$, in which E denotes the modulus of elasticity and A the area of the cross-section.

The **linear shrinkage of castings** is approximately as follows:

Bar iron, rolled	1:55	Cast iron	1:96	Steel, puddled	1:72
Bell metal	1:65	Gun metal	1:134	Steel, wrought	1:64
Bismuth	1:265	Iron, fine grained	1:72	Tin	1:128
Brass	1:65	Lead	1:92	Zinc, cast	1:62
Bronze	1:63	Steel castings	1:50	8 Cu + 1Sn (by wt.)	1:184

Specific Heat

Units of Heat. The mean **British thermal unit** (B.t.u.) is defined as the $\frac{1}{180}$ part of the heat required to raise the temperature of 1 lb. of water from 32 deg. to 212 deg. fahr. This is substantially equal to the heat required to raise 1 lb. of water from 63 deg. to 64 deg. fahr.

The **mean calorie** is $\frac{1}{100}$ of the heat required to raise the temperature of 1 g. of water from 0 deg. to 100 deg. cent. It is practically the same as the 17½-deg. calorie, that is the heat required to raise 1 g. of water from 17 deg. to 18 deg. cent. The 15-deg. calorie is also used extensively. Because of the variation of the heat capacity of water, this is slightly larger than the mean or 17½-deg. calorie. The present tendency is toward the mean calorie (and mean B.t.u.) as the standard heat unit.

In countries which have adopted the metric system, engineers employ the **kilogram calorie** (or "large calorie") as the unit in heat measurements. 1 kilogram calorie = 1000 g. calories = 3.968 B.t.u. (1 B.t.u. = 0.252 kilogram calorie). This is the "wärmeeinheit" (WE) mentioned in German texts.

Specific Heat. The specific heat of a substance is the ratio of the heat required to raise the temperature of unit weight of the substance 1 deg. to the heat required to raise the temperature of unit weight of water 1 deg. at some specified temperature. The specific heat is thus numerically equal to the quantity of heat required to raise the temperature of a unit weight of the substance by 1 deg.

Denoting by c the specific heat, the heat required to raise the temperature of M lb. of a substance from t_1 to t_2 is $Q = Mc(t_2 - t_1)$, provided c is a constant.

In general, c varies with the temperature, though for moderate temperature ranges a constant mean value may be taken. If, however, c is taken as variable, then $Q = M\int_{t_1}^{t_2} c\,dt$. The *mean* specific heat from 0 deg. to t deg. is given by $c_m = \frac{1}{t}\int_0^t c\,dt$. If $c = a_1 + a_2t + a_3t^2 + \ldots$,

$$c_m = a_1 + \tfrac{1}{2}a_2t + \tfrac{1}{3}a_3t^2 + \ldots$$

Specific Heat of Water. The specific heat of water between 32 deg. and 212 deg. fahr. has been investigated by Barnes, Ludin, Dieterici, and others (see Marks and Davis's "Steam Tables," p. 88). For this range of temperatures, two distinct values of the specific heat may be noted, according as (1) the pressure on the water is the saturation pressure corresponding to the temperature, or (2) constant atmospheric pressure. In Table 3 the values of the specific heat are according to the first system. For a full discussion of this topic see Marks and Davis's "Steam Tables," p. 90.

The **specific heat of salt solutions** increases slowly with rising temperature. Table 6, due to Gröber, gives the specific heat of solutions of NaCl for various temperatures and concentrations. The values are probably more accurate than those given by Siebel in Table 11.

Temperature of Mixtures

The temperature of a mixture of weight $M_1 + M_2$ lb. consisting of M_1 lb. of a substance at temperature t_1 and with specific heat c_1 and M_2 lb. of a substance at temperature t_2 with a specific heat c_2, is given by the equation

$t_m = (M_1c_1t_1 + M_2c_2t_2)/(M_1c_1 + M_2c_2)$. In general, $t_m = \Sigma Mct/\Sigma Mc$.

If it be required to raise the temperature of M_1 lb. of a substance having the specific heat c_1 from the temperature t_1 to t_m, the weight M_2 required of a second substance at temperature t_2 and having a specific heat c_2 is

$$M_2 = M_1c_1(t_m - t_1)/c_2(t_2 - t_m)$$

If M_1 lb. of a gas (corresponding to V_1 cu. ft.) at t deg. be mixed with M_2 lb. of the same gas (corresponding to V_2 cu. ft.) the pressure being constant, then the temperature of the mixture is $t_m = (M_1t_1 + M_2t_2)/(M_1 + M_2) = \{(V_1 + V_2)/[(V_1/T_1) + (V_2/T_2)]\} - 459.6$, in which T_1 and T_2 are the absolute temperatures.

Changes of State Effected by Heat

Table 7. Freezing Mixtures

(The lowest temperature that may be produced by a freezing mixture is the freezing point of the solution)

Heat of Vaporization (Table 15). The latent heat of vaporization is the quantity of heat in B.t.u. required to convert 1 lb. of a liquid into vapor at the same temperature under a constant external pressure. The latent heat depends upon the temperature at which the process takes place.

For the **latent heats of steam** at different pressures, see p. 324; and for the **latent heats of refrigerating media**, see pp. 333, 336 and 337.

One cubic foot of water at atmospheric pressure and at the temperature t will dissolve the volumes of gas (in cu. ft. at 32 deg. fahr. and at atmospheric pressure) given in Table 16.

TRANSMISSION OF HEAT

Preliminary Statements. There are three methods by which heat may be propagated or conveyed from one place to another.

1. By **Conduction.** In this method heat passes from one body to another or from one part of a body to another by contact. It is assumed that the warmer molecules impart heat to the colder ones.

2. By **Convection.** Heat is carried from place to place by the medium with which it is associated. Thus, in a hot-water heating system, heat is carried from the furnace through the building by the water in the system; in a boiler, heat is carried through the mass of water by the currents produced by circulation.

3. By **Radiation.** A source of heat, as the sun or a fire, gives off energy in the form of radiant heat. This energy is assumed to be propagated in all directions as a wave motion in the ether, and radiation falling upon a body is to some extent absorbed by it. According to the modern **theory of exchanges,** all bodies whose molecules are in vibration are sources of radiation. If two bodies, one hotter than the other, are placed within an enclosure, there is a continual interchange of energy between them. The hotter body A radiates more energy than it absorbs, the colder body B absorbs more than it radiates. The result is an equalization of temperature, but even after the equilibrium of temperature the process of radiation continues, each body radiating and absorbing energy.

Transmission of Heat by Convection and Conduction

Phenomena of Heat Transmission. In the cases of heat transmission that usually occur in practice—in boilers, condensers, the cooling of engine cylinders, etc.—heat is transmitted from one fluid to another through a wall separating the two. The character of the process is shown in Fig. 1. At the surface of the plate there is a film of the hot fluid of indefinite thickness. This film offers a considerable resistance to the transmission, as shown by the temperature difference $t_1 - t'_1$ through it. A corresponding film on the other side of the plate offers resistance measured by the temperature drop $t'_2 - t_2$. Let Q denote the total heat in B.t.u. transmitted in z hours through a plate area of A sq. ft. Then, for film f_1, $Q = k_1Az(t_1 - t'_1)$; for the plate, $Q = (K/b)\,Az\,(t'_1 - t'_2)$; for the film f_2, $Q = k_2Az\,(t'_2 - t_2)$.

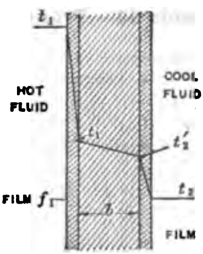

FIG. 1.

The coefficients k_1 and k_2 are the **conductances** of the films f_1 and f_2, respectively, K is the thermal conductivity of the plate and, analogously, (K/b) is the conductance of the plate. The reciprocals of these, viz., $1/k_1$, $1/k_2$, b/K, are the **resistances** of the two films and plate, respectively. The total resistance R to the flow is the sum of the separate resistances, $R = (1/k_1) +$

$(1/k_2) + (b/K)$, and the conductance of the two films and plate is $k_0 = 1/R$. Hence, $Q = k_0 Az\ (t_1 - t_2)$.

If the wall is composed of several layers of different materials having thicknesses b', b'', b''', etc., and thermal conductivities K', K'', K''', etc., the total resistance is $R = (1/k_1) + (1/k_2) + (b'/K') + (b''/K'') + (b'''/K''') + \ldots$, and $k_0 = 1/R$.

The **resistance of the fluid film** depends upon the kind of fluid and the character of the motion of the fluid along the wall. The resistance of a film of hot gas is very high. It has been estimated that in certain cases 98 per cent. of the available temperature drop is required to force the heat through the gas film. If the hot fluid is saturated steam, condensation insures a film of water in contact with the plate and the resistance is relatively small compared with that of a gas film. The film resistance is considerably influenced by the motion of the fluids along the plates. If the hot gas, as in a boiler tube, is given a high velocity the resulting sweeping action partially destroys the film and decreases the resistance. The same is true on the water side of the wall. It is well established that the **rate of heat transmission is dependent on** the **velocity of** the **fluid** along the plate.

A layer of soot or scale on a plate has the effect of making a composite wall. The resistance is increased by b'/K', where b' is the thickness and K' the thermal conductivity of the layer. If k_0 is the total conductance for the clean plate, the ratio of the heat transmitted to that transmitted through the clean plate is

$$Q'/Q = \frac{1}{k_0}\Big/\left(\frac{1}{k_0} + \frac{b'}{K'}\right) = 1\Big/\left(1 + \frac{b'k_0}{K'}\right)$$

The experiments of Clement and Garland (*Bulletin* No. 40, Engineering Experiment Station, University of Illinois) afford valuable data on the **transmission of heat from steam to water.** A stream of water was made to flow at various velocities through a steel tube of 0.985 in. inside diam. and with walls 0.134 in. thick. The tube was surrounded by steam, and the temperature of the outer wall of the tube was measured by thermo-couples. The temperature of the inner wall was calculated from the known conductivity of the metal composing the tube. The results of one series of tests are shown in Table 18.

Table 18. Transmission of Heat from Steam to Water through Steel Tubes

No. of test	Temperatures, deg. fahr.				Velocity of water, ft. per sec.	B.t.u. transmitted per min. per sq. ft.	Conductances, B.t.u. per sq. ft. per sec.		
	of steam	of outside wall	of inside wall	of water, mean			Steam film	Water film	Both films and wall
1	330.2	220.0	165	69.0	17.13	3995	0.606	0.694	0.255
2	330.0	229.4	177	70.8	14.05	3756	0.621	0.591	0.246
3	330.0	233.1	185	74.6	10.39	3455	0.594	0.524	0.225
4	330.2	241.8	197	78.07	8.06	3260	0.614	0.457	0.215
5	330.2	257.4	220	89.5	4.25	2672	0.611	0.340	0.185
6	330.2	267.1	234	110.2	2.31	2370	0.625	0.318	0.179

It appears from these results that the velocity of flow has a marked effect on the conductance of the water film and upon the rate of transmission from the steam to the water.

Conductance of Fluids. As stated in a preceding paragraph, the rate of transmission of heat between a fluid and a metal surface depends upon the conductance of the fluid film. If h denotes the difference of temperature between the fluid and the plate wall, and k the conductance, then $Q = kzAh$. The value of k depends upon the nature of the fluid and also upon the velocity of the fluid along the surface. The following values may be taken for the conditions stated (k = B.t.u. per sq. ft. per hour per deg. fahr. difference of temperature):

1. For boiling water .... $k = 800$ to 1200
2. For condensing steam........................ $k = 2000$

The experiments of Clement and Garland show a mean value of $0.61 \times 3600 = 2200$, approx.

3. Water, not boiling:

If the water is at rest,........................ $k = 100$.

If the water is in motion, k will depend upon the velocity. In the experiments of Clement and Garland k varied from 730 with a velocity of 1.45 ft. per sec. to 2500 with a velocity of 17.13 ft. per sec.

4. Air at Rest. Take h as the difference between the temperature of the surface and the mean temperature of the air in the room. Then, for vertical surfaces,

$k = 0.62 + 0.009h$ for $h < 20$ deg, and $k = 0.385 \sqrt[4]{h}$ for $h > 20$ deg., or

for h =	0	5	10	25	50	100	200	300	400
k =	0.62	0.665	0.71	0.86	1.04	1.22	1.45	1.60	1.72

5. Transmission of Heat from the Surface of a Rotating Cylinder to Air, as in flywheels, armatures, etc. According to the experiments of Hinlein, for

Smooth Surfaces (polished copper).

Thermal Conductivity. The resistance of the plate to heat transmission is b/K, the conductance K/b. The number K in this expression is called the **thermal conductivity** of the material of the plate. The thermal conductivity of a substance may be defined as the quantity of heat (B.t.u.) that flows in a unit of time (1 hr.) through unit area of plate (1 sq. ft.) of unit thickness (1 ft.) having unit difference of temperature (1 deg. fahr.) between its faces. This definition follows from the relation

$$Q = KAz(t'_1 - t'_2)/b, \text{ or } K = Qb/Az(t'_1 - t'_2).$$

It will be observed that the conductivity K involves an element of length, while the conductance k does not.

The thermal conductivity of different materials varies greatly. For metals and alloys K is high, while for certain insulating materials, as asbestos, cork, and silk, K is very low. In general, K **varies with the temperature.** In the case of metals K usually decreases with rising temperature, while for most other substances the reverse is true. Tables 19 to 24, collected from various sources, give values of thermal conductivity.

Table 20. Thermal Conductivities of Miscellaneous Solid Substances

(See also Table 21)

(The values of K in the table below are to be regarded as rough average values for the temperature range indicated)

The conductivities of air and steam are given as functions of the temperature by the relations: K (for air) $= 0.01221\ (1 + 0.00132\ t)$ and K (for steam) $= 0.00882\ (1 + 0.00219\ t)$.

For t (deg. fahr.) =	32	50	100	200	300
K (for air) =	0.0127	0.0130	0.0138	0.0154	0.0170
K (for steam) =	0.0095	0.0098	0.0107	0.0127	0.0146
For t (deg. fahr.) =	400	500	600	700	800
K (for air) =	0.0187	0.0203	0.0219	0.0235	0.0250
K (for steam) =	0.0165	0.0184	0.0204	0.0223	0.0242

Heat Transmission Between Fluids Separated by a Plate. The following are important examples of heat transmission through plates or tubes. ucke's "Engineering Thermodynamics," p. 550):

luid giving up heat	Fluid receiving heat	Examples of heat transmission
Liquid	(a) Liquid	Liquid heat exchangers, etc.
	(b) Gas	Hot-water radiators; cooling-tower surfaces.
	(c) Boiling liquid	Brine coolers; hot-liquid evaporators.
2. Gas	(a) Liquid	Brine coolers in cold-storage rooms; air coolers with water or brine coils; economizers.
	(b) Gas	Steam superheaters; air-cooled motors.
	(c) Boiling liquid	Steam boilers; direct-expansion ammonia coils.
3. Condensing vapor	(a) Liquid	Condensers; feed-water heaters.
	(b) Gas	Steam radiators.
	(c) Boiling liquid	Vacuum evaporators.

Let Q = heat transmitted per hour, k_0 = coefficient of heat transfer = conductance of wall, with scale, soot, and fluid films, A = area in sq. ft. through which transfer is in process, and h_m = mean temperature difference for the process. Then $Q = k_0Ah_m$.

If one of the fluids is condensing or boiling under constant pressure the temperature remains constant during the heat transfer. In case 3(c) both fluids remain at constant temperature and h_m is simply the difference. In all other cases the temperature of one fluid or of both fluids changes during the process. If h_1 is the initial temperature difference and h_2 the final temperature difference, then the mean temperature difference for the process is given by $h_m = (h_1 - h_2)/\log_e(h_1/h_2)$.

Coefficient of Heat Transmission

The **value of** the **coefficient** k_0 depends on a number of conditions, viz.: the character of the fluids, the velocity of the fluids along the separating surfaces, the condition of the surface, and the shape of the surface. In general, k_0 is small when one of the fluids is a gas. The following rough values are given by Lucke for the cases stated in the preceding paragraph:

Case	Fluids	Values of k_0 (B.t.u. per hour per sq. ft. per deg. fahr.)
1 (a)	Liquid—Liquid	50–75
1 (b)	Liquid—Gas	2–6
1 (c)	Liquid—Boiling liquid	10–100
2	Gas—Liquid, gas, or boiling liquid	2–5
3 (a)	Condensing vapor—Liquid	150–350, 1000 under special conditions
3 (b)	Condensing vapor—Gas	2–4
3 (c)	Condensing vapor—Boiling liquid	400–600

For some of the most important cases the variation of k_0 with external conditions has been investigated. The following is a résumé of some of the results.

1. Transmission Between Steam and Water (Condensers, etc.). According to the exhaustive experiments of Orrok (*Trans. A. S. M. E.*, vol. 32) the value of k_0 depends upon the following factors:

(a) k_0 is approximately proportional to the square root of the velocity of the cooling water.

(b) k_0 is inversely proportional to the eighth root of the mean difference of steam and water temperatures.

(c) k_0 depends upon the material of the tube and upon the cleanliness of the tube.

(d) k_0 is reduced in a marked degree by the presence of air in the condenser. Thus if p_s denotes the pressure of the steam alone and p_t the total pressure ($= p_s +$ pressure of air), then k_0 varies as $(p_s/p_t)^5$.

Orrok (1914) gives the following equation as representing the results of **tests on condensers** under various conditions: $k_0 = 350\, c_1c_2(p_s/p_t)^2 \times \sqrt{w}$, in which c_1 ($= 0.5$ to 1.0) is the cleanliness coefficient, and c_2 a coefficient depending on the material of the tubes. For copper, $c_2 = 1.0$; for Admiralty mixture, 0.98 (oxidised, 0.97); for Muntz metal, 0.95; for aluminum bronze, 0.92. The exponent for (p_s/p_t) is now taken as 2 instead of 5. w denotes the velocity of the water in ft. per sec.

The variation of k_0 with the water velocity has received attention from a number of experimenters. The following are some of the relations obtained (*Trans. A. S. M. E.*, vol. 32):

Ser, $k_0 = 520 \sqrt[3]{w}$; Hagemann, $282 \sqrt{w}$; Josse, $487 \sqrt[3]{w}$; Allen, $220 \sqrt{w}$; Stanton, $340 \sqrt[3]{w}$; Orrok, $308 \sqrt{w}$; Clement and Garland, $270 \sqrt[3]{w}$.

Carrier (*Trans. A. S. M. E.*, vol. 33), gives the following formula as representing the results of tests on condensers: $k_0 = 1/[0.000394 + (0.00255/w)]$.

2. Steam and Boiling Liquids. Where **steam coils** are **used for evaporation** of water or other liquids the following coefficients of transmission may be used (Hausbrand, "Evaporating, Condensing and Cooling Apparatus"):

Let d = diameter of pipe and l = length, both in feet; then $k_0 = 1250/\sqrt{dl}$. This value holds for copper pipe, when the boiling liquid is water. For wrought-iron pipe take 0.75 and for cast-iron pipe 0.5 of this value. In practice, ½ of these values should be assumed.

In the case of thick, viscous liquids, the size of pipe has little influence on the rate of transmission, and the following values of k_o may be taken: For long heating coils, 130–150; for short heating coils, 160–180; for thin steam pipes, 200.

3. Steam to Air. Carrier (*Trans. A. S. M. E.*, vol. 33) deduces the following formula for the coefficient of transmission under the conditions that obtain in **hot-blast heating** systems: $k_0 = 1/[a + (b/w)]$, in which w denotes the velocity of the air, ft. per min., and a and b are constants depending on the type of heater. Tests on a Buffalo standard heater with 50 lb. steam pressure, gave $a = 0.0447$, $b = 50.66$. For Vento cast-iron heaters the test showed $a = 0.047$, $b = 61.0$.

Conduction of Heat through Steam Pipes.—Pipe Coverings. The coefficient of heat transmission through bare steam pipes varies with the steam pressure. Assuming the air to be still, k_0 may be taken as about 2.1 for low steam pressure (5 or 6 lb. gage), and 3.0 or 3.1 for a pressure of 90 or 100 lb. gage. Table 25 gives the results of tests by the Johns-Manville Co. on heat conduction through bare pipe and pipe with various insulating coverings. Outside temperature, 72 deg. fahr.

Table 25. Heat Conduction through Bare and Covered Steam Pipes

(Johns-Manville Co., New York)

Transmission of Heat by Radiation

The **absorption capacity** of a body for radiation is the ratio of the heat absorbed to the entire radiation received on the surface of the body. The **absolute "black body"** absorbs all the radiation received; hence its absorption capacity is 1. Bodies that are good absorbers have also high capacity for radiation. Bodies that are good reflectors, as polished steel or silver, have correspondingly small absorption capacity and radiating power. Table 26 gives the relative absorbing, radiating and reflecting properties of certain bodies.

Table 26. Relative Radiating and Reflecting Capacities

Substance	Absorbing or radiating capacity	Reflecting power	Substance	Absorbing or radiating capacity	Reflecting power
Water	100	....	Steel, polished	17	83
Marble	93–98	7–2	Tin	15	85
Glass	90	10	Brass, dead polished	11	89
Ice	85	15	Brass, bright	7	93
Cast iron, polished	25	75	Copper, hammered	7	93
Wrot. iron, polished	23	77	Gold	5	95
Mercury	23	77	Silver, polished	3	97
Zinc	19	81			

The Stefan-Boltzmann Law. The radiating power of a body is proportional to the fourth power of the absolute temperature of the body. This law holds exactly for an absolute black body; for other bodies it holds with sufficient exactness for practical purposes.

Let A = area of radiating surface, sq. ft., z = time in hours, T = absolute temperature on the Fahrenheit scale, and Q = heat radiated in B.t.u. Then

$$Q = CAz\,(T/100)^4$$

The radiation constant C depends on the substance and on the character of the radiating surface. For the absolute black body, C = 0.1618. Values of C for various substances are given in Table 27.

Table 27. Radiation Constants of Various Materials

Material	Temp. range of experiment, deg. fahr.	C	Material	Temp. range of experiment, deg. fahr.	C
Glass, smooth	70	0.154	Red sandstone*	140–400	0.10
Brass, dull	100–660	0.0362	Italian marble*	140–400	0.095
Lampblack	32–100	0.154	Granite*	140–400	0.0745
Copper, slightly polished	100–540	0.0278	Dolomite*	140–400	0.0685
Wrought-iron, dull, oxidized	70–670	0.154	Clay	140–400	0.065
Wrought-iron, clean, bright	85–225	0.0562	Field soil	140–400	0.063
Wrought-iron, highly polished	105–480	0.0467	Chalk	140–400	0.051
Zinc, dull	120–545	0.034	Gravel	140–400	0.0481
Cast iron, rough, highly oxidized	105–480	0.157	Water	140	0.112
Lime plaster, rough, white	50–195	0.151	Ice	32	0.106
Basalt*	140–400	0.120	Gold plate, shining but not polished	70	0.082
Slate*	140–400	0.115			
Humus	140–400	0.110			

* Finished smooth, but not shining.

The simplest case of heat radiation is that in which a body having an external surface A of uniform temperature t_1 is enclosed within a second surface having a uniform temperature t_2. Let C_1, C_2 and C be the radiation constants for the two surfaces and for the absolute black body, respectively. Then the heat transmitted by radiation in z hours is

$$Q = Az[(T_1/100)^4 - (T_2/100)^4]/[(1/C_1) + (1/C_2) - (1/C)]$$

The following example (Dalby, *Inst. M. E.*, Oct., 1909) shows an application of this formula to steam boilers. Let the temperature of the furnace be 3000 deg. and that of the boiler plate or tubes, 800 deg. fahr., abs. The constant C_1 of the incandescent carbon may be taken as equal to the constant C of the black body, and C_2 for iron may be taken as 0.154. The heat radiated per sq. ft. of the boundary per hour is consequently

$$0.154[(3000/100)^4 - (800/100)^4] = 124{,}100 \text{ B.t.u.}$$

Ray and Kreisinger (Breckenridge, "Study of Four Hundred Steaming Tests," U. S. Geol. Survey, 1907) have studied the **relations between heat transmitted by radiation and by convection** in a Heine boiler. It was found that the heat transmitted by radiation increased with the temperature, as indicated by the Stefan law. The ratio of heat received by radiation to that received by convection varied from 3 to 15 per cent.

GENERAL PRINCIPLES OF THERMODYNAMICS

Notation:

Q, q = quantity of heat absorbed, B.t.u.
p = absolute pressure, lb. per sq. ft.
M = weight of substance under consideration, lb.
V, v = volume, cu. ft.
t = temperature, deg. fahr.
$T = t + 459.6$ = absolute temperature.
U, u = internal energy, B.t.u.
I, i = heat content at constant pressure, B.t.u.
S, s = entropy.
$J = 777.7$ = mechanical equivalent of heat.
$A = 1/J$ = reciprocal of mechanical equivalent.
c_p = specific heat at constant pressure.
c_v = specific heat at constant volume.
W = external work performed during a change of state.

In this notation small letters denote magnitudes referred to unit weight of the substance, capital letters corresponding magnitudes referred to M units of weight. Thus, v denotes the volume of 1 lb., $V = Mv$, the volume of M lb. Similarly, $U = Mu$, $S = Ms$, etc. Subscripts are used to indicate different states; thus, p_1, v_1, T_1, u_1, s_1, refer to the initial state, p_2, v_2, T_2, u_2, s_2 refer to the final state. Q_{12} is used to denote the heat absorbed by a body during the change from state 1 to state 2, and W_{12} denotes the external work done during the same change.

State of a Substance.—Characteristic Equations. Assuming that the substance under consideration (as air or steam) is homogeneous and of uniform density and temperature, and that it is subjected to a uniform pressure, the state of the substance is given by the values of p, v, and T. In general, two of these three variables may be changed independently, and the value of the third will then depend upon the values assigned to these two. That is, if v and T are taken to vary independently, then $p = f(v, T)$. The equation that expresses the relation between p, v, and T is called the **characteristic equation** of the substance in question.

For **perfect gases** the characteristic equation has the simple form

$$pv = RT.$$

This is approximately the equation of air, oxygen, nitrogen, and hydrogen. For certain gases, the equation of van der Waals

$$p = \frac{BT}{v - b} - \frac{a}{v^2}$$

represents quite accurately the states of the substance. The empirical equation $v - c = (BT/p) - [(1 + 3ap^{1/2})\, m/T^n]$ applies to **superheated steam.**

Any magnitude that depends upon the state of the substance may be used as a variable to describe the state. In addition to p, v, and T, the entropy s, energy u, and heat content i may be so used.

Fundamental Laws of Thermodynamics

Transformations of Energy are subject to two general laws: (1) The law of **conservation of energy,** which may be stated as follows: The total energy of an isolated system remains constant and cannot be increased or diminished by any physical process whatever. (2) The law of **degradation of energy,** according to which the result of any transformation of energy is a reduction in the quantity of energy available for transformation into useful work.

The following are familiar examples of degradation: Work transformed into heat through friction; electrical energy transformed into heat in the conducting system; flow of heat from a body of higher temperature to one of lower temperature; throttling or wire-drawing processes.

The First Law of Thermodynamics is the conservation law applied to the transformation of heat into work, or *vice versa*. When work is expended in producing heat, the quantity of heat generated is equivalent to the work done; conversely, when heat is employed to do work, a quantity of heat precisely equivalent to the work done disappears.

The first law is expressed symbolically by the equation $W = JQ$, in which W denotes the work and J the **mechanical equivalent of heat.** The following are the values of the constant J in various units:

$$1 \text{ gram-calorie} = 4.184 \text{ joules}$$
$$1 \text{ kg.-calorie} = 426.65 \text{ m.-kg.}$$
$$1 \text{ B.t.u.} = 777.64 \text{ ft.-lb.}$$

For ordinary calculations the values 427 and 778 are sufficiently accurate. Another useful relation is

$$1 \text{ h.p.-hr.} = 2546 \text{ B.t.u.}$$

In writing the equations of thermodynamics it is frequently convenient to use the reciprocal of J, which is denoted by A; thus $A = 1/J$.

The Energy Equation. The first law applied to a change of state of a substance is expressed by the equation

$$JQ_{12} - W_{12} = E_2 - E_1$$

in which E_1 denotes the total energy of the substance in the initial state and E_2 the total energy in the final state. The total energy E is made up of the internal energy U and the external kinetic energy. The latter comes into consideration in the flow of fluids. In case the kinetic energy remains constant or $= 0$, the energy equation becomes

$$Q_{12} = U_2 - U_1 + AW_{12}$$

If the work W arises from the overcoming of fluid pressure, then $W = \int pdV$ and the equation takes the form

$$dQ = dU + ApdV, \text{ or } Q_{12} = U_2 - U_1 + A\int_{V_1}^{V_2} pdV$$

The change of energy depends upon the initial and final states of the system only. The external work depends, however, on the relation between p and V during the change of state, that is, upon the path; hence the heat absorbed also depends upon the path.

If a system passes through a closed cycle of processes and returns to its initial state, the change of energy for the cycle is zero; hence for a closed cycle the heat absorbed by the system is the equivalent of the external work. This statement is expressed symbolically by the equation $J(Q) = (W)$, where (Q) denotes the heat absorbed for the cycle and (W) the net work performed. If the change of state is adiabatic, the heat absorbed is zero and the external work is gained at the expense of the intrinsic energy of the system. That is, $W_{12} = U_1 - U_2$.

The Second Law of Thermodynamics is essentially the law of degradation of energy. While the first law gives a relation that must be satisfied in any transformation of energy, it is the second law that gives information regarding the possibility of transformation and the availability of a given form of energy for transformation into work. The following is a general statement of the second law: **No change in a system of bodies that takes place of itself can increase the available energy of a system.**

A more concrete statement is that of Kelvin, namely: It is impossible by means of inanimate material agency to derive mechanical effect from any portion of matter by cooling it below the temperature of surrounding objects. In effect, Kelvin's statement denies the possibility of deriving work directly from the heat contained in the atmosphere.

The availability of a given quantity of heat energy for transformation into work is given by the efficiency of the **ideal Carnot engine.** Thus, if T denote the temperature of the source of heat and T_0 that of the refrigerator, or coldest body available, then the efficiency is $e = (T - T_0)/T = 1 - (T_0/T)$. If heat Q is taken from the source the part $Q[1 - (T_0/T)]$ may be transformed into work under ideal conditions, but the part $Q(T_0/T)$ at least must be rejected.

Entropy. Experience shows that every actual physical process is irreversible and accompanied by frictional effects. As a result the actual irreversible process is accompanied by a decrease of the quantity of energy available for transformation into work, or, what is the same thing, an increase of unavailable energy. The increase of unavailable energy is the product of two factors: one is T_0, the lowest absolute temperature available (usually the temperature of the atmosphere), the other is a term of the form Q/T or $\int dQ/T$. To this second factor the name **increase of entropy** is given.

When the conception of increase of entropy is applied to the system composed of all the bodies involved in a change, that is, to an isolated system, it appears that the increase of entropy is a measure of the thermodynamic degeneration produced by the change. According to the law of degradation every natural change is accompanied by thermodynamic degeneration, therefore it is accompanied by an increase of entropy. The following important principle is evident: The direction of a process, physical or chemical, that occurs of itself is such as will bring about an increase of entropy of the system. This principle is the foundation of the application of thermodynamics to chemistry.

The conception of increase of entropy may be extended to a body not isolated but in thermal communication with other bodies. In this case the change of entropy is given by the relation

$$S_2 - S_1 = \int_{T_1}^{T_2} \frac{dQ}{T} + \int_{T_1}^{T_2} \frac{dH}{T}$$

in which Q denotes heat absorbed by the body from outside and H heat generated within the system through friction. For a reversible frictionless change, the increase of entropy is simply $\int_{T_1}^{T_2} \frac{dQ}{T}$.

The entropy of the body, as thus defined, depends on the state only; hence S may be used with p, V, and T as a variable defining the state. For reversible frictionless changes, the defining equation gives $dQ = TdS$; hence the energy equation may be written $TdS = dU + ApdV$.

General Thermodynamic Relations. The first law gives the **energy equation**

$$dQ = dU + ApdV \tag{1}$$

the second law gives the **entropy equation**

$$dQ = TdS \tag{2}$$

A third general equation is obtained by the introduction of a magnitude analogous to the energy u and defined by the relation

$$i = u + Apv \quad (I = U + ApV)$$

This is called the **heat content at constant pressure,** for the reason that $I_2 - I_1 = Q_{12}$ for a change at constant pressure. By the introduction of I, Eq. (1) takes the form

$$dQ = dI - AVdp \tag{3}$$

By various transformations the following relations are derived from these three fundamental equations:

1. **Maxwell's thermodynamic relations:**

$$\left(\frac{\partial T}{\partial v}\right)_s = -A\left(\frac{\partial p}{\partial s}\right)_v \qquad \left(\frac{\partial s}{\partial v}\right)_T = A\left(\frac{\partial p}{\partial T}\right)_v$$

$$\left(\frac{\partial T}{\partial p}\right)_s = A\left(\frac{\partial v}{\partial s}\right)_p \qquad \left(\frac{\partial s}{\partial p}\right)_T = -A\left(\frac{\partial v}{\partial T}\right)_p$$

2. **Relations involving specific heats:**

$$c_v = \left(\frac{\partial q}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v \qquad c_v = \left(\frac{\partial u}{\partial T}\right)_v$$

$$c_p = \left(\frac{\partial q}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p \qquad c_p = \left(\frac{\partial i}{\partial T}\right)_p$$

$$c_p - c_v = AT\left(\frac{\partial v}{\partial T}\right)_p\left(\frac{\partial p}{\partial T}\right)_v$$

$$\left(\frac{\partial c_v}{\partial v}\right)_T = AT\left(\frac{\partial^2 p}{\partial T^2}\right)_v \qquad \left(\frac{\partial c_p}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p$$

3. **Relations involving q, u, i, and s:**

$$dq = c_v dT + AT\left(\frac{\partial p}{\partial T}\right)_v dv \qquad dq = c_p dT - AT\left(\frac{\partial v}{\partial T}\right)_p dp$$

$$du = c_v dt + A\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]dv, \quad di = c_p dT - A\left[T\left(\frac{\partial v}{\partial T}\right)_p - v\right]dp$$

$$ds = c_v\frac{dT}{T} + A\left(\frac{\partial p}{\partial T}\right)_v dv = c_p\frac{dT}{T} - A\left(\frac{\partial v}{\partial T}\right)_p dp$$

The derivatives involved in these relations are found from the characteristic equation of the substance under investigation. Thus, for a perfect gas,

$pv = BT$, whence $\left(\frac{\partial p}{\partial T}\right)_v = \frac{B}{v}$, $\left(\frac{\partial v}{\partial T}\right)_p = \frac{B}{p}$. Substitution of these expressions in the preceding equations gives the following results for gases:

$$c_p - c_v = AB$$

$$dq = c_v dT + Apdv \qquad dq = c_p dT - Avdp$$

$$du = c_v dT \qquad di = c_p dT$$

$$ds = c_v \frac{dT}{T} + AB\frac{dv}{v} = c_p\frac{dT}{T} - AB\frac{dp}{p}.$$

As an example of the use of the Clausius relation $\left(\frac{\partial c_p}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p$, consider the case of superheated steam, the equation of which is $v - c = \frac{BT}{p} - (1+3ap^{1/2})\frac{m}{T^n}$.

$\left(\frac{\partial^2 v}{\partial T^2}\right)_p = -\frac{mn(n+1)}{T^{n+2}}(1+3ap^{1/2})$, whence $\left(\frac{\partial c_p}{\partial p}\right)_T = \frac{Amn(n+1)}{T^{n+1}}(1+3ap^{1/2})$, and

$c_p = \frac{Amn(n+1)}{T^{n+1}}p(1+2ap^{1/2}) + f(T)$.

It follows that c_p for superheated steam varies with the temperature and also with the pressure.

Graphical Representation. The change of state of a substance may be shown graphically by taking any two of the six variables p, V, T, S, U, I, as independent co-ordinates and drawing a curve to represent the successive values of these two variables as the change proceeds. While any pair may be chosen, there are three systems of graphical representation that are specially useful.

1. p and V. The curve (Fig. 2) represents the simultaneous values of p and V during the change from state 1 to state 2. The area between the curve and the axis OV is given by the integral $\int_{V_1}^{V_2} pdV$ and therefore represents the external work W_{12} done by the gas during the change. The area included by a closed cycle represents the work of the cycle (as in the indicator diagram of the steam engine).

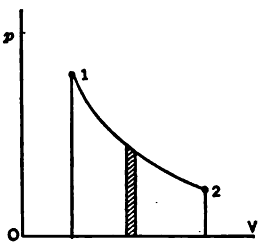

FIG. 2.

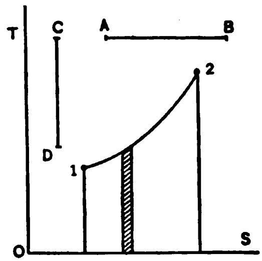

FIG. 3.

2. T and S (Fig. 3). The absolute temperature T is taken as the ordinate; the entropy S as the abscissa. The area between the curve of change of state and the S-axis is given by the integral $\int_{S_1}^{S_2} TdS$, and it therefore represents the heat Q_{12} absorbed by the substance from external sources provided there are no irreversible frictional effects. On the T-S diagram an isothermal is a straight line, as AB, parallel to the S-axis; a reversible adiabatic is a straight line, as CD, parallel to the T-axis.

In the case of internal generation of heat through friction, as in steam turbines, the increase of entropy is given by $\int_{T_1}^{T_2} \frac{dH}{T}$ (see p. 312) and the area under the curve represents the heat H thus generated. In this case an adiabatic is *not* a straight line parallel to the T-axis.

3. I and S. In the system of representation devised by Dr. Mollier, the heat content I is taken as the ordinate and the entropy S as the abscissa. If on this diagram (Fig. 4) a line of constant pressure, as 12, be drawn, the heat absorbed during the change at constant pressure, is given by $Q_{12} = I_2 - I_1$, and this is represented by the line segment 23. The **Mollier diagram** is specially useful in problems that involve the flow of fluids, throttling, and the action of steam in turbines. The advantage lies in the fact that heat and work are represented by line segments instead of areas. A Mollier diagram for steam is given on p. 330, and for ammonia on p. 334.

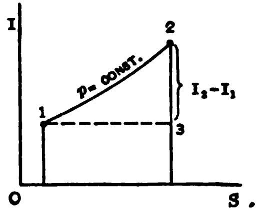

FIG. 4.

PERFECT GASES

Laws of Gases. The so-called perfect gases are those that obey very closely the laws of Boyle and Gay-Lussac. The two laws are combined in the characteristic equations $pv = RT$, $pV = MRT$, in which R is a constant for any gas. The value of R for a gas is inversely proportional to the molecular weight m of the gas and is given by the relation $1544/m$.

Since for a perfect gas $\left(\frac{\partial p}{\partial T}\right)_v = \frac{R}{v} = \frac{T}{p}$, the general equation (p. 313) becomes $\left(\frac{\partial u}{\partial v}\right)_T = AT\left(\frac{\partial p}{\partial T}\right)_v - Ap = 0$; that is, the internal energy u is independent of the volume and depends on the temperature only.

Specific Heats. According to the experiments of Regnault and others the specific heats c_p and c_v of diatomic gases (oxygen, nitrogen, etc.) are practically constant for considerable ranges of temperature, and in ordinary applications that involve only moderate ranges of temperature they may be taken as constant. Other gases, as superheated steam, ammonia, and carbon dioxide, show a considerable variation of specific heat with the temperature. The values of c_p and c_v in Table 28 are therefore to be considered as approximately correct for the range 32 deg.–400 deg. fahr. For further discussion of specific heats of various gases and of superheated steam, see pp. 365, and 327.

The difference of the specific heats c_p and c_v is given by the relation $c_p - c_v = AR = 1.9855/m$, or approximately $2/m$. The ratio c_p/c_v is denoted by k, and the value of k for diatomic gases is about 1.4.

Specific Weight and Specific Volume. Referred to standard atmospheric pressure and a temperature of 32 deg. fahr., the weight of a cubic foot of gas is 0.002788 m lb. and the volume of one pound in cubic feet is $358.65/m$. The **mol** is frequently taken as the unit of weight for gases. The mol is defined as m lb. where m denotes the molecular weight; thus, for oxygen, 1 mol = 32 lb. For any gas, therefore, the volume of 1 mol at 32 deg. fahr. and atmospheric pressure is 358.65 cu. ft. If M' denotes the weight in mols, then $M = M'm$, and the characteristic equation becomes

$$pV = 1544\ M'T, \quad \text{or} \quad ApV = 1.9855\ M'T$$

The specific heats referred to the mol as the unit of weight are mc_p and mc_v, respectively, and $mc_p - mc_v = 1.9855$ ($= 2$, approx.); $mc_p = 1.9855k/(k - 1)$; $mc_v = 1.9855/(k - 1)$.

Taking $k = 1.4$ for diatomic gases, then approximately $mc_p = 7$, $mc_v = 5$.

* For more accurate values of specific heats, see pp. 365, 1514.

Gas Mixtures. Let V denote the total volume of the mixture, M_1, M_2, M_3 . . . the weights of the constituent gases, R_1, R_2, R_3 . . . the corresponding gas constants, and R_m the constant for the mixture. The **partial pressures** of the constituents, that is, the pressures that the constituents would have if occupying the total volume V, are $p_1 = M_1R_1T/V$, $p_2 = M_2R_2T/V$, etc.

According to Dalton's law, the **total pressure** p **of the mixture** is the sum of the partial pressures; that is, $p = p_1 + p_2 + p_3 + \ldots$ Let $M = M_1 + M_2 + M_3 + \ldots$ denote the total weight of the mixture; then $pV = MR_mT$ and $R_m = \Sigma(M_iR_i)/M$. Also $p_1/p = M_1R_1/MR_m$, $p_2/p = M_2R_2/MR_m$, etc.

Let V_1, V_2, V_3, . . . denote the volumes that would be occupied by the constituents at pressure p and temperature T (these are given by the volume composition of the gas). Then $V = V_1 + V_2 + V_3 + \ldots$ and the apparent molecular weight m_m of the mixture is $m_m = \Sigma(m_iV_i)/V$. Then $R_m = 1544/m_m$.

Volume of 1 lb. at 32 deg. fahr. and atmos. pressure $= 358.65/m_m$.

Weight of 1 cu. ft. at 32 deg. fahr. and atmos. pressure $= 0.002788m_m$.

The **specific heats of the mixture** are, respectively

$$c_p = \Sigma(M_ic_{pi})/M, \qquad c_v = \Sigma(M_ic_{vi})/M.$$

Energy, Heat Content, and Entropy. If a gas changes from an initial state p_1, V_1, T_1, to a final state p_2, V_2, T_2, the following equations hold:

$$U_2 - U_1 = Mc_v\,(T_2 - T_1) = A(p_2V_2 - p_1V_1)/(k-1)$$

$$I_2 - I_1 = Mc_p\,(T_2 - T_1) = Ak(p_2V_2 - p_1V_1)/(k-1).$$

$$S_2 - S_1 = M\left[c_v \log_e \frac{T_2}{T_1} + AR \log_e \frac{V_2}{V_1}\right] = M\left[c_p \log_e \frac{T_2}{T_1} - AR \log_e \frac{p_2}{p_1}\right].$$

$$= M\left[c_p \log_e \frac{V_2}{V_1} + c_v \log_e \frac{p_2}{p_1}\right].$$

In general, the energy per unit weight is $u = c_vT + u_0$,
the heat content is $i = c_pT + i_0$,
and the entropy is $s = c_v \log T + AR \log v + s_0$
$= c_p \log T - AR \log p + s'_0 = c_p \log v + c_v \log p + s''_0$

The two fundamental equations for gases are

$$dq = c_vdT + Apdv, \qquad dq = c_pdT - Avdp.$$

Special Changes of State

In the following formulæ the subscripts 1 and 2 refer to the initial and final states, respectively.

1. Constant Volume: $p_2/p_1 = T_2/T_1$. $Q_{12} = U_2 - U_1 = Mc_v\,(t_2 - t_1)$. $Q_{12} = A\,V(p_2 - p_1)/(k-1)$. $W = 0$. $s_2 - s_1 = Mc_v \log_e(T_2/T_1)$.

2. Constant Pressure: $V_2/V_1 = T_2/T_1$. $W_{12} = p(V_2 - V_1) = MR\,(t_2 - t_1)$. $Q_{12} = Mc_p\,(t_2 - t_1) = AkW_{12}/(k-1)$. $s_2 - s_1 = Mc_p \log_e(T_2/T_1)$.

3. Isothermal. (Constant Temperature): $p_2/p_1 = V_1/V_2$. $U_2 - U_1 = 0$. $W_{12} = MRT \log_e(V_2/V_1) = p_1V_1 \log_e(V_2/V_1)$. $Q_{12} = AW_{12}$. $s_2 - s_1 = Q_{12}/T = MAR \log_e(V_2/V_1)$.

4. Adiabatic: $T_2/T_1 = (V_1/V_2)^{k-1} = (p_2/p_1)^{(k-1)/k}$. $p_1V_1^k = p_2V_2^k$.

$$AW_{12} = U_1 - U_2 = Mc_v(t_1 - t_2). \quad Q_{12} = 0. \quad s_2 - s_1 = 0.$$

$$W_{12} = (p_1V_1 - p_2V_2)/(k-1) = p_1V_1[1 - (p_2/p_1)^{(k-1)/k}]/(k-1).$$

5. Polytropic. This name is given to the change of state which is represented by the equation pV^n = const. The polytropic curve usually represents sufficiently well actual expansion and compression curves in motors and air compressors. By giving n different values the preceding changes are made special cases of the polytropic change, thus,

for $n = 1$,	pv = const.	isothermal
$n = k$,	pv^k = const.	adiabatic
$n = 0$,	p = const.	constant pressure
$n = \infty$,	v = const.	constant volume

For a polytropic change the specific heat is constant and is given by the relation $c_n = c_v(n-k)/(n-1)$; hence for $1 < n < k$, c_n is negative. This is the case in **air compression.** The following are the principal formulæ:

$p_1V_1^n = p_2V_2^n$. $\quad T_2/T_1 = (V_1/V_2)^{n-1} = (p_2/p_1)^{(n-1)/n}$.

$$W_{12} = (p_1V_1 - p_2V_2)/(n-1) = p_1V_1[1 - (p_2/p_1)^{(n-1)/n}]/(n-1).$$

$$Q_{12} = Mc_n(t_2 - t_1).$$

$$AW_{12} : U_2 - U_1 : Q_{12} = k - 1 : 1 - n : k - n$$

Construction of Polytropic Curves (Fig. 5). Through the origin O a line OA is drawn at any convenient angle a with the V-axis. Then a second line OB is drawn making the angle b with the p-axis, where angle b is determined by the relation $(1 + \tan b) = (1 + \tan a)^n$. From the initial point 1 (p_1, V_1) locate points C and D on the axes. Then, by drawing 45-deg. lines between the axes and the auxiliary lines, as shown in the figure, the successive points on the curve, 2, 3, 4, etc., are obtained.

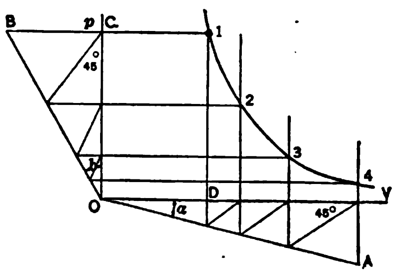

Fig. 5.—Graphical Construction for Polytropic Curves.

Determination of Exponent n. Lay off successive values of p and V, measured at chosen points on the curve under investigation, on logarithmic cross-section paper; or, lay off values of log p and log V on ordinary cross-section paper. If n is a constant, the points will lie in a straight line, and the slope of the line gives the value of n.

If two representative points (p_1, V_1 and p_2, V_2) be chosen, then

$$n = (\log p_1 - \log p_2)/(\log V_1 - \log V_2).$$

Several pairs of points should be used in order to test the constancy of n.

Changes of State with Variable Specific Heat. In case of a considerable range of temperature, as in the internal-combustion motor, the assumption of constant specific heat is not permissible, and the equations referring to changes of state must be suitably modified. Experiments on the specific heat of various gases show that the specific heat may be taken as a linear function of the temperature: thus, $c_v = a + bT$; $c_p = a' + bT$.

From the fundamental equation for gases, $dq = c_v dT + Apdv$, the following expressions are found for the change of energy and entropy, respectively:

$$U_2 - U_1 = M[a(T_2 - T_1) + 0.5b\,(T_2^2 - T_1^2)]$$

$$S_2 - S_1 = M[a \log_e (T_2/T_1) + b(T_2 - T_1) + AR \log_e (V_2/V_1)].$$

For an adiabatic change,

$$W_{12} = J(U_1 - U_2)$$

$$AR \log_e (p_2/p_1) = (a + AR) \log_e (T_2/T_1) + b(T_2 - T_1)$$

$$AR \log_e (V_1/V_2) = a \log_e (T_2/T_1) + b(T_2 - T_1)$$

Ideal Cycles with Perfect Gases

Gases are used as heat media in several important types of motors. In air compressors, air engines, and air refrigerating machines, atmospheric air is the medium. In the internal-combustion engine the medium is a mixture of products of combustion. Motors using gases are operated in certain well-defined cycles, which are described in the following sections. In the analyses given ideal conditions that cannot be attained by actual motors are assumed. However, conclusions derived from such analyses are usually valid for the modified actual cycle.

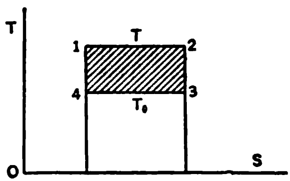

FIG. 6.—Carnot Cycle.

In the following the subscripts 1, 2, 3, etc., refer to corresponding points shown in the figures. The work of the cycle is denoted by (W) and the net heat absorbed by (Q).

Carnot's Cycle. The Carnot cycle (Fig. 6) has historical interest only. It consists of two isothermals and two adiabatics. The heat absorbed along the upper isothermal 12 is $Q_{12} = MART \log_e (V_2/V_1)$, and the heat transformed into work, represented by the cycle area is $A(W) = Q_{12}[1 - (T_0/T)]$.

Hence $\quad (W) = MR(T - T_0) \log_e (V_2/V_1)$

If the cycle is traversed in the reverse sense, $Q_{43} = MART_0 \log_e (V_3/V_4)$ is the heat absorbed from the cold body (brine), and the ratio $Q_{43} : A(W) = T_0 : (T - T_0)$ is the **coefficient of performance** of the refrigerating machine.

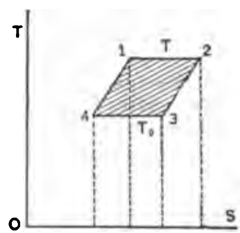

FIG. 7.—Stirling Cycle.

Stirling and Ericsson Cycles. In the Stirling air engine (Fig. 7) the adiabatics of the Carnot cycle are replaced by constant-volume curves; in the Ericsson engine by constant-pressure curves. By the use of a regenerator the heat Q_{23} rejected during the operation 23 is stored and is given back to the medium during the operation 41. In the ideal case, $Q_{23} = Q_{41}$, hence the heat absorbed from the source is $Q_{12} = MART \log_e V_2/V_1$, as in the Carnot cycle, and the efficiency is identical with that of the Carnot cycle.

Air engines of the Stirling and Ericsson type, in which the medium is separated from the furnace by a metal wall, have been failures, and have been replaced by the internal-combustion type, in which the air comes into direct contact with the fuel inside of the working cylinder. The rapid chemical action supported by the medium itself makes possible the rapid heating of large quantities of air to a very high temperature. And by proper cooling of the outside surface of the metal walls, the deterioration of the metal is prevented even at high temperatures.

The ideal cycles usually employed for internal-combustion engines may be classified in two groups: 1. Explosive—Otto. 2. Non-explosive—Diesel, Joule.

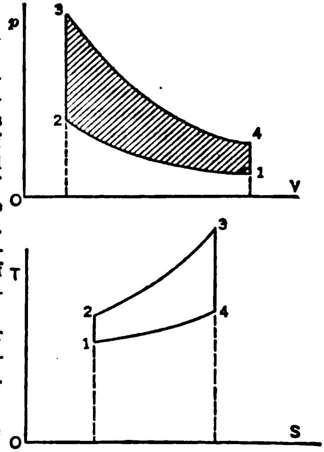

FIG. 8.—Otto Cycle.

The Otto Cycle (Fig. 8). Adiabatic (or polytropic) compression 12 is followed by ignition and rapid heating at constant volume, 23. This is followed by adiabatic expansion, 34. Assuming compression and expansion to be adiabatic, the following relations hold:

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} = \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}} = \left(\frac{p_3}{p_4}\right)^{\frac{k-1}{k}} = \left(\frac{V_1}{V_2}\right)^{k-1}.$$

$$Q_{23} = Mc_v(T_3 - T_2).$$

$$(W) = JQ_{23}[1 - (T_1/T_2)] = JMc_v(T_3 - T_4 - T_2 + T_1)$$

$$\text{Efficiency} = 1 - \frac{T_1}{T_2} = 1 - \left(\frac{V_2}{V_1}\right)^{k-1} = 1 - \left(\frac{p_1}{p_2}\right)^{\frac{k-1}{k}}.$$

If the compression and expansion curves are polytropics with the same value of n, replace k by n in the first relation above. In this case,

$$(W) = [(p_3V_3 - p_4V_4) - (p_2V_2 - p_1V_1)]/(n-1) = MR(T_3 - T_4 - T_2 + T_1)/(n-1).$$

The **mean effective pressure** of the diagram is given by

$$p_m = ap_1[(p_3/p_2) - 1],$$

where a has the values given in the following table.

	$p_2/p_1 =$	3	4	5	6	8	10	12	14	16
(n = 1.4)..........	$a =$	1.70	1.94	2.13	2.31	2.62	2.88	3.10	3.31	3.50
(n = 1.3)..........	$a =$	1.69	1.92	2.11	2.28	2.57	2.81	3.08	3.22	3.39
(n = 1.2)..........	$a =$	1.68	1.90	2.08	2.25	2.51	2.74	2.94	3.12	3.27

The Joule Cycle (Fig. 9) consists of two adiabatics and two constant-pressure lines. The following relations hold:

$$V_3/V_2 = V_4/V_1 = T_3/T_2 = T_4/T_1.$$

$$\frac{T_2}{T_1} = \frac{T_3}{T_4} = \left(\frac{V_1}{V_2}\right)^{k-1} = \left(\frac{V_4}{V_3}\right)^{k-1} = \left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}$$

$(W) = JMc_p(T_3 - T_2 - T_4 + T_1)$. Efficiency $= (W)/JQ_{23} = 1 - (T_1/T_2)$.

For the use of the Joule cycle in refrigeration, see p. 346.

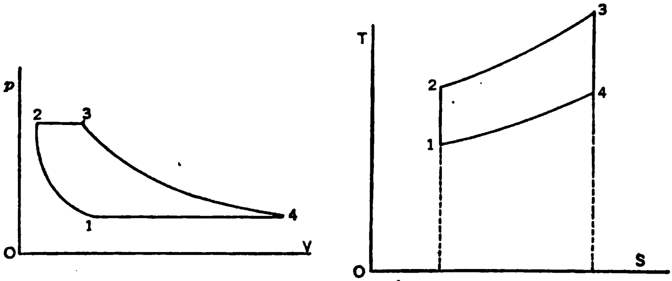

Fig. 9.—Joule Cycle.

The Diesel Cycle. In the Diesel oil engine air is compressed to a pressure of about 500 lb. per sq. in. Fuel is then injected into the air and, as the temperature is above the ignition point, burns at nearly constant pressure (23, in Fig. 10). Adiabatic expansion of the products of combustion is followed by exhaust and suction of fresh air, as in the Otto cycle.

The work obtained is

$$(W) = JM[c_p(T_3 - T_2) - c_v(T_4 - T_1)],$$

and the efficiency of the ideal cycle is

$$1 - [(T_4 - T_1)/k(T_3 - T_2)].$$

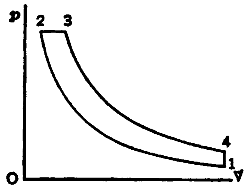

Fig. 10.—Diesel Cycle.

Air Compression. It is assumed that the compressor works under ideal conditions without clearance and without friction losses. If the compression from p_1 to p_2 (Fig. 11*a*) follows the law pV^n = const., the work represented by the indicator diagram is

$$W = n(p_2V_2 - p_1V_1)/(n - 1) = np_1V_1[(p_2/p_1)^{(n-1)/n} - 1]/(n - 1).$$

The temperature at the end of compression is given by $T_2/T_1 = (p_2/p_1)^{(n-1)/n}$. The work W is smaller the smaller the value of n, and to reduce n from the adiabatic value 1.4 is the office of the water jacket. Under usual working conditions, n is about 1.3.

When the pressure p_2 is high it is advantageous to divide the process into two or more stages and cool the air between the cylinders. The saving effected is best shown on the T-S plane (Fig. 11*b*). With single-stage compression, 12 represents the compression from p_1 to p_2, and if the constant-pressure line 23 is drawn cutting the isothermal through point 1 in point 3, the area 1′1233′ represents the work W. When two stages are used, 14 represents the compression from p_1 to an intermediate pressure p', 45 cooling at constant pressure in the intercooler between the cylinders, and 56 the compression in the second stage. The area under 14563 represents the work of the two stages and the area 2456 the saving effected by compounding. This saving is a maximum when $T_4 = T_6$, and this is the case when the intermediate pressure p' is given by $p' = \sqrt{p_1 p_2}$.

The total work in two-stage compression is

$$n\, p_1 V_1 \left[(p'/p_1)^{(n-1)/n} + (p_2/p')^{(n-1)/n} - 2\right] /(n-1).$$

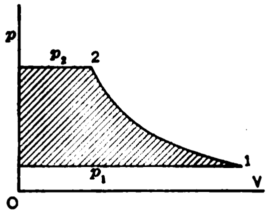

FIG. 11*a*.

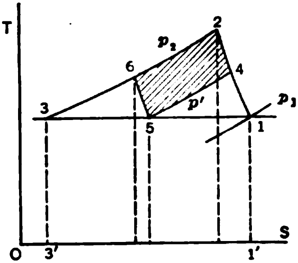

FIG. 11*b*.

Air-compressor Cycle.

VAPORS

General Characteristics of Vapors. Let a gas be compressed at constant temperature; then, provided this temperature does not exceed a certain critical value, the gas begins to liquefy at a definite pressure, which depends upon the temperature. At the beginning of liquefaction, a unit weight of gas will also have a definite volume v'', depending on the temperature. In Fig. 12, AB represents the compression and the point B gives the **saturation** pressure and volume. If the compression is continued the pressure remains constant with the temperature, as indicated by BC, until at C the substance is in the liquid state with the volume v'.

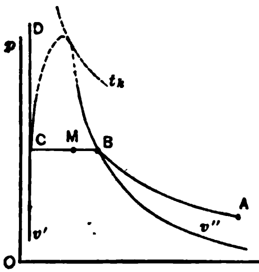

FIG. 12.

The curves v' and v'' giving the volumes for various temperatures at the end and beginning of liquefaction, respectively, may be called the **limit curves.** A point B on curve v'' represents the state of **saturated vapor**; a point C on the curve v' represents the liquid state; and a point M between B and C represents a mixture of vapor and liquid of which the part $x = MC/BC$ is vapor and the part $1 - x = BM/BC$ is liquid. The ratio x is called the **quality of the mixture.** The region between the curves v' and v'' is thus the region of liquid and vapor mixtures. The region to the right of curve v'' is the region of **superheated vapor.** The curve v'' dividing these regions represents the so-called **saturated vapor.**

For saturated vapor or a mixture of vapor and liquid, the pressure is a function of the temperature only, and the volume of the mixture depends upon the temperature and quality x. That is, $p = f(t)$, $v = F(t, x)$.

For the vapor in the superheated state the volume depends on pressure and temperature $[v = F_1(p, t)]$, and these may be varied independently.

Critical States. If the temperature of the gas lies above a definite temperature t_k called the **critical temperature,** the gas cannot be liquefied by compression alone. The saturation pressure corresponding to t_k is the **critical pressure** and is denoted by p_k. At the critical state the limit curves v' and v'' merge; hence for temperatures above t_k it is impossible to have a mixture of vapor and liquid. Table 30 gives the critical data for various gas; also the boiling temperature t_b corresponding to atmospheric pressure.

Thermal Properties of Saturated Vapors and of Vapor and Liquid Mixtures

Notation:

v' = volume in cu. ft. of 1 lb. of liquid.
v'' = volume in cu. ft. of 1 lb. of saturated vapor, at given temperature.
c' = specific heat of liquid.
c'' = specific heat of saturated vapor, at given temperature.
r = latent heat, or heat required to vaporize 1 lb. of liquid at given constant pressure and temperature.
$AL = Ap(v'' - v')$ = external latent heat, *i.e.*, the heat equivalent of the external work performed during vaporization.
$l = r - Ap(v'' - v')$ = internal latent heat.
i', i'' = heat content of liquid and saturated vapor, respectively.
u', u'' = internal energy of liquid and saturated vapor, respectively.
s' = entropy of the liquid.
s'' = entropy of saturated vapor.

For a unit weight (1 lb.) of saturated vapor the following relations exist:

$$i'' = i' + r. \qquad u'' = u' + l. \qquad s' = \int_{491.6}^{T} c' dT/T. \qquad s'' = s' + (r/T).$$

$r/T = A\, dp/dt\, (v'' - v')$ (Clapeyron's equation), the derivative dp/dt being determined from the relation $p = f(t)$ between temperature and pressure at saturation.

For a unit weight of mixture of vapor and liquid, quality x, these relations become $i = i' + xr, \quad u = u' + xl, \quad s = s' + (xr/T)$;
also $\qquad v = v' + x(v'' - v')$.

Tables of Thermal Properties of Vapors

Water Vapor. The experimental data relating to the properties of water vapor have been correlated by Marks and Davis; and the values given in the Marks and Davis tables may be accepted as the most accurate that have yet been published.

The **relation between pressure and temperature** is most satisfactorily represented by Marks's equation

$$\log p = 10.515354 - (4873.71/T) - 0.00405096T + 0.000001392964T^2.$$

For the **heat content** i'' **of saturated steam** Davis has deduced the equation

$$i'' = 1150.3 + 0.3745(t - 212) - 0.00055(t - 212)^2.$$

This applies to the range 212 deg. to 400 deg. fahr.

The **heat content** i' **of water between 32 deg. and 212 deg. fahr.** is deduced from the experiments of Barnes and Dieterici, and above 212 deg. from the experiments of Dieterici and Regnault. With these fundamental data the remaining properties are readily calculated. For an exhaustive discussion of sources and methods see Marks and Davis, "Steam Tables and Diagrams," pp. 87–106. For density and specific heat of water at saturation pressures see Table 3.

For **condenser calculations** a more detailed table of the properties of saturated steam at temperatures from 50 deg. to 130 deg. fahr. is given in Table 32, which is calculated from the Marks and Davis tables. Vacuums are stated with reference to a 30-in. barometer; the standard atmosphere is equal to 30 in. of mercury when the mercury is at 58.4 deg. fahr. Absolute pressures are given in lb. per sq. in. and also in in. of mercury at 32 deg. fahr.

Properties of Superheated Steam. An experimental basis for the properties of superheated steam is furnished by the researches carried on in the Munich laboratory. Volume measurements have been given by Knoblauch, Linde, and Klebe; specific-heat measurements by Knoblauch and

Jakob and by Knoblauch and Mollier. These two sets of measurements are connected by the Clausius thermodynamic relation

$$\left(\frac{\partial c_p}{\partial p}\right)_T = -AT\frac{\partial^2 v}{\partial T^2}.\quad \text{(See p. 313.)}$$

Table 32. Steam Table for Use in Condenser Calculations

Goodenough (*Bulletin* No. 75, Engr. Exper. Station, Univ. of Ill.) gives the following equations for volume and specific heat, which satisfy this relation and at the same time represent accurately the results of the experiments:

$$v - 0.017 = 0.59465\,(T/p) - (1 + 0.0513p^{1/2})\,(m/T^4). \quad \log m = 10.82500.$$

$$c_p = 0.320 + 0.000126T + (23{,}583/T^2) + p(1 + 0.0342p^{1/2})\,(C'/T^5),$$

where p = lb. per sq. in. Also

$$i = 0.320T + 0.000063T^2 - (23{,}583/T) - p(1 + 0.0342p^{1/2})\,(C''/T^4) + 948.7.$$

$$u = 0.2099T + 0.000063T^2 - (23{,}583/T) - p(1 + 0.02992p^{1/2})\,(C'''/T^4) + 948.7.$$

$$s = 0.73683 \log T + 0.000126T - (11{,}792/T^2) - 0.254 \log p - (C^{iv}p/T^5)\,(1 + 0.0342p^{1/2}) - 0.0809.$$

$$\log C' = 11.39361;\ \log C'' = 10.79155;\ \log C''' = \log C^{iv} = 10.69464.$$

The quotient $\int_{t_s}^{t} c_p dt/(t - t_s)$ gives the **mean specific heat of superheated steam** between the saturation temperature t_s and any chosen higher temperature. Table 33 gives values of c_{pm} thus calculated for various pressures and superheats.

Table 33. Mean Specific Heat of Superheated Steam

Pressure, lb. per sq. in.	Superheat, deg. fahr.

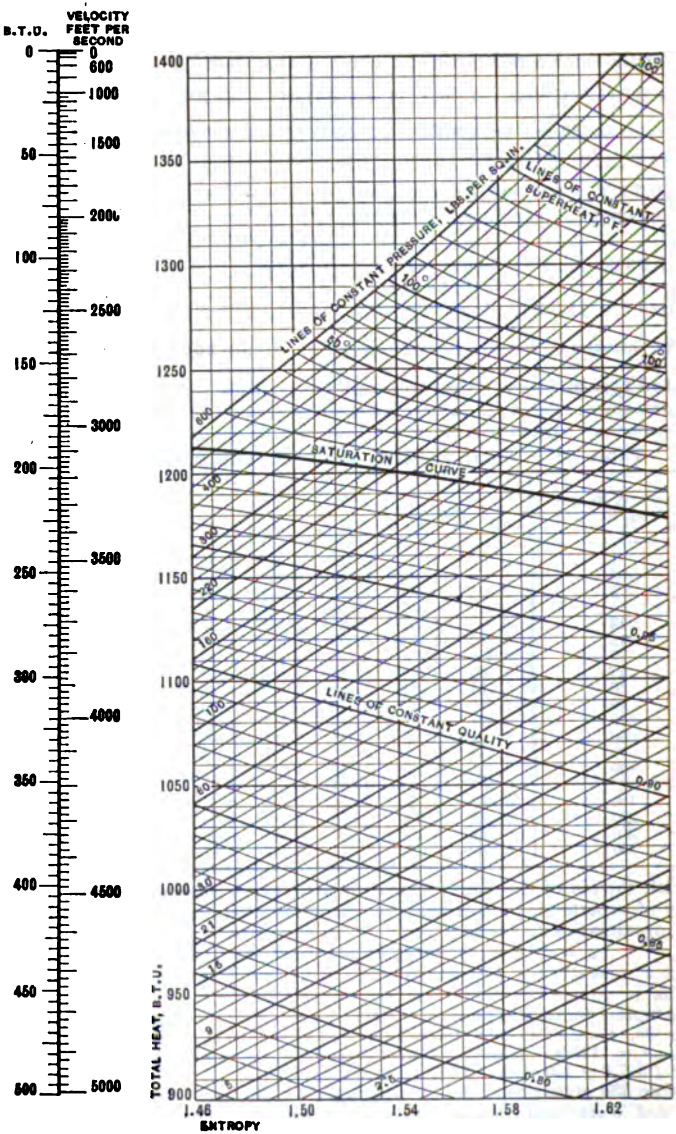
With the aid of the table of mean specific heats, the heat content and entropy of superheated steam may be calculated easily and with a good degree of approximation. Thus,

$$i = i'' + c_{pm}(t - t_s), \qquad s = s'' + c_{pm} \log_e (T/T_s),$$

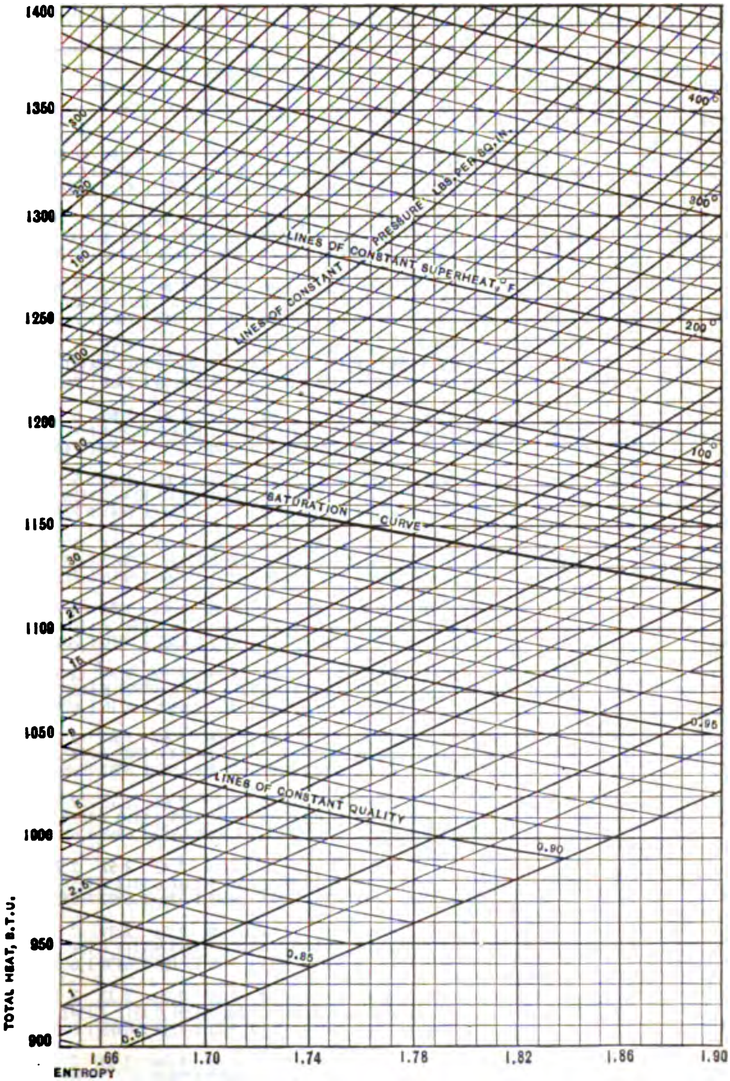
where i'' and s'' [$= s' + (r/T)$] are saturation values taken from the table on p. 325.

Example. Steam at a pressure of 100 lb. per sq. in. is superheated 240 deg. From Table 33, $c_{pm} = 0.519$, and from Table 31, $i'' = 1186.3$, $s'' = 1.6020$, $t_s = 327.8$. Hence, $i = 1186.3 + 0.519 \times 240 = 1310.9$ B.t.u., $s = 1.6020 + 0.519 \log_e [(567.8 + 459.6)/(327.8 + 459.6)] = 1.7402$.

Table 33*a* gives properties of superheated steam condensed from the steam tables of Marks and Davis. A Mollier diagram for steam is given on the following pages.



Total-heat-Entropy Diagram



(Mollier Diagram) for Steam.

Table 33a. Properties of Superheated Steam
(Condensed from Marks and Davis's "Steam Tables and Diagrams")
v = Specific volume in cu. ft. per lb.; i = Total heat in B.t.u. per lb.;
s = Entropy

The relation between pressure and temperature is derived from the vapor-pressure law, using as a basis the Marks equation (p. 327) connecting the pressure and temperature of saturated steam. For a given pressure p, let T_w denote the saturation temperature (absolute) of water vapor and T_a the corresponding temperature of ammonia vapor. Then

$$T_a = 1/[(1.70356/T_w) - 0.0002242].$$

Below 160 deg. fahr. the volume v' of liquid ammonia is given by

$$v' = 0.06335 - 0.016 \log (273.2 - t).$$

The difference $v'' - v'$ is found from the Clapeyron relation (p. 323), and from this v'', the specific volume of the saturated vapor, is determined. The latent heat is calculated from the empirical formula

$$\log r = 1.856064 + 0.37 \log (273.2 - t).$$

Superheated Ammonia. The specific volume of superheated ammonia is given by the characteristic equation of Mosher, viz.:

$$v + 0.10 = 0.6321\ (T/p) - (79{,}433 \times 10^8/T^5).$$

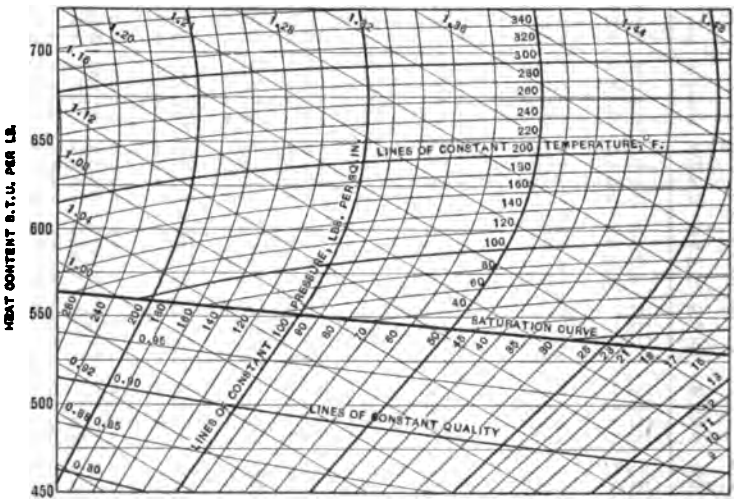
The specific heat at constant pressure is given by the empirical formula

$$c_p = 0.382 + 0.000174T + (Cp/T^6). \quad \log C = 13.644705.$$

For the heat content and entropy the following formulæ are deduced from the preceding:

$$i = 0.382T + 0.000087T^2 - (C'p/T^5) - 0.0185p + 358. \quad \log C' = 12.945734.$$

$$s = 0.8796 \log T + 0.000174T - 0.2695 \log p - (C''p/T^6) - 0.8266.$$
$$\log C'' = 12.866554.$$



Total-heat-Entropy Diagram (Mollier Diagram) for Ammonia.

Table 35 gives these properties of superheated NH_3 for various pressures and degrees of superheat. A Mollier diagram for ammonia is given above. In using this diagram it should be noted that the constant-entropy lines are diagonals (not verticals), and that adiabatics have the same slope as these diagonals.

Sulphur Dioxide (SO_2). The properties of saturated vapor of SO_2 given in Table 36 are based on the researches of Cailletet and Mathias. Certain of these properties are given by the following empirical formulæ:

$$c' = 0.3194 + 0.00065(t - 32). \qquad v' = 0.0113.$$

$$s' = 0.00065(t - 32). \qquad r/T = 0.3327 - 0.00129\,(t - 32).$$

Carbon Dioxide (CO_2). The properties of CO_2 vapor have been investigated experimentally by Amagat. The results are given in Table 37. The following are the empirical formulæ devised by Mollier:

Critical temperature, T_k = 547.83 deg. fahr., absolute.

$$p = 42.2056\,[(T/180) - 1]^{4.525}\;;\qquad r = 0.6816T^{0.43}(T_k - T)^{0.43}$$

$$c' = 0.000185T + 0.285\,(r/T) + 0.215\,r/(T_k - T)$$

$$s' = 0.10155 + 0.000185(t - 32) - r/2T$$

Table 36. Properties of Sulphur Dioxide

Properties of Other Refrigerating Fluids. In addition to the three uids whose properties have been given in the preceding tables, the following uids have been used to some extent:

Ethyl chloride (C_2H_5Cl); methyl chloride (CH_3Cl); nitrous oxide (N_2O) and Pictet's fluid, a mixture of SO_2 and CO_2 in the proportion of 64 parts SO_2 to 44 parts CO_2 by weight.

The **vapor pressures** of these fluids are given in Table 38. The other thermal properties are not at present well known and the values here given must be regarded as rude approximations. Nitrous oxide closely resembles carbon dioxide in its behavior: the vapor pressure and the density of the two fluids are nearly identical.

The **latent heat** of ethyl chloride is given as 174.5 B.t.u., and that of methyl chloride as 174 B.t.u., temperature not specified, but presumably under atmospheric pressure. Cailletet and Mathias give the following formula for the latent heat of N_2O: $r^2 = 237.15\,(97.5 - t) - 0.928(97.5 - t)^2$.

From this formula the following values are found:

for $t =$	−20	0	20	40	60	80	deg. fahr.
$r =$	122.7	120.4	113.2	102.8	87.1	62.2	

The **specific heat** of N_2O vapor at constant pressure is 0.225. The specific heat of the vapor of ethyl chloride is given by Regnault as 0.274 between 66 deg. and 340 deg. fahr.; the specific heat of the liquid is 0.4276 between −18 deg. and 40 deg. fahr.

The **density** of N_2O may be taken the same as that of CO_2. According to Regnault, the density of ethyl chloride gas is 2.2268 times the density of air.

Special Changes of State. Mixtures of Vapor and Liquid

1. Isothermal or Constant Pressure: t = const. p = const. If the initial and final qualities are x_1 and x_2, respectively, then

$$Q = Mr(x_2 - x_1). \qquad U_2 - U_1 = Ml(x_2 - x_1).$$
$$L = p(V_2 - V_1) = Mp\,(v'' - v')(x_2 - x_1).$$

2. Constant Volume:

$$x_2 = x_1\,(v''_1 - v'_1)/(v''_2 - v'_2) = x_1\,v''_1/v''_2, \text{ approx.}$$
$$Q = U_2 - U_1 = M\,[(i'_2 + x_2l_2) - (i'_1 + x_1l_1)]$$

3. Adiabatic: s = const.

$$s'_1 + (x_1r_1/T_1) = s'_2 + (x_2r_2/T_2). \qquad Q = 0.$$
$$L = J(U_1 - U_2) = JM[(i'_1 + x_1l_1) - (i'_2 + x_2l_2)].$$

The relation between p and v during an adiabatic change may be represented approximately by the equation pv^n = const. The exponent n is not constant, however, but varies with the initial quality and initial pressure, as shown by Table 39.

Table 39. Values of n (Water Vapor)

Initial quality	Initial pressure, lb. per sq. in. absolute											
	20	40	60	80	100	120	140	160	180	200	220	240
1.00	1.131	1.132	1.133	1.134	1.136	1.137	1.138	1.139	1.141	1.142	1.143	1.145
0.95	1.127	1.128	1.129	1.130	1.131	1.131	1.132	1.133	1.134	1.135	1.136	1.137
0.90	1.123	1.123	1.124	1.124	1.125	1.125	1.126	1.126	1.127	1.127	1.128	1.129
0.85	1.119	1.119	1.119	1.119	1.120	1.120	1.120	1.120	1.120	1.120	1.120	1.121
0.80	1.115	1.115	1.114	1.114	1.114	1.114	1.113	1.113	1.113	1.113	1.112	1.112
0.75	1.111	1.110	1.110	1.109	1.109	1.108	1.107	1.106	1.106	1.105	1.104	1.104

The volume at the end of expansion (or compression) is $V_2 = V_1\,(p_1/p_2)^{1/n}$, and the external work

$$W = (p_1V_1 - p_2V_2)/(n - 1) = p_1V_1[1 - (p_2/p_1)^{(n-1)/n}]/(n - 1)$$

4. Constant Quality: For a change of state with the quality x constant, an approximate relation between p and v for water vapor, is

$$pv^{1.0631} = 484.2\,x^{1.0631}.$$

For dry steam $x = 1$, and the relation becomes $p^{0.9406}v'' = 327.7$.

This formula may be used for calculating approximately the volume v'' of saturated steam for a given pressure p.

Mixture of Gases and Vapors

Moisture in the Atmosphere. Atmospheric air always contains a certain amount of water vapor mixed with it. The pressure of the vapor cannot exceed the saturation pressure corresponding to the temperature of the atmosphere. Generally, the vapor is in a superheated state, and the pressure is less than the saturation pressure. For a mixture of water vapor and air it may be assumed that Dalton's law holds. Thus, the pressure p_a indicated by the barometer is the sum of p', the pressure of the vapor, and p'', the pressure of the air. On the T-S plane, Fig. 13, let A denote the state of superheated water vapor at the temperature t of the atmosphere, and let m denote the weight of the vapor per

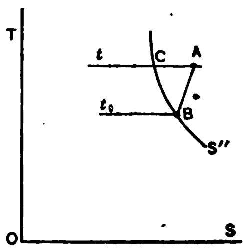

Fig. 13.

cubic foot. Point C represents vapor in the saturated condition at the same temperature t. The density or weight per cubic foot is greater in state C than in state A. Denoting by m_1 the weight per cubic foot in state C, the ratio m/m_1 is the **relative humidity** of the air under the given conditions. If the mixture be cooled at constant pressure, the curve AB represents the change of state of the vapor, and at some lower temperature t_0 the vapor becomes saturated and upon further cooling begins to condense. The temperature t_0 is called the **dew point** corresponding to the state A. If p'_B and p'_C denote the vapor pressures corresponding to the temperatures t_0 and t, respectively (at points B and C), then the relative humidity is approximately the ratio p'_B/p'_C.

Properties of Moist Air.

Let t = temperature of air, deg. fahr.
$T = t + 459.6$, the corresponding absolute temperature.
h = relative humidity.
B = barometric pressure, in inches of mercury.
e = pressure of *saturated* vapor corresponding to temperature t, in inches of mercury.
D' = weight per cu. ft. of saturated vapor at temperature t, lb.
D'' = weight per cu. ft. of dry air at temperature t and pressure B, lb.
D = weight per cu. ft. of mixture at temperature t, and with relative humidity h, lb.
R = 53.34, the characteristic constant of dry air.
R_m = characteristic constant of mixture.

The **partial pressure of** the **vapor** is he, that of the air $B - he$. Hence, by **volume**, the mixture has he/B parts of vapor, and $(B - he)/B$ parts of air; that is, the addition of moisture reduces the effective volume of air 100 he/B per cent.

The constant R_m of the mixture is given by $R_m = 53.34/[1 - 0.378(he/B)]$.

The **weight per cu. ft.** of the mixture is $D = hD' + [D''(B - he)/B]$, and this reduces to $D = 1.326(B/T) - 0.501(he/T)$.

These formulæ apply only when the vapor pressure is small relative to the total pressure. Table 40 facilitates the use of the preceding equations.

Example. The temperature of the air is 84 deg. fahr., the relative humidity 0.70, and the barometric pressure 29.94 in.

From Table 40, the vapor pressure e for 84 deg. is 1.171 in. of mercury and weight of 1 cu. ft. of saturated vapor is 12.37 gr. Hence the air contains $12.37 \times 0.70 = 8.69$ gr. of moisture per cu. ft. and can absorb $12.37 - 8.69 = 3.68$ gr. more before condensation ensues. If the air is cooled the air will become saturated at the pressure $he = 1.171 \times 0.70 = 0.82$ in. of mercury, which corresponds to the temperature 73.5 deg. fahr. This is the dew point. The weight of the mixture per cu. ft. is obtained from the factors in the last two columns of the table: thus, $D = (29.94 \times 0.002439) - (0.70 \times 0.00108) = 0.07226$ lb. The volume of 1 lb. is therefore $1/0.07226 = 13.84$ cu. ft.

Measurement of Humidity. Two methods are available for the determination of the relative humidity of air. 1. The **dew-point method,** in which the dew point is found directly by observing the temperature at which moisture forms on a cooled surface. 2. The **evaporative method,** in which the degree of humidity is deduced from the cooling effect due to the evaporation of moisture in air partially saturated. In the ordinary **wet-bulb psychrometer** the bulb of one thermometer is covered with cloth or wick saturated with water and the bulb of the second thermometer is bare. Evaporation from the wet bulb causes a lowering of temperature, and the difference of the

readings of the two thermometers is the **wet-bulb depression.** The psychrometer with stationary wet bulb is considered unreliable and the **sling psychrometer,** in which the wet bulb is kept in motion, is advocated by the U. S. Weather Bureau.

In the determination of humidity by the evaporative method two temperatures and three vapor pressures come under consideration. These are:

t = dry-bulb temperature.
t' = wet-bulb temperature.
e = vapor pressure corresponding to t.
e' = vapor pressure corresponding to t'.
e_0 = vapor pressure corresponding to dew point t_0.

Various formulæ connecting these temperatures and pressures have been proposed. W. H. Carrier (*Trans. A. S. M. E.*, vol. 33, p. 1005) has deduced rationally the following formula, which may be used with confidence:

$$e_0 = e' - [(B - e')(t - t')/(2800 - 1.3t')].$$

The humidity is given immediately by the relation $h = e_0/e$. According to Carrier, the wet-bulb depression $t - t'$ indicated by the sling psychrometer is subject to a mean radiation error of about 1.6 per cent.; therefore, the observed depression should be increased by this amount before insertion in the formula.

The chart, Fig. 14, prepared by Mr. Carrier on the basis of his psychrometric formula, is convenient in the solution of most problems in hygrometry. The horizontal scale gives dry-bulb temperatures, and the inclined lines wet-bulb temperatures. The relative humidity is read directly from the intersection of these constant-temperature lines. Thus, if the dry-bulb temperature is 78 deg. and the wet-bulb temperature is 65 deg., the humidity is found to be 0.50. The main vertical scale gives the weight of vapor in grains per lb. of dry air. In the case just given, this weight is 71 gr.

The curve marked "total heat" is convenient in calculating the heat that must be removed in cooling air and extracting moisture from it. The ordinates of the curve give the sum of the sensible heat in the air above 0 deg. fahr. and the latent heat of the contained vapor. The following example (from Carrier) illustrates the use of the curve.

Required the refrigeration necessary to cool 1 lb. of air containing 98 gr. of moisture, with a dry-bulb temperature of 95 deg. to a final temperature of 40 deg. saturated. Taking 95 on the horizontal scale and 98 on the main vertical scale, it is found that the wet-bulb temperature is 75 deg. Following the inclined line marked 75 deg. to the saturation curve (*i.e.*, dry-bulb temperature = 75 deg.), and then vertically to the total-heat curve, the total heat corresponding to this condition is found to be 37.8 B.t.u. The total heat at 40 deg. is found to be 15.3 B.t.u., and the difference 22.5 B.t.u. is the heat that must be abstracted per pound of air cooled.

Evaporation and Drying

Boiling in a Vacuum. Multiple Effects. Evaporation in a vacuum is employed in the **evaporation of** sugar and salt **solutions,** milk and other liquids containing water. The same process may be used in drying grain or other wet granular materials. The advantage of evaporation in a vacuum lies in the fact that the liquid will boil at a lower temperature than under atmospheric pressure; hence the range of temperature between the two fluids is increased and with it the rate of heat transmission. The lower temperature of boiling also permits the use of exhaust steam in certain cases. Furthermore, a low temperature of evaporation is imperative in the case of certain organic substances, as milk, gelatine, etc.

Economy of operation demands the use of multiple-effect evaporating systems. In these, the steam arising from the boiling liquid in the first

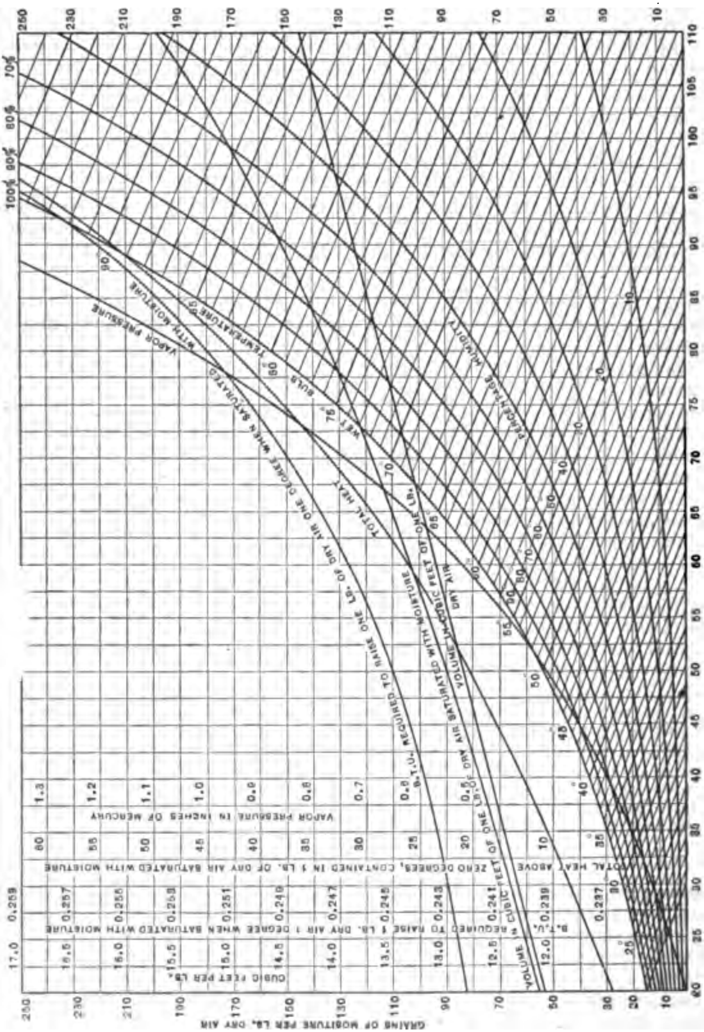

FIG. 14.—Humidity and Psychrometer Chart (Carrier).

vessel is carried to a second vessel in which the boiling temperature is 30 deg. or more lower than in the first vessel. Similarly, steam from the boiling liquid in the second vessel is used as a heating medium in a third vessel, and so on.

An exhaustive treatment of vacuum evaporation is given in Hausbrand's "Evaporating, Condensing and Cooling Apparatus." A good discussion is contained in Creighton's "Steam Engine," chap. xvii.

Theory of Evaporation in a Vacuum.

Let M = weight of liquid introduced in first vessel.
M_1 = water evaporated from liquid in first vessel.
M_2, M_3, etc. = water evaporated from liquid in second, third, etc., vessels.
M_0 = weight of liquid withdrawn from last vessel.
G = weight of steam introduced into first vessel.
t_0 = temperature of liquid entering first vessel.
t, t_2, t_3, etc. = mean temperatures of boiling liquid in first, second, third, etc., vessels.
i = heat content of steam G, r = latent heat of same.
i_1, i_2, i_3, etc. = heat contents of vapor in successive vessels.
r_1, r_2, r_3, etc. = latent heats of vapor in successive vessels.

The heat equations are deduced by the aid of two principles: 1. The heat supplied to a vessel is equal to the heat given out by it. 2. The weight of heating steam used in a vessel is equal to the weight of condensed water formed in the vessel.

For the first vessel, the heat equation is:

$$G(i - t_1 + 32) = M(t_1 - t_0) + M_1r_1$$

For the second vessel:

$$Mi(i_1 - t_2 + 32) = M_2r_2 - (M - M_1)(t_1 - t_2)$$

For the third vessel:

$$M_2(i_2 - t_3 + 32) = M_3r_3 - (M - M_1 - M_2)(t_2 - t_3)$$

For a triple-effect system, $M - M_1 - M_2 = M_0$; hence with M and M_0 known, M_1, M_2, and M_3 can be calculated provided the temperatures and pressures within the vessels are known.

Hausbrand points out that the temperatures t_1, t_2, etc., depend upon the form and size of the heating surfaces, the density of the boiling liquid, and other factors, and that these temperatures are therefore not predetermined. By assuming various values for the intermediate temperatures and calculating the effects in the separate vessels, he arrives at the following conclusions:

1. The smallest amount of heating steam required to produce a certain amount of evaporation is used in all multiple evaporators, when the fall in temperature is the same in each vessel.

2. However the fall of temperature in the separate vessels be arranged, the weight of heating steam to be supplied to the first vessel varies only within narrow limits. Hence the economy of the system is but slightly affected by the temperature distribution between the vessels.

3. The ratio of the evaporation in the first vessel to the total evaporation averages as follows:

For the double-effect........................	$M_1 = 0.466\ (M - M_0)$
For the triple-effect........................	$M_1 = 0.300\ (M - M_0)$
For the quadruple-effect....................	$M_1 = 0.216\ (M - M_0)$

The probable range of values is:

For the double-effect $M_1/(M - M_0) = 0.434$ to 0.484; for the triple-effect, 0.2777 to 0.3152; for the quadruple-effect, 0.1926 to 0.2335.

4. The evaporation is in all cases the least in the first vessel, but the increase

in the following vessels is not great, at most 4 per cent. As a mean, the following ratios may be taken:

	1st	2nd	3d	4th
Double-effect	1	1.045		
Triple-effect	1	1.01	1.04	
Quadruple-effect	1	1.005	1.012	1.02

5. The ratio of the evaporation in the last vessel to the total evaporation is

For the double-effect	0.534
For the triple-effect	0.3703
For the quadruple-effect	0.284

Heating Surface. The heat Q transmitted from steam to boiling fluid in a vessel is given by $Q = kAh$, in which A is the heating surface in sq. ft., h the difference in temperature between the steam and boiling fluid and k the coefficient of heat transmission in B.t.u. per sq. ft. per hr. per deg. fahr. difference of temperature. The value of k is not the same for the different vessels of a multiple-effect system. From the experiments of Claassen the ratios for different vessels may be taken as follows:

	1st	2nd	3d	4th
Double-effect	1	0.66		
Triple-effect	1	0.70	0.33	
Quadruple-effect	1	0.91	0.75	0.55

The value of k depends on many conditions and is difficult to ascertain with accuracy. Creighton ("Steam Engines," p. 524) suggests the following values for cane-sugar evaporators: First vessel, $k = 385$; second, $k = 300$; third, $k = 205$; fourth, $k = 110$. If the fall of temperature in each effect is the same, the heating surfaces must be made larger in the successive vessels. It is usually considered better practice to keep the heating surfaces practically the same and make the temperature drops larger in the successive vessels.

The water evaporated per hr. per sq. ft. of surface varies considerably with the conditions of operation. Hausbrand gives the following figures as the result of practical experience.

Ordinary vertical evaporators with brass heating tubes of 3 ft. long and over evaporate from liquids that present no obstacles to evaporation, as follows:

With single-effect	14.0–16.0 lb. per sq. ft. per hr.
With double-effect	6.0– 7.2 lb. per sq. ft. per hr.
With triple-effect	4.0– 5.0 lb. per sq. ft. per hr.
With quadruple-effect	3.5– 4.2 lb. per sq. ft. per hr.

With iron tubes the evaporation is decreased 10 to 15 per cent. In the case of liquids that evaporate with difficulty, the evaporation may be very much smaller.

The Steam Engine

The Rankine Cycle. The ideal Rankine cycle is generally employed by engineers as a standard of reference by which the performance of steam engines and steam turbines is measured. Fig. 15 shows this cycle on the T-S and p-V planes. AB represents the heating of the water in the boiler, BC represents evap-

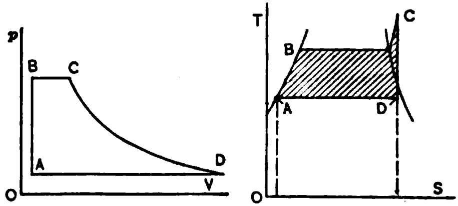

FIG. 15.—Rankine Cycle.

oration (and superheating if there is any), CD the assumed adiabatic expansion in the engine cylinder, and DA condensation in the condenser.

Let i_a, i_b, i_c, i_d represent the heat content per lb. of steam in the four states A, B, C, and D, respectively. Then the heat transformed into work, represented by the area $ABCD$, is $Q_a = i_c - i_d$.

The heat expended on the fluid is $i_c - i_a$; hence the thermodynamic **efficiency of the cycle** is $E_t = (i_c - i_d)/(i_c - i_a)$.

The **steam consumption** of the ideal Rankine engine in lb. per h.p.-hr. is $N_r = 2546/Q_a = 2546/(i_c - i_d)$. For steam consumptions per kw-hour (for use in steam turbine calculations) see pp. 980 and 981.

The performance of an engine is frequently stated in terms of the heat used per h.p.-hr. For the ideal Rankine engine this is

$$Q_r = 2546/E_t = 2546\,(i_c - i_a)/(i_c - i_d).$$

Efficiency of the Actual Engine. Let Q denote the heat transformed into work per lb. of steam by the actual engine; then if Q_1 is the heat furnished by the boiler per lb. of steam, the thermodynamic **efficiency of the engine** is $E_t = Q/Q_1$.

The efficiency thus defined is however misleading, as it takes no account of the conditions of operation, as regards boiler and condenser pressures, superheat, or quality of steam. It is customary therefore to define the efficiency as the ratio Q/Q_a, where Q_a is the **available heat**, or the heat that might possibly be transformed under ideal conditions. This efficiency for engines and turbines ranges from 0.50 to 0.80. The efficiency may also be expressed in terms of steam consumed; thus, if N_a is the steam consumption of the actual engine and N_r is the steam consumption of the ideal Rankine engine under similar conditions, then $E = N_r/N_a$.

Example. Suppose the boiler pressure to be 180 lb. per sq. in. absolute, superheat 150 deg., and the condenser pressure 3 in. of mercury. From the steam tables or diagram the following values are found: $i_c = 1279.9$, $i_d = 940$, $i_a = 82.9$. The available heat is $Q_a = 1279.9 - 940 = 339.9$ B.t.u., and the thermodynamic efficiency of the cycle is $339.9/(1279.9 - 82.9) = 0.284$. The steam consumption per h.p.-hr. is $2546/339.9 = 7.5$ lb., and the heat used per h.p.-hr. is $2546/0.284 = 8960$ B.t.u. If an actual engine working under the same conditions has a steam consumption of 11.4 lb. per h.p.-hr., its efficiency is $7.5/11.4 = 0.658$, and its heat consumption per h.p.-hr. is $8960/0.658 = 13{,}600$ B.t.u.

Calorimetric Analysis of the Steam Engine. The first attempt to determine quantitatively the thermal actions in the steam-engine cylinder is due to Hirn. By **Hirn's method**, equations are derived for the heat interchanges between the steam and the cylinder walls, and the quantities involved are such as may be determined from an accurate test. In Fig. 16, points 1, 2, 3 and 0 represent cut-off, release, compression, and admission, respectively. Let U_0, U_1, U_2, U_3 represent the energy per lb. of fluid at the corresponding points. Let M denote the weight of fluid supplied per stroke, and M_0 the weight of fluid caught in the clearance space. Let Q_a, Q_b, Q_c, Q_d denote respectively the quantities of heat absorbed by the cylinder walls from the fluid during the processes represented by a, b, c, and d on the diagram; and let W_a, W_b, W_c, and W_d denote the external work performed during the corresponding parts of the cycle. Let Q denote the heat brought into the cylinder per stroke by the working fluid; thus, $Q = Mi$, where i is the heat content of

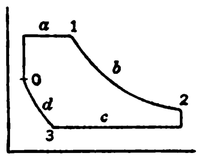

FIG. 16.

the entering steam. Finally, let i' denote the heat content of the liquid at the pressure of the exhaust steam, G the weight of condensing water used per stroke, and t', t'' the initial and final temperatures of the cooling water. Then the heat interchanges are expressed by the following equations:

$$Q_a = Q + U_0 - U_1 - AW_a. \qquad Q_b = U_1 - U_2 - AW_b.$$
$$Q_c = U_2 - U_3 - Mi - G(t'' - t') + AW_c. \qquad Q_d = U_3 - U_0 + AW_d.$$

In getting the expressions for U_0, U_1, etc., there are five unknown quantities, namely M_0, and the four qualities x_0, x_1, x_2, x_3. Between these there are four relations. Let V_0 denote the volume of the clearance space, and V_1, V_2, V_3 the spaces swept through by the piston up to the points 1, 2, 3. Also let $s = v'' - v'$, the difference between the volume of vapor and liquid. Then

$$V_0 = M_0(x_0s_0 + v'). \qquad V_0 + V_1 = (M + M_0)(x_1s_1 + v').$$
$$V_0 + V_2 = (M + M_0)(x_2s_2 + v'). \qquad V_0 + V_3 = M_0(x_3s_3 + v').$$

If one quality be known or assumed, these four equations give M_0 and the remaining qualities. It is usually assumed that the steam in the cylinder is nearly or quite dry at the beginning of compression, hence $x_3 = 1$.

For an exhaustive treatment of the calorimetric analysis of steam engines, see Peabody's "Thermodynamics," 5th ed., chap. xi.

REFRIGERATION

Air Refrigeration. When air is used as a medium for refrigeration, the reversed Joule cycle is employed (see p. 321). The refrigerating machine has four essential organs: 1. A compressor in which the air is compressed. 2. A cooling coil surrounded by water. 3. An expansion cylinder. 4. A brine coil. Fig. 17 represents ideal p-V and T-S diagrams. Point A represents the state of the air entering the compressor from the brine coil or cold room, AB represents the compression, BC the cooling of the air at constant pressure, CD the expansion of air in the expansion cylinder, and DA the absorption of heat by the air during the passage through the brine coils. In the p-V diagram $ABEF$ represents the indicator diagram of the compressor, $ECDF$ that of the expansion cylinder. The difference, area $ABCD$, represents the work that must be furnished from external sources. In the T-S diagram area B_1BCC_1 represents the heat absorbed from the air by the cooling water, area C_1DAB_1, the heat absorbed by the air from the brine, and area $ABCD$ the heat equivalent of the work required to drive the machine. The temperature at point A must be somewhat lower than the brine temperature, the temperature at C somewhat above the temperature of the cooling water. With the open-cycle machine the lower pressure p_1 is atmospheric pressure; with a closed-cycle machine, as the Allen dense-air machine, p_1 may be 40 to 60 lb. per sq. in. and p_2 as high as 200 lb. per sq. in.

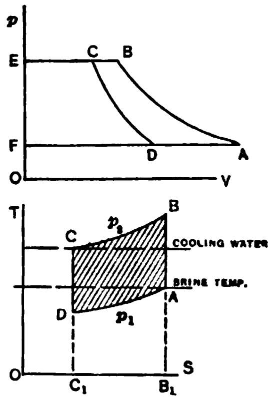

FIG. 17.—Air Refrigeration Cycle.

Let Q = heat in B.t.u. absorbed from brine (or cold room) per min.
M = weight of air circulated per min., lb.
c_p = 0.24, specific heat of air at constant pressure
W = work required per min., ft.-lb.

V_c = displacement volume of compressor cylinder, cu. ft.
V_e = displacement volume of expansion cylinder, cu. ft.
n = number of working strokes per min.

With assumed adiabatic compression and expansion the following relations hold:

$$T_b/T_a = T_c/T_d = (p_2/p_1)^{(k-1)/k}. \qquad M = Q/c_p(T_a - T_d).$$
$$W = 778Q(T_b - T_a)/T_a. \qquad \text{H.P.} = W/33{,}000.$$
$$V_c = MBT_a/144p_1n. \qquad V_e = MBT_d/144p_1n.$$

Vapor Compression Machines. The essential organs of a vapor compression system are the same as in the system using air, except that the expansion cylinder is replaced by an expansion valve through which the liquefied medium flows from the high-pressure condensing coils to the low-pressure brine coils. The cycle of operation is best shown on the T-S plane (Fig. 18). The point B represents the state of the refrigerating medium leaving the brine coils and entering the compressor. Usually in this state the fluid is nearly dry saturated vapor, that is, point B is near the saturation curve S''. BC represents the adiabatic compression, during which the fluid is usually superheated. In the state C the superheated vapor passes into the cooling coils and is cooled at constant pressure, as indicated by CD, and then condensed at temperature T_2 as shown by DE. The liquid now flows through the expansion valve into the brine coils. This is a throttling process and the final-state point A is located on the T_1-line in such a position as to make the heat content for state A (= area $OHGAA_1$) equal to the initial heat content at E (= area $OHEE_1$). The mixture of liquid and vapor now absorbs heat from the brine and vaporizes, as indicated by AB.

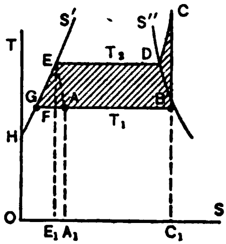

Fig. 18.—Vapor Compression Refrigeration Cycle.

The **heat absorbed from the brine,** represented by area A_1ABC_1, is

$$Q_1 = i_b - i_a = i_b - i_e.$$

The **heat rejected to the cooling water,** represented by area C_1CDEE_1, is

$$Q_2 = i_c - i_e = c_p(T_c - T_d) + r_2$$

where r_2 denotes the latent heat at the upper temperature T_2, and c_p the specific heat of the superheated vapor. The **work** that must be **supplied per pound of fluid circulated** is $W = J(Q_2 - Q_1) = J(i_c - i_b)$.
The ratio $JQ_1/W = (i_b - i_e)/(i_c - i_b)$ is sometimes called the **coefficient of performance.**

If Q denotes the heat that is required to be absorbed from the brine per hr., then the **weight of fluid circulated per hour** is $M = Q/(i_b - i_a)$; or, if B is taken on the saturation curve, $M = Q/(i''_1 - i'_2)$.

The work per hr. is $W = JM(i_c - i''_1) = JQ\,(i_c - i''_1)/(i''_1 - i'_2)$ ft.-lb., and the **h.p. required** is $H = Q(i'_c - i''_1)/2546(i''_1 - i'_2)$.

If v''_1 is the volume of the saturated vapor at the temperature T_1 in the brine coils, and n the number of working strokes per min., the **displacement volume of the compressor cylinder** is $V = Mv''_1/60n$.

The values of i''_1, i_2 in the preceding formulæ are found in the tables of saturated vapors. The heat content i_c of the superheated vapor may be determined in the case of ammonia from Table 35 for superheated ammonia.

Vapors Used in Refrigeration. The three vapors that are principally used for refrigeration are **ammonia** (NH_3), **carbon dioxide** (CO_2) and **sulphur dioxide** (SO_2). The temperatures of the working fluid in the condensing and brine coils are fixed by the temperature of cooling water and the temperature at which the brine is to be kept, respectively. Since for a vapor the pressure depends on the temperature only, the discharge and suction pressures that must be used are dependent on the properties of the fluid employed. Another consideration in the choice of a fluid is the volume of fluid required for a given amount of refrigeration. In general, the fluid for which the ratio (latent heat : specific volume) is greatest requires the smallest cylinder displacement per unit of refrigeration.

Taking 70 deg. fahr. as the temperature of the fluid in the condensing coils and 15 deg. as that in the cooling coils, the following are the conditions for the available vapors:

Pressures, lb. per sq. in.:	NH_3	CO_2	SO_2	Ethyl chloride	Methyl chloride	Nitrous oxide	Pictet's fluid
Suction	42.7	391	15.2	6.0	25.9	431	20.3
Discharge	129.2	847	49.6	20.0	73.3	832	51.6
Relative volume per unit weight of refrigeration	4.4	1	12.0	....	....	...	....

With SO_2 the pressures are low but the volume of medium is comparatively large, while with CO_2 small volume is accompanied by extremely high pressures. In the case of ammonia the pressures are reasonable and the volume of fluid required is not excessive; hence ammonia is preferred for most classes of service.

Refrigeration Produced by Ammonia and Carbon Dioxide. Tables 41 and 42 give the refrigeration produced in B.t.u. per h.p.-hr. under different conditions. It is assumed that there are no losses in the cycle, except that inherent in the use of the expansion valve. The temperature at the top of the column is that of the vapor in the brine coil, while at the side is given the temperature of the condensed fluid as it enters the expansion valve. For example, under a pressure p of 150 lb. with a temperature t_0 of 20 deg. fahr. in the brine coils and a temperature of 70 deg. fahr. at the expansion valve, the refrigeration produced in an ammonia machine without losses is 17,800 B.t.u. per h.p.-hr.; this is 90 per cent. of the refrigeration that would be produced if the liquid temperature were reduced to 20 deg., the temperature in the brine coils.

For other tables of the theoretical performance of ammonia compression machines, with the liquid assumed to arrive at the expansion valve at its saturation temperature, see pp. 1715 and 1716.

Absorption System of Refrigeration. The essential organs of a vapor absorption system are:

1. The **generator** or still, in which ammonia gas is driven off from a solution of ammonia in water through the agency of heat. Usually a steam coil is used for this purpose. The generator takes the place of the compressor in the compression system. 2. The **condenser**, in which the ammonia gas is condensed. 3. The **expansion valve.** 4. The **brine coil**, in which the ammonia by vaporizing absorbs heat from the brine. 5. The **absorber**, in which the ammonia returning from the brine coil is absorbed by a weak solution of ammonia in water. 6. The **pump**, which returns the rich liquor from the absorber to the generator.

Between the generator and absorber there are two channels of communication: one through the condenser, expansion valve, brine coil, absorber, and pump, as noted above; through the other, the weak solution in the generator passes directly to the absorber and there absorbs the gas coming from the brine coil. As in the compression system, there is a region of high pressure including the generator and condenser, and a region of low pressure including the brine coil and absorber. The pump is used to force the strong solution from the lower pressure of the absorber against the higher pressure in the generator.

For efficient operation of an absorption system certain auxiliary organs are required. The **analyzer** forms the upper part of the generator and receives the rich solution from the pump. The solution descends over a series of disks or trays until it meets the boiling liquid in the still. The vapor rising from the still thus comes in intimate contact with the descending liquid and is thus enriched in ammonia and deprived of water.

The **rectifier** is placed between the analyzer and condenser. It consists of a coil surrounded by cooling water, and its function is to remove water vapor from the mixture of water and ammonia driven off from the generator.

The **exchanger** is placed between the generator and absorber. It is evidently desirable that the rich solution entering the still should be at as high a temperature as possible and the weak solution entering the absorber from the still should be as cool as possible. The hot weak solution passing from the generator to the absorber gives up heat to the cooler strong solution passing from the pump to the generator.

Table 41. Refrigeration Produced by Ammonia in B.t.u. per H.p.-Hour

Heat Balance. An exact thermodynamic analysis of the absorption system is difficult because the properties of ammonia solutions are imperfectly known. The first law may, however, be applied, and from it may be derived an equation giving the heat balance for the system.

For 1 lb. of anhydrous ammonia passing through the condenser, expansion valve, and brine coil, G lb. of rich solution must be circulated by the pump and $G - 1$ lb. of weak solution enters the absorber. The weight G depends on the strengths of the strong and weak solutions. Taking x_1 as the strength of the former (x_1 = lb. of NH_3 in 1 lb. of solution) and x_2 as the strength of the latter, $G = (1 - x_2)/(x_1 - x_2)$.

For example, if the strength of the strong liquor is 0.25, and that of the weak liquor 0.10, $G = 0.90/(0.25 - 0.10) = 6$. Hence, for 1 lb. of ammonia passing through the expansion valve, 6 lb. of strong liquor must be circulated by the pump and 5 lb. of weak liquor will reach the absorber.

For 1 lb. of ammonia passing the expansion valve, the following quantities of heat will be absorbed or rejected at various points in the system:

Q_1 = heat imparted to the fluid in the generator.
Q_2 = heat absorbed by the fluid in the brine coils.
Q_3 = heat rejected to the cooling water as fluid passes through condenser.

Q_4 = heat withdrawn from fluid in absorber.
Q_5 = heat equivalent of work of pump.
Q_6 = heat loss by radiation, etc.

The following equation expresses the **heat balance** for the system:

$$Q_1 + Q_2 + Q_5 = Q_3 + Q_4 + Q_6.$$

Some of the heat quantities are readily calculated. The **heat Q_2 absorbed in the brine coils,** as in the compression system, is $Q_2 = i''_1 - i'_2$, where i''_1 is the heat content of the saturated vapor corresponding to the temperature of the fluid in the brine coil, and i'_2 is the heat content of the liquid corresponding to the temperature of the liquid entering the expansion valve.

If it is assumed that the fluid enters the condenser in the dry saturated state, the heat Q_3 is simply the latent heat r corresponding to the temperature of the fluid in the condenser.

The pump forces G lb. of rich liquor from the pressure p_1 in the absorber to the pressure p_2 in the generator. Hence if v is the volume of 1 lb. of the rich liquor, $Q_5 = Gv(p_2 - p_1)/778$.

The **heat Q_4 withdrawn from the absorber** is found as follows: Let t_1 denote the temperature of the gas in the brine coils, t_0 the temperature of the fluid in the absorber, and t' the temperature of the weak solution entering the absorber. In general, $t_0 > t_1$, and $t_0 < t'$. The entering vapor (1 lb.) receives heat $c\ (t_0 - t_1)$, c being the specific heat of the vapor, which may be taken as 0.5. The entering weak solution gives up the heat $(G - 1)\ c'\ (t' - t_0)$, where c' denotes the specific heat of the weak liquor; this may be taken as 1. The absorption of 1 lb. of gas by the weak solution develops the heat of absorption Q_a, the magnitude of which depends upon the concentrations of the weak and strong solutions, as shown in the following paragraph. Hence,

$$Q_4 = Q_a + (G - 1)\ (t' - t_0) - 0.5\ (t_0 - t_1).$$

Heat of Absorption. Let the weak solution of ammonia in water be composed of n lb. of water to 1 lb. of NH_3. The concentration of the solution is $x = 1/(1 + n)$. If now the solution absorb m lb. of ammonia gas, the strength of the resulting solution is $x_2 = (1 + m)/(1 + n + m)$. Let x denote the mean concentration, that is, $x = \frac{1}{2}(x_1 + x_2)$. Then, according

Table 43. Ammonia Absorption Machine.—Heats of Absorption Q_a and Weights G of Strong Liquor Circulated

to the experiments of Hilde Mollier (*Mitteil. über Forschungsarbeiten*, Heft 63), the heat of absorption Q_a is given by the formula

$$Q_a = 887 - 350x - 400x^2.$$

For example, let the weak solution be composed of 1 lb. NH_3 to 9 lb. of water, and let 2 lb. of NH_3 gas be added. Then $x_1 = 1/(1 + 9) = 0.10$, $x_2 = (1 + 2)/(1 + 9 + 2) = 0.25$, $x = 0.175$. Then $Q_a = 887 - (350 \times 0.175) - [400 \times (0.175)^2] = 814$ B.t.u. The formula holds good for values of x up to about 0.60. For this value and higher values Q_a remain constant and is 540 B.t.u.

For various concentrations of the strong and weak solutions Table 43 gives values of Q_a and of G, the weight of strong solution circulated.

Linde's Regenerative Refrigeration Process. The Joule-Thomson effect (see p. 361) has been used effectively by Linde for the **liquefaction of air** and other gases. Referring to Fig. 19, air is compressed to a pressure of about 65 atmospheres and is discharged into a pipe leading to the chamber *c*. The air in its passage to *c* is cooled by water. From *c* the air passes through an expansion valve into a vessel *d*, in which a pressure of about 22 atmospheres is maintained. The throttling in the expansion valve causes a drop in temperature given by the equation

$$t_2 - t_3 = k(p_1 - p_2)/T_2^2.$$

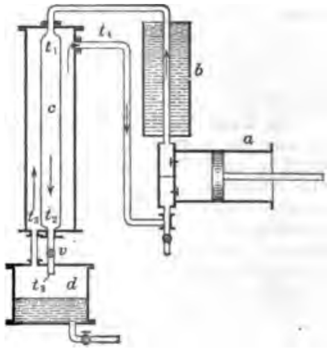

Fig. 19.—Linde Regenerative Refrigeration Process.

The air now passes back to the compressor and in so doing cools the air in *c*. In the actual machine the counter-current apparatus, which in the figure is shown as the chamber *c* and the space surrounding it, consists of two concentric spiral pipes about 330 ft. long. By the cooling action of the return current of air the temperature t_2 gradually sinks, and, as shown by the preceding equation, the temperature t_3 sinks more rapidly. Ultimately t_3 becomes lower than the critical temperature of air (− 220 deg. fahr.), and liquefaction begins.

By the use of the regenerative process liquid air or other gas may be produced continuously and in relatively large quantities by the simple mechanical process of compression. The necessary lowering of temperature is effected by repeated throttling of the gas and a second refrigerating medium is not required.

FLOW OF COMPRESSIBLE FLUIDS

References. An exhaustive discussion of the flow of fluids is given in Zeuner's "Technical Thermodynamics," vol. 1, pp. 225–271; vol. 2, pp. 153–196. The general theory is given in Lucke's "Engineering Thermodynamics," pp. 1083–1127; in Peabody's "Thermodynamics," 5th ed., chap. vxii; in Goodenough's "Principles of Thermodynamics," chap. xiii, and in Stodola's "Steam Turbines," pp. 4 and 45. For experimental results, consult Gutermuth, *Zeit. Ver. Deutsch Ing.*, vol. 48; Buchner, *Zeit. Ver. Deutsch Ing.*, vol. 49; Rateau, "Flow of Steam through Nozzles"; Rosenhain, *Proc. Inst. C. E.*, vol. 140; Wilson, *Engg.* (London), vol. 13.

Important **examples of** the **flow** of compressible fluids are the following: 1. The flow of air and steam through orifices and short tubes or nozzles, as in the steam turbine. 2. The flow of compressed air, steam, and illuminating gas in long mains. 3. The flow of low-pressure gases, as furnace gases in ducts and chimneys or air in ventilating ducts (see pp. 923 and 1359). 4. The flow of gases in moving channels, as in the centrifugal fan (see p. 1531).

Notation.

Let M = weight in lb. of fluid flowing past a given section per sec.
F = area of section, sq. ft.
w = mean velocity in ft. per sec. at the given section.
h = height of cross-section above an assumed datum.
v = volume per unit weight (cu. ft. per lb.).
p = pressure of fluid at given section. lb. per sq. ft.
u = internal energy of fluid, B.t.u. per lb.
i = heat content, B.t.u. per lb.
Q_{12} = heat entering the flowing fluid between sections F_1 and F_2.
R_{12} = energy expended in overcoming internal and external friction between sections F_1 and F_2.

The cross-sections of the tube or channel are denoted by F_1, F_2, etc., Fig. 20, and the various magnitudes pertaining to these sections are denoted by corresponding subscripts. Thus, at section F_1, the velocity, volume, pressure, energy, are respectively w_1, v_1, p_1, u_1; at section F_2 they are w_2, v_2, p_2, u_2.

FIG. 20.

Fundamental Equations. The **condition of continuity** is expressed by the equation

$$M = F_1w_1/v_1 = F_2w_2/v_2, \quad \text{or} \quad dv/v = (dF/F) + (dw/w).$$

The principle of conservation of energy leads to the equation

$$[(w_2^2 - w_1^2)/2g] + J(u_2 - u_1) + p_2v_2 - p_1v_1 + h_2 - h_1 = JQ_{12};$$

or, introducing the expression for heat content $i = u + Apv$,

$$[(w_2^2 - w_1^2)/2g] + J(i_2 - i_1) + h_2 - h_1 = JQ_{12}.$$

If the sections are taken an infinitesimal distance apart, this energy equation takes the form

$$(wdw/g) + Jdi + dh = JdQ.$$

A second fundamental equation is obtained by the further application of the energy equation, taking the friction work R into account. It is

$$dQ + AdR = du + Apdv = di - Avdp.$$

Combining these last equations,

$$(wdw/g) + vdp + dR + dh = 0.$$

Usually $h_1 - h_2$ and Q_{12} are so small as to be negligible. In this case the two fundamental equations become

$$(w_2^2 - w_1^2)/2g = J(i_1 - i_2); \quad (w_2^2 - w_1^2)/2g = -\int_1^2 vdp - R_{12}$$

For gases, $i_1 - i_2 = c_p(T_1 - T_2) = Ak(p_1v_1 - p_2v_2)/(k - 1)$; hence

$$[(w_2^2 - w_1^2)/2g] = Jc_p(T_1 - T_2) = k(p_1v_1 - p_2v_2)/(k - 1).$$

For a mixture of vapor and liquid, $i = i' + xr$; therefore

$$[(w_2^2 - w_1^2)/2g] = J[i'_1 + x_1r_1 - (i'_2 + x_2r_2)].$$

Flow Through Orifices

A case of special importance is the **flow** of a gas or vapor from a reservoir into a region of lower pressure **through an orifice or short tube.** In Fig. 21 the section F_1 is taken within the reservoir where the pressure is p_1, and the section F_2 is taken at the plane of the orifice. The pressure

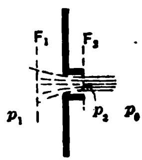

FIG. 21.

at this section is taken as p_2, and the pressure in the region into which the jet is flowing is taken as p_0. The initial velocity w_1 is so small that w_1^2 may be neglected in comparison with w_2^2. Hence

$$w_2^2/2g = J(i_1 - i_2), \text{ and } w_2 = 223.7\sqrt{i_1 - i_2}$$

The character of the flow depends on the ratio p_0/p_1, and two distinct cases may be noted. Let the law of frictionless adiabatic expansion of the fluid in question be $p_1v_1^n = pv^n = \text{const}$. For gases, $n = k$, for steam n has the value given in Table 39, p. 338, and for superheated steam or ammonia n may be taken as 1.3. Take $p_m = p_1[2/(n+1)]^{n/(n-1)}$; then p_m is the **critical pressure.** For gases $p_m/p_1 = 0.53$, approx.; for saturated steam the ratio is about 0.575; and for moderately superheated steam, about 0.55.

CASE 1. $p_0 > p_m$. Then $p_2 = p_0$, and the discharge M is given by the equation

$$M = \frac{F_2}{v_2}\sqrt{2gp_1v_1\frac{n}{n-1}\left[1 - \left(\frac{p_0}{p_1}\right)^{\frac{n-1}{n}}\right]}$$

Thus the weight flowing per second depends upon the two pressures p_1 and p_0.

CASE 2. $p_0 \lesseqgtr p_m$. Then $p_2 = p_m$, that is, p_2 remains constant whatever lower value the pressure p_0 may take. In this case the discharge is

$$M = F_2\left(\frac{2}{n+1}\right)^{\frac{1}{n-1}}\sqrt{2g\frac{n}{n+1}\frac{p_1}{v_1}}.$$

Hence the discharge depends upon p_1 only and is not influenced by the pressure p_0.

Formulæ for Discharge of Air. When the back pressure p_0 exceeds the critical pressure $p_m = 0.53\ p_1$,

$$M = 2.05\ Fp_0\sqrt{\frac{1}{T}\left(\frac{p}{p_0}\right)^{0.286}\left[\left(\frac{p}{p_0}\right)^{0.286} - 1\right]}$$

in which p and T refer to the air in the reservoir. Values $(p/p_0)^{0.286}$ are given on p. 318. $[(n-1)/n = 0.286$ when $n = 1.4]$

When p_0 is equal to or less than p_m, $M = 0.53\,Fp/\sqrt{T}$.

For a small difference of pressure, $M = 1.1\,F\sqrt{(p/T)(p - p_0)}$

In these three formulæ F is to be taken in sq. in. when p is taken in lb. per sq. in. The discharge as calculated by the formula should be multiplied by a **coefficient of discharge** to take account of friction, contraction, etc. From the experiments of Zeuner and others, the following mean values of this coefficient are obtained:

Orifices in a thin plate	0.64
Short cylindrical pipe, inner corners not rounded	0.75 to 0.84
Well-rounded mouthpiece	0.98

Formulæ for Discharge of Saturated Steam. When the back pressure p_0 is less than the critical pressure p_m, the discharge depends upon the area of orifice F and reservoir pressure p. There are three formulæ widely used to express the discharge G in terms of F and p, as follows:

1. Napier's equation, $M = Fp/70$.
2. Grashof's formula, $M = 0.0165F\,p^{0.97}$.
3. Rateau's formula, $M = Fp(16.367 - 0.96 \log p)/1000$.

In these formulæ F is to be taken in square inches, p in lb. per sq. in. Napier's formula is merely convenient as a rough check. The coefficient of discharge may be taken as 1; that is, no correction is required. For flow of saturated and superheated steam see also p. 983.

Table 44. Values of $p^{0.97}$ for Use in Grashof's Formula

p	$p^{0.97}$	p	$p^{0.97}$	p	$p^{0.97}$	p	$p^{0.97}$
15	13.8	50	44.5	110	95.5	225	191.2
20	18.3	55	48.8	120	104.0	250	212.0
25	22.7	60	53.1	130	112.4	275	232.0
30	27.1	70	61.6	140	120.7	300	253.0
35	31.5	80	70.1	150	129.1		
40	35.8	90	78.6	175	150.0		
45	40.1	100	87.1	200	170.6		

When the back pressure p_0 is greater than the critical pressure p_m the velocity and discharge are found most conveniently from the general formulæ of flow. From the steam tables (p. 324) or from the **Mollier chart** (p. 330) find the initial heat content i_1 and the final heat content i_0 after adiabatic expansion; also the specific volume v_0 in the final state. See Fig. 22. Then

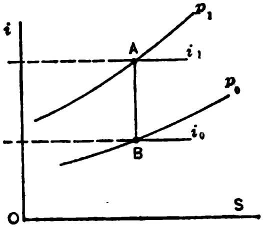

FIG. 22.

$$w = 223.7\sqrt{i_1 - i_0} \qquad \text{and} \qquad M = Fw/v_0.$$

The same method is used in the case of steam initially superheated.

Example. Required the discharge through an orifice ½ in. in diameter of steam at 140 lb. per sq. in. super heated 110 deg.; back pressure, 90 lb. per sq. in.

From the Mollier chart, $i_1 = 1253$, and $i_0 = 1213$. Also $v_0 = 5.26$ cu. ft.

$$w = 223.7\sqrt{1253 - 1213} = 1413 \text{ ft. per sec.}$$
$$F = 0.1964 \text{ sq. in.} = (0.1964/144) \text{ sq. ft.},$$
$$M = Fw/v_0 = (0.1964/144) \times (1413/5.26) = 0.366 \text{ lb. per sec.}$$

Flow Through Diverging Nozzles. At the throat, or smallest cross-section of the nozzle (Fig. 23) the pressure takes the value $p_m = 0.57\ p_1$. The weight discharged is fixed by the area F_m of the throat and the reservoir pressure p_1, and may be found from Grashof's or Rateau's formula. The diverging part of the nozzle permits further expansion to the back pressure p_0, the velocity of the jet meanwhile increasing from w_m, the critical velocity at the throat, to w_0 given by the fundamental equation $w_0 = 223.7\sqrt{i_1 - i_0}$.

The frictional resistances in the nozzle have the effect of decreasing the jet energy $w_0^2/2g$ and correspondingly increasing the energy and heat content of the flowing fluid. Thus, if i_0 is the heat content in the final state with frictionless expansion, $i'_0(>i_0)$ is the heat content when friction is taken into account; hence $w'_0{}^2/2g = J(i_1 - i'_0)$ is less than $w_0^2/2g = J(i_1 - i_0)$. The loss of kinetic energy in B.t.u. is $i'_0 - i_0$, and the ratio of this loss to the available kinetic energy, that is $(i'_0 - i_0)/(i_1 - i_0)$, is denoted by y. For values of y, see p. 356.

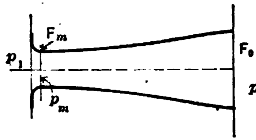

FIG. 23.

The **design of a nozzle for a given discharge** M with pressure p_1 and p_0 is most conveniently effected with the aid of the Mollier chart. Determine p_m, the critical pressure, and i_1, i_m, i_0, assuming frictionless flow. Then

$$w_m = 223.7\sqrt{i_1 - i_m}, \quad \text{and} \quad w'_0 = 223.7\sqrt{(1 - y)(i_1 - i_0)}.$$

Next find v_m and v'_0. Then, from the equation of continuity,

$$F_m = Gv_m/w_m, \text{ and } F'_0 = Gv'_0/w'_0.$$

The following example illustrates the method.

Example. Required the throat and end sections of a nozzle to deliver 0.7 lb. of steam per sec. The initial pressure is 160 lb., the back pressure 15 lb., and the steam is initially superheated 100 deg.; $y = 0.15$.

The critical pressure is $160 \times 0.55 = 88$ lb. On the Mollier chart (Fig. 24) the point A representing the initial state is located, and line of constant entropy (a frictionless adiabatic) is drawn from A. This cuts the curves $p = 88$ and $p = 15$ in the points B and C, respectively. The three values of i are found to be $i_1 = 1251$, $i_m = 1198$, $i_0 = 1065$. Of the available drop in heat content, $i_1 - i_0 = 186$ B.t.u., 15 per cent. or 27.9 B.t.u. is lost through friction. Hence, $CD = 27.9$ is laid off and D is projected horizontally to point C' on the curve $p = 15$. Then C' represents the final state of the steam, and the quality is found to be $x = 0.94$. The specific volume in the state C' is $26.27 \times 0.94 = 24.7$ cu. ft. Likewise the specific volume for the state B is found to be 5.2 cu. ft.

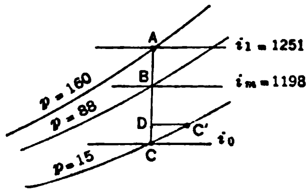

FIG. 24.

For the velocities at throat and end sections,

$$w_m = 223.7\sqrt{1251 - 1198} = 1629 \text{ ft. per sec.}$$
$$w_0 = 223.7\sqrt{186 - 27.9} = 2813 \text{ ft. per sec.}$$
$$F_m = (0.7 \times 5.2)/1629 = 0.00223 \text{ sq. ft.} = 0.322 \text{ sq. in.}$$
$$F_0 = (0.7 \times 24.7)/2813 = 0.0061 \text{ sq. ft.} = 0.88 \text{ sq. in.}$$

The diameters are $d_m = 0.64$ in. and $d_0 = 1.06$ in.

Velocity Coefficients. Loss of Energy y. On account of friction losses the actual velocity w attained by the jet is less than the velocity w_0 calculated under ideal conditions. That is, $w = xw_0$, where x (<1) is a velocity coefficient. Evidently the coefficient x is connected with the coefficient y (see p. 355), giving the loss of energy by the relation $y = 1 - x^2$.

For **orifices in thin plates,** the experiments of Zeuner on air and of Gutermuth and Bendemann on saturated and superheated steam indicate that x has the value of 0.97 to 0.975.

For **flow through nozzles,** Stodola states that the energy loss varies from $y = 0.05$ for short tubes to $y = 0.15$ for long tubes. The most comprehensive experiments in this field are those of Briling (*Mitteil, über Forsch.-arb.*, 68) and of Josse and Christlein (*Zeit. Ver. Deutsch. Ing.*, 1911, p. 2081). Briling used slightly superheated steam and two nozzles, one cylindrical with a diam. of 0.254 in. and length of 1.18 in., the other a slightly converging nozzle with a minimum diam. of 0.34 in. For the cylindrical tube he found $x = 0.95$; for the convergent tube x increased from 0.92 to 0.965 as the velocity increased. These results indicate an energy loss of 10 per cent. in the cylindrical tube and of 7 to 16 per cent. in the convergent tube. The experiments of Josse and Christlein were made on 6 De Laval nozzles having ratios of maximum to minimum sectional areas ranging from 1.185 to 12.94. Under the most favorable conditions, with a tube properly proportioned for the pressure drop, the experiments showed a value of $x = 0.94$ for a velocity of 2000 ft. per sec. and a value around 0.95 for velocities of 2500 to 3500 ft. per sec. Taking $x = 0.945$ as a mean value, the energy loss is,

$$y = 1 - x^2 = 1 - 0.945^2 = 0.107, \text{ or } 10.7 \text{ per cent.}$$

Josse and Christlein also made experiments on the friction loss in a set of **three guide vanes,** which take the place of nozzles in turbines of the Rateau type. Under favorable conditions with slightly superheated steam the mean value $x = 0.923$ was found. The corresponding loss of energy is $y = 0.148$ or 14.8 per cent. With high superheat and a velocity of 2200 ft. per sec., the value $x = 0.95$ was obtained, but at about 800 ft. per sec. x dropped to about 0.85. Rosenhain's experiments give values of x for several types of nozzles. Table 45 gives data and results (see Peabody's "Thermodynamics," p. 442).

Table 45. Values of the Velocity Coefficient x for Various Types of Nozzles

(Rosenhain, *Proc. Inst. C. E.*, vol. 140, p. 199)

Ratio of greatest to least diameter	Taper	Initial pressure	Velocity coefficient, x	Loss of energy, y
1.56	1:20	150.0	0.946	0.105
1.96	1:12	275.0	.....	.....
1.36	1:12	97.5	0.972	0.045
1.28	1:12	80.0	0.903	0.185
1.39	1:30	105.0	0.913	0.166
1.32	1:30	90.0	0 929	0.137
1.26	1:30	77.5	0.901	0.188
1.19	1:30	62.5	0.914	0.165
1.12	1:30	50.0	0.914	0.165

Lewicki's experiments on **small divergent nozzles** showed values of x lying around 0.955 to 0.96. The loss of energy was therefore 8 to 9 per cent.

Flow of Gases and Vapors in Mains

General Equations of Flow. In addition to the notation of the preceding section, let L = length of pipe in feet, d = diam. in *feet*, assumed to be constant, p_1 and p_2 = initial and final pressures in main, lb. per sq. in., and D = weight of fluid, lb. per cu. ft.

The general equations of flow (p. 353) are applicable. It is assumed (1) that the pipe is horizontal, whence $dh = 0$; (2) that there is no transmission of heat, whence $dQ = 0$; (3) that the temperature does not change, or $di = 0$. With these assumptions the general equation of flow is $dR = -vdp$. When the velocity of flow exceeds a certain **critical velocity**, as it does in all practical cases, the frictional resistance is found to be approximately proportional to the square of the velocity and inversely proportional to the hydraulic mean depth of the channel. For a circular pipe, therefore, the resistance varies inversely as the diameter and $dR = cw^2dL/d$. Hence $vdp + (cw^2dL/d) = 0$. The integration of this equation leads to two sets of formulæ that under various disguises are in common use.

1. When the **drop in pressure is small** relative to the initial pressure p_1. In this case integration gives the approximate equation

$$p' = cw^2L/vd, \qquad (a)$$

in which $p' = p_1 - p_2$, the drop in pressure.

Taking V as the volume of air flowing through the main per minute, $V = \frac{1}{4}\pi d^2w \times 60$. Substituting this in the formula, and taking $v = 1/D$, the resulting expression is $V = k\sqrt{p'd^5/DL}$, which is the equation used by Cox, Halsey, and others (*Am. Mach.*, Aug. 20, 1896).

2. When the **drop in pressure is considerable**. In this case integration of the general equation gives the following:

$$p_1^2 - p_2^2 = (2/9\pi^2)(cM^2RTL/d^5) \qquad (b)$$

in which M is the weight of air flowing in lb. per sec.; d and L are taken in ft.. and p_1 and p_2 in lb. per sq. in.

Let V_a = volume of air at atmospheric pressure (*i.e.*, free air) flowing per min. Then the preceding formula may be given the form $p_1^2 - p_2^2 = k'V_a^2L/d^5$. This form of equation is used by Frank Richards (*Power*, vol. 32, p. 2138). Professor C. R. Richards (*Bulletin* No. 63, Univ. of Ill. Eng. Exp. Station) gives the same equation in the form $V_a = 3.061\sqrt{d^5p_1^2(1 - r^2)/KL}$, in which $r = p_2/p_1$, the ratio of final to initial pressure.

Of the many equations that have been proposed for the flow of gas in mains, all that have any claim to validity are deduced by obvious transformations from either eq. (*a*) or eq. (*b*).

Coefficients of Friction. The coefficient c in the general equation $dR = cw^2dL/d$ should be a constant if the frictional resistance, as assumed, varies as the square of the velocity and inversely as the diam. of the pipe. The coefficients k, k', and K in the derived formulæ involve the coefficient c with certain other constants depending on the units employed. Thus in the Cox-Halsey formula $V = k\sqrt{p'd^5/DL}$ with d in inches, the relation between the coefficients is $k^2c = 3600\pi^2/(16 \times 12^5)$. Halsey takes $k = 58$, basing this value on the experiments in connection with the Mt. Cenis tunnel. Stockalper's experiments on the pipe lines of the St. Gotthard tunnel indicate values of k between 63 and 73. If k be given the mean constant value 65, the corresponding constant value of c is 0.00000213.

In the equation $p_1^2 - p_2^2 = k'V_a^2L/d^5$, with d in *inches*, the relation between k' and c is $c = 0.00406k'$. The coefficient k' is usually taken as 0.0006 for compressed air, though Richards (*Power*, vol. 32, p. 2138) assumes the value 0.0005. The corresponding values of c are respectively 0.00000243 and 0.00000203.

Unwin ("Compressed Air Transmission"), on the strength of the experiments of Riedler and Stockalper, finds that the coefficient of friction decreases as the size of the pipe increases and gives the formula $K = 0.0027[1 + (3/10d)]$, d in *feet*. This expression for the coefficient is appropriate for the Unwin formula, which is the one used by Professor C. R. Richards. However, the expression $K = 0.003[1 + (3.6/d)]$, d in *inches*, is used by Professor Richards and others. Martin [*Engg.* (London), Mar. 19, 1897] makes use of Unwin's law of the variation of K with the pipe diameter and suggests the following expression for k (in which d is in *inches*) to replace the constant 58 used by Halsey: $k = \sqrt{7000/[1 + (3.6/d)]}$.

The formula therefore becomes $V = \sqrt{7000p'd^5/DL[1 + (3.6/d)]}$, or $p' = w^2L[1 + (3.6/d)]/7000Dd^5$.

Probably the most trustworthy experiments on the friction of compressible fluids in pipes are those of Fritzsche (*Mitt. über Forschungsarbeit.*, 60). According to these experiments the coefficient c varies with the pipe diam., the velocity of flow and the density of the fluid. With the system of units here employed (p in lb. per sq. in., d and L in ft., etc.) the coefficient c is given by

$$c = 0.0000022/d^{0.269}(wD)^{0.148}$$

Taking $D = \dfrac{1}{v} = \dfrac{144p}{RT}$, the expression for c takes the form

$$c = 0.0000022(R/144)^{0.148}(T/pw)^{0.148}d^{-0.269}$$

For air, $R = 53.34$; for steam, $R = 85.7$.

Table 46 gives for air values of 1,000,000 c, corresponding to various values of the ratio T/pw and for pipe diameters varying from 1 in. to 48 in. Intermediate values are readily found by interpolation. For steam, increase the tabular values by 7 per cent.

Table 46. Values of 1,000,000 c (For Air)

Diam. in inches	Values of the ratio T/pw														
	0.03	0.04	0.05	0.06	0.08	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50	0.55

Table 47 gives a comparison between the coefficients of friction suggested by various authorities. Two cases are assumed: (1) 6-in. pipe, 80 lb. pressure; (2) 36-in. pipe, 80 lb. pressure.

Table 47. Comparison of Coefficients of Pipe Friction of Various Authorities

Velocity ft. per sec.	Values of 1,000,000c for 6-in. pipe				Values of 1,000,000c for 36-in. pipe			
	Fr.	U	U_1	M	Fr.	U	U_1	M
20	1.95	1.86	2.07	2.04	1.21	1.28	1.43	1.40
30	1.84	1.86	2.07	2.04	1.14	1.28	1.43	1.40
40	1.76	1.86	2.07	2.04	1.09	1.28	1.43	1.40
50	1.70	1.86	2.07	2.04	1.06	1.28	1.43	1.40

Column marked "Fr." gives Fritzsche's values. These decrease as the velocity increases. Column U gives values from the equation $K = 0.0027 \times [1 + (3.6/d)]$, while column U_1 gives the modified Unwin values from $K = 0.003 \times [1 + (3.6/d)]$. Column M gives Martin's values from $k^2 = 7000/[1 + (3.6/d)]$.

Unwin recommends the constant value $K = 0.003$ for all pipes above 12 in. in diam. This corresponds to the value $1{,}000{,}000c = 1.30$. Inspection of the table of Fritzsche's coefficients shows that this value is a fair average for pipes larger than 12 in. in diam. However, for small values of pw, low pressure or small velocity the coefficient may be considerably higher than 1.30, and for large values of pw it may be much lower. It is probable that **Fritzsche's coefficients** should be given the preference in accurate calculations.

Summary of Formulæ. In the calculation of the flow of a gas the desired result is usually (1) the drop in pressure for flow under given conditions, or (2) the diam. of pipe required for a predetermined drop in pressure. The known or assumed data are: L, length of pipe in ft.; M, weight flowing past any cross-section per sec.; T, the temperature; D, the weight per cu. ft., and w, the velocity.

CASE 1. The loss of pressure is relatively small. Denoting the drop $p_1 - p_2$ by p',

$$p' = c\frac{w^2D}{d}L = c\frac{w^2}{vd}L = 1.273c\frac{Mw}{d^3}L = 1.62\,c\frac{M^2}{Dd^5}L$$

If V, the volume flowing per sec., is taken instead of M, the last formula becomes $p' = 1.62cV^2DL/d^5$, whence $V = 0.786\sqrt{p'd^5/cDL}$. For the pipe diameter,

$$d = 1.1\sqrt[5]{cM^2L/Dp'} = 1.1\sqrt[5]{cV^2DL/p'}.$$

CASE 2. When the drop of pressure is considerable,

$$p_1^2 - p_2^2 = 625cM^2L/d^5 = 625cV^2D^2L/d^5.$$

If V_a is the volume of free air per sec., the formula becomes $p_1^2 - p_2^2 = 3.63cV_a^2L/d^5$, whence $V_a = 0.525\sqrt{d^5(p_1^2 - p_2^2)/cL}$ and $d = 1.294\sqrt[5]{cV_a^2L/(p_1^2 - p_2^2)}$.

The ratio T/pw, which is used in finding the value of c, may be expressed in terms of M or V_a, as follows: Taking 27,740 as the mean value of the product RT *for air*, $T/pw = 2.12d^2/M = 27.7\,d^2/V_a$.

Example. Required the diam. of a pipe 10,000 ft. in length for a flow of 50 cu. ft. of free air per sec.; initial pressure, 120 lb. per sq. in.; permissible drop in pressure 10 per cent., or 12 lb.

Since d is unknown, a trial value of c must be assumed. Let this be 1.6×10^{-6}. Then $d = 1.294\sqrt[5]{\dfrac{1.6\times10^{-6}\times 50^2\times 10{,}000}{120^2 - 108^2}} = 0.556$ ft. $= 6.67$ in. Taking a 7-in. pipe, $T/pw = 0.188$. From Table 46, $c = 1.68 \times 10^{-6}$. Hence $p_1^2 - p_2^2 = 3.63 \times 1.68 \times 10^{-6} \times 50^2 \times 10{,}000 \div \left(\frac{7}{12}\right)^5 = 2257$, and $p_2 = 110.8$ lb.

Flow of Steam in Pipes. Since for the relatively short pipes ordinarily used to convey steam the drop in pressure is small, the approximate formula $p' = cw^2L/vd$ is applicable. In the case of saturated steam the product pv'' (v'' = specific volume) remains nearly constant for a considerable range of pressure. Taking a mean value for this product, the equation of flow takes the forms $p' = KcM^2L/pd^5$, $M = \sqrt{p'pd^5/KcL}$. Evidence regarding the value of the coefficient c is conflicting. The experiments of Eberle indicate that c is practically constant for all conditions. On the other hand, experiments conducted for the Bavarian Revision-Verein seem to show that the empirical formulæ given by Fritzsche for air apply also to saturated and superheated steam. In the formulæ given by Martin, Hawksley, and Hurst, c is taken as constant; the formulæ of Babcock and Unwin make c vary with the diam. of pipe according to the law $c = K[1 + (3.6/d)]$, with d in inches. A comparison of different formulæ is made by Professor Gebhardt in *Power*, June, 1907. See also Lucke's "Engineering Thermodynamics," p. 1117.

Eberle's value of the coefficient c is 2.225×10^{-6} with d in ft. and 2.667×10^{-5} with d in in. Fritzche's values of c are those for air (p. 359) increased by 7 per cent.; hence $p' = 1.07cw^2L/vd$, where c is to be taken from Table 46.

In the second formula, $p' = KcM^2L/pd^5$, take c from the table of air coefficients. K has the following values: When p is less than 60 lb. per sq. in., $K = 685$. When p is greater than 60 lb. per sq. in., $K = 780$. The formula used by Martin and others is $p' = KM^2L/Dd^5$, and with M in lb. per min. and d in in., k has the following values: Martin, 0.0003133; Hawksley, 0.0003370; Hurst, 0.0003126.

Babcock's formula is $p' = k\,[1 + (3.6/d)](M^2L/Dd^5)$, with $k = 0.0001321$ (M in lb. per min. and d in in.).

As an example, take saturated steam at a pressure of 80 lb. per sq. in. flowing in a main 500 ft. long and 6 in. in diam. Under these conditions $T/pw = 0.129$, and from the table of coefficients $c = 1.69 \times 10^{-6}$. The specific volume is 5.47 cu. ft. per lb. and $D = 0.1829$ lb. per cu. ft. $M = 2.7$ lb. per sec. $= 162$ lb. per min. Then by the first formula, $p' = 1.07cw^2L/vd = 1.86$ lb. per sq. in.

By the approximate formula $p' = 780cM^2L/pd^5 = 1.92$ lb. per sq. in.

By Babcock's formula, $p' = 1.96$ lb.; by Eberle's $p' = 2.28$ lb., and by Martin's formula, $p' = 2.89$ lb.

The discrepancy due to the different assumed coefficients is evident. In the light of the best experimental evidence available at the present time, preference should be given to Fritzche's coefficients.

Throttling

Throttling or Wire-drawing. When a fluid flows from a region of higher pressure into a region of lower pressure through a valve or constricted passage, it is said to be throttled or wire-drawn. Examples are seen in the passage of steam through pressure-reducing valves, in the flow through ports and passages in the steam engine, and in the expansion valve of the refrigerating machine.

The **general equation applicable to throttling processes** is derived from the general equation for the flow of fluids, namely,

$$(w_2^2 - w_1^2)/2g = (i_1 - i_2)J.$$

The velocities w_2 and w_1 are practically equal, and it follows that $i_1 = i_2$; that is, in a throttling process the initial and final values of the heat content are equal.

For a mixture of liquid and vapor, $i = i' + xr$, hence the equation of throttling is $i'_1 + x_1r_1 = i'_2 + x_2r_2$. In the case of a perfect gas, $i = c_pT + i_0$, hence the equation of throttling is $c_pT_1 + i_0 = c_pT_2 + i_0$, or $T_1 = T_2$.

Joule-Thomson Effect. The investigations of Joule and Lord Kelvin showed that an actual gas experiences a drop in temperature when throttled. The ratio of the observed drop in temperature to the drop in pressure, that is, dT/dp, is the **Joule-Thomson coefficient.** According to these investigators, this coefficient varies inversely as the square of the absolute temperature, but is independent of the pressure. More recent experiments indicate, however, that the coefficient also varies with the pressure.

The **cooling effect produced by throttling** has been applied by Linde to the liquefaction of gases. See p. 352.

Loss Due to Throttling. A throttling process in a cycle of operations always introduces a loss of efficiency. If T_0 is the temperature corresponding to the back pressure, the loss of available energy is the product of T_0 and the increase of entropy during the throttling process. The following example illustrates the calculation in the case of ammonia passing through the expansion valve of a refrigerating machine.

Example. The liquid ammonia at a temperature of 70 deg. fahr. passes through the valve into the brine coil in which the temperature is 20 deg. and the pressure is 47.75 lb. per sq. in. The initial heat content of the liquid ammonia (see Table 24) is $i'_1 = 42.1$, and therefore the final heat content is $i'_2 + xr_2 = -12.6 + 556.3x_2 = 42.1$, whence $x_2 = (42.1 + 12.6)/556.3 = 0.0985$. From the table the initial entropy is $s'_1 = 0.0813$. The final entropy is $s'_2 + (xr_2/T_2) = -0.0262 + 0.0985 \times 1.1599 = 0.0880$. $T_0 = 20 + 460 = 480$; hence the loss of refrigerating effect is $480 \times (0.0880 - 0.0813) = 3.2$ B.t.u.

COMBUSTION

Fuels. For special properties of various fuels, see p. 594. In general, fuels may be classed under three heads: 1. Gaseous fuels. 2. Liquid fuels. 3. Solid fuels.

The combustible elements that characterize fuels are carbon and hydrogen. Sulphur is also a possible constituent. The complete combustion of carbon gives as a product carbon dioxide, CO_2; the combustion of hydrogen gives water, H_2O.

Combustion of Gaseous Fuels

Combustion Equations. The approximate molecular weights of the important elements and compounds are as follows:

Gas	H_2	O_2	N_2	CO	CO_2	H_2O	CH_4	C_2H_4	C_2H_6O
Molecular weight	2	32	28	28	44	18	16	28	46

For the elements C and H, the equations of complete combustion are:

$$\begin{cases} C + O_2 = CO_2 \\ 12 \text{ lb.} + 32 \text{ lb.} = 44 \text{ lb.} \end{cases} \qquad \begin{matrix} H_2 + \tfrac{1}{2}O_2 = H_2O \\ 2 \text{ lb.} + 16 \text{ lb.} = 18 \text{ lb.} \end{matrix}$$

For a combustible compound, as CH_4, the equation may be written

$$CH_4 + x \cdot O_2 = y \cdot CO_2 + z \cdot H_2O.$$

Comparing the two members of the equation, with respect to equal numbers of atoms, it is seen that

$$y = 1, z = 2, \; 2x = 2y + z, \text{ or } x = 2$$

Hence
$$\begin{cases} CH_4 + 2O_2 = CO_2 + 2H_2O \\ 16 \text{ lb.} + 64 \text{ lb.} = 44 \text{ lb.} + 36 \text{ lb.} \end{cases}$$

The coefficients in the combustion equation give the combining volumes of the gaseous components. Thus, in the last equation 1 cu. ft. of CH_4 requires for combustion 2 cu. ft. of oxygen and the resulting products of combustion are 1 cu. ft. of CO_2 and 2 cu. ft. of H_2O. The coefficients multiplied by the corresponding molecular weights give the combining weights. These are conveniently referred to 1 lb. of the fuel. In the combustion of CH_4, for example, 1 lb. of CH_4 requires $64/16 = 4$ lb. of oxygen for complete combustion and the products are $44/16 = 2.75$ lb. of CO_2 and $36/16 = 2.25$ lb. of H_2O.

Air Required for Combustion. The composition of air is approximately 0.23 O_2 and 0.77 N_2 by weight, or 0.21 O_2 and 0.79 N_2 by volume. For exact analyses it may be sometimes necessary to take account of the water vapor mixed with the air, but ordinarily this is neglected.

The minimum weight of air required for the combustion of 1 lb. of a fuel is the weight of oxygen required, as found from the combustion equation, divided by 0.23. Likewise, the minimum volume of air required for the combustion of 1 cu. ft. of a fuel gas is the volume of oxygen divided by 0.21. For example, in the combustion of CH_4 the weight of air required per lb. of CH_4 is $4/0.23 = 17.4$ lb. and the volume of air per cu. ft. of CH_4 is $2/0.21 = 9.54$ cu. ft. Ordinarily in practice more air is provided than is required for complete combustion. Let a denote the minimum weight required and xa the weight of air admitted; then $x - 1$ is the **excess coefficient.**

Products of Combustion. The products arising from the complete combustion of a fuel are CO_2 and H_2O. Accompanying these are the nitrogen brought in with the air and the oxygen in the excess of air. Hence the products of combustion contain principally CO_2, H_2O, N_2, and O_2. The **presence of CO indicates incomplete combustion.** The composition of the products of combustion is readily calculated from the combustion equations, as shown by the following illustrative example.

Example. A producer gas having the volume composition given is burned with 20 per cent. excess of air; required the volume composition of the exhaust gases.

	V	Coefficients in reaction equations O_2	CO_2	H_2O	Coefficients multiplied by V O_2	CO_2	H_2O
H_2	0.08	0.5	0	1	0.04	0	0.08
CO	0.22	0.5	1	0	0.11	0.22	0
CH_4	0.024	2	1	2	0.048	0.024	0.048
CO_2	0.066	0	1	0	0	0.066	0
N_2	0.61	0	0	0	0	0	0
	1.0				0.198	0.31	0.128

For 1 cu. ft. of the producer gas, 0.198 cu. ft. of O_2 is required for complete combustion. The minimum volume of air required is 0.198/0.21 = 0.943 cu. ft. and with 20 per cent. excess the air supplied is 0.943 × 1.2 = 1.132 cu. ft. Of this 0.238 cu. ft. is oxygen and 0.894 cu. ft. is N_2. Consequently, for 1 cu. ft. of the fuel gas, the exhaust gas contains

			or		
CO_2		0.31 cu. ft.		CO_2	15.7 per cent.
H_2O		0.128 cu. ft.		H_2O	6.5 per cent.
N_2	0.61 + 0.894 =	1.504 cu. ft.		N_2	75.8 per cent.
O_2 (excess)	0.238 − 0.198 =	0.040 cu. ft.		O_2	2.0 per cent.
		1.982 cu. ft.			100.0 per cent.

Volume Contraction. As a result of chemical action there is usually a change of volume; for example, in the reaction $2H_2 + O_2 = 2H_2O$, three volumes (two of H_2 and one of O_2) contract to two volumes of water vapor. In the example just given the volume of producer gas and air supplied is 1 cu. ft. gas + 1.132 cu. ft. air = 2.132 cu. ft., and the corresponding volume of the exhaust gas is 1.982 cu. ft., showing a contraction of about 7 per cent. For a hydrocarbon having the composition C_mH_n, the relative volume contraction is $[1 - (n/4)]$; thus for CH_4 and C_2H_4 there is no change of volume, for C_2H_2 the contraction is ½ volume, and for C_2H_6 there is an increase of ½ in volume.

The change of volume accompanying a chemical reaction causes a corresponding change in the gas constant R. Let R' denote the constant for the mixture of gas and air (1 lb. of gas and xa lb. of air) before combustion, and R'' the constant of the mixture of resulting products of combustion. Then, if y is the resulting contraction of volume, $R''/R' = (1 + xa - y)/(1 + xa)$.

Heating Value. A chemical change is accompanied by the generation or absorption of heat. The union of a combustible with oxygen produces heat, and the heat thus generated when 1 lb. of combustible is completely burned is called the **heating value** or the **calorific power** of the combustible, Heating values are determined experimentally by various forms of calorimeters. See p. 603.

For a gaseous fuel, an accurate definition of the heating value requires specification of the external conditions under which the combustion proceeds. Two heating values may thus be distinguished:

1. The **heating value at constant volume** (H_v) is the quantity of heat rejected to external surroundings when the temperature and volume of the combustion products are brought to the temperature and volume, respectively, of the gaseous mixture before burning.

2. The **heating value at constant pressure** (H_p) is the quantity of heat rejected when the temperature and pressure of the products are brought back to the temperature and pressure, respectively, of the gaseous mixture before burning.

If there is no change of volume due to the combustion, the heat values H_p and H_v are the same. When there is a contraction of volume H_p exceeds H_v by the heat equivalent of the work done on the gas during the contraction. For example, in the burning of CO according to the equation $CO + \frac{1}{2}O_2 = CO_2$, there is a contraction of $\frac{1}{2}$ volume. Taking 62 deg. fahr. as the temperature, the volume of 1 lb. CO at atmospheric pressure is 13.6 cu. ft.; hence the equivalent of the work done at atmospheric pressure is $\frac{1}{2} \times 13.6 \times 2116/778 = 18.5$ B.t.u., which is about 0.4 per cent. of the heating value of CO. Since the difference between H_p and H_v is so small in most fuels, it is usually neglected.

Strictly speaking, the **heating value varies with the temperature of the original gaseous mixture** (to which temperature the products of combustion are finally reduced). Thus if H_p^0 denote the heating value at 0 deg. and c'_p and c''_p the specific heats of the gaseous mixture and combustion products, respectively; then at temperature t, $H_p = H_p^0 + m(c'_p - c''_p)t$. The specific heats c'_p and c''_p are usually slightly different, and therefore H_p depends on the temperature at which the process is carried on. As a rule, the variation of H_p with t is not taken into consideration; if a standard temperature is required, however, 62 deg. fahr. is usually taken.

Lower Heating Value. The heating values defined in the preceding paragraphs are known as the **higher heating values.** With combustibles containing hydrogen, it is customary to base calculations relating to gas-engine efficiencies on another value called the **lower heating value of the fuel.** When in a calorimetric determination of the heating value of a fuel gas the products of combustion are cooled to the original temperature of the mixture, say 62 deg. fahr., most of the water vapor is condensed, and the measured quantity of heat H_p thus includes the latent heat recovered during this condensation. If the heat recovered by condensation is subtracted from H_p, the remainder is the so-called lower heating value of the combustible. Let H'_p denote the lower heating value and w the weight of H_2O produced by the combustion of 1 lb. of the fuel; then $H'_p = H_p - wr$.

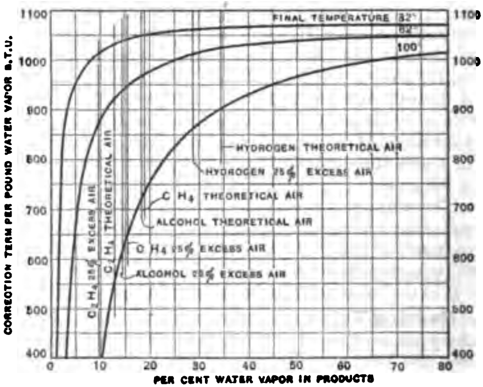

FIG. 25.—Correction Factors for Determining the Lower Heating Value of Fuels.

The factor r is frequently but incorrectly assumed to be the latent heat of steam at 212 deg. (970.4 B.t.u.) or the latent heat at 32 deg. (1073 B.t.u.). As a matter of fact, r varies with the conditions and depends upon the following factors: 1. Percentage of hydrogen in fuel; 2. Weight of air used; 3. Moisture in air and fuel; 4. Temperature adopted as a standard. The curves shown in Fig. 25 have been worked out by Mr. John A. Dent. They show for three temperatures, 32 deg., 62 deg., and 100 deg. fahr., values of r corresponding to various proportions of H_2O by volume in the products of combustion. As an example, suppose CH_4 to be burned with 25 per cent. excess of air. The H_2O formed is 15.5 per cent. of the volume of the combustion products; and for 62 deg. fahr., $r = 945$, while for a standard temperature of

100 deg., $r = 650$. From the combustion equation $w = 2.25$ lb. Taking the higher heating value of CH_4 as 23,840, the lower heating value for a standard temperature of 62 deg., under the conditions stated, is

$$H'_p = 23{,}840 - (2.25 \times 945) = 21{,}704 \text{ B.t.u.}$$

Heating Value per Unit Volume. Since the consumption of a fuel gas is more easily measured by its volume than by weight, it is convenient to express heating values in terms of volumes. For this purpose a standard pressure and temperature must be assumed. It is customary to take atmospheric pressure and 62 deg. fahr.; then the heating value per lb. multiplied by the weight of 1 cu. ft. of the gas under these conditions gives the **heating value of a cubic foot.** For example, the weight of 1 cu. ft. of CO at 14.7 lb. pressure and at 62 deg. fahr. is 0.0734 lb., and the heating value per lb. is 4380 B.t.u.; hence the heating value per cu. ft. is $4380 \times 0.0734 = 322$ B.t.u.

If the gas has some other pressure and temperature, say p_1 and t_1, the heating value per cu. ft. is found by multiplying the heating value per cu. ft. under standard conditions by $35.5p_1/(t_1 + 459.6)$.

Table 48 gives data relating to the combustion of gaseous compounds. In calculating the low heating value it is assumed that the theoretical weight of air is used and 62 deg. fahr. is taken as the standard temperature.

Table 48. Combustion of Gases

Heating Value per Unit Volume of Mixture. Let a denote the volume of air required for the combustion of 1 cu. ft. of fuel gas and xa the value of air actually admitted, $x - 1$ being therefore the excess. Then the volume of the mixture of fuel gas and air is $1 + xa$, and the quotient $H/(1 + xa)$ may be called the heating value per cu. ft. of mixture. This magnitude is useful in comparing the relative volumes of mixture required with different fuel gases. Thus a lean gas, as blast-furnace gas or producer gas, has a low heating value H but the value of a is correspondingly low. On the other hand, a rich gas, like natural gas, has a high heating value but requires a large volume of air for combustion.

Specific Heat of Gases. The calculation of the temperature attained upon the combustion of a fuel under given conditions requires a knowledge of the variation of the specific heats of gases. At the present time the laws governing this variation are not very accurately known. It is known, however, that in the case of **simple gases,** as air, nitrogen, oxygen, CO, etc., the specific heat varies with the temperature, while if the law $pv = RT$ is closely obeyed, the specific heat is independent of the pressure. For a second group of gases like water vapor, H_2O, and CO_2, which are **moderately superheated vapors,** the specific heat varies with both the temperature and pressure. For air at moderate temperatures see p. 1513.

Equations connecting c_p or c_v with the temperature t have been given by Langen, Pier, and Holborn and Henning. The following give the mean **molecular specific heat** at constant pressure between 0 deg. cent. and t deg. cent. The molecular specific heat is the specific heat multiplied by the molecular weight.

(*a*) For diatomic gases. Air, O_2, H_2, N_2, CO:

Langen	$6.8 + 0.0006t$
Pier	$6.9 + 0.00045t$
Holborn and Henning	$6.58 + 0.000532t$

(*b*) For CO_2:

Langen	$8.7 + 0.0026t$
Pier	$8.8 + 0.0033t - 0.00000095t^2 + 0.0000000001t^3$
Holborn and Henning	$8.84 + 0.003267t - 0.000000792t^2$

(*c*) For H_2O:

Langen	$7.9 + 0.00215t$
Pier	$8.065 + 0.0005t + 0.0000000002t^3$
Holborn and Henning	$8.43 - 0.0003815t + 0.000000792t^2$

From these expressions for mean specific heat, expressions for the **actual** (or instantaneous) **specific heat** are derived by multiplying the coefficient of t by 2, the coefficient of t^2 by 3, and so on. To get the **specific heat per lb.,** divide by the molecular weight; thus, for oxygen, divide by 32; for CO_2, by 44, etc.

The linear equations of Langen are most convenient and are probably as rustworthy as any. For temperatures on the Fahrenheit scale, **Langen's ormulæ for actual specific heat** become respectively:

(*a*) For simple gases (m = molecular weight):

$$\left.\begin{aligned} c_v &= \frac{1}{m}(4.77 + 0.000667t) \\ &= \frac{1}{m}(4.48 + 0.000667T) \\ c_p &= \frac{1}{m}(6.75 + 0.000667t) \\ &= \frac{1}{m}(6.46 + 0.000667T) \end{aligned}\right\}$$

(*b*) For CO_2:

$$\left.\begin{aligned} c_v &= 0.15 + 0.000066t \\ &= 0.12 + 0.000066T \end{aligned}\right\} \qquad \left.\begin{aligned} c_p &= 0.195 + 0.000066t \\ &= 0.165 + 0.000066T \end{aligned}\right\}$$

(*c*) For H_2O:

$$\left.\begin{aligned} c_v &= 0.324 + 0.000133t \\ &= 0.263 + 0.000133T \end{aligned}\right\} \qquad \left.\begin{aligned} c_p &= 0.435 + 0.000133t \\ &= 0.374 + 0.000133T \end{aligned}\right\}$$

Investigations on the specific heats of other important gases are lacking. For CH_4 and C_2H_4 the following may be taken as rough estimates of the *mean* specific heats:

For CH_4

$$\left.\begin{aligned} c_p &= 0.481 + 0.00028t \\ &= 0.225 + 0.00028T \end{aligned}\right\} \qquad \left.\begin{aligned} c_v &= 0.356 + 0.00028t \\ &= 0.100 + 0.00028T \end{aligned}\right\}$$

For C_2H_4

$$\left.\begin{aligned} c_p &= 0.335 + 0.00021t \\ &= 0.118 + 0.00021T \end{aligned}\right\} \qquad \left.\begin{aligned} c_v &= 0.264 + 0.00021t \\ &= 0.047 + 0.00021T \end{aligned}\right\}$$

An expression for the **specific heat of a gaseous mixture** may be found from the formulæ for the specific heats of the components. Let M', M'', M''', etc., be the weights of the several components, and suppose the specific heats to be given by $a' + b'T$, $a'' + b''T$, $a''' + b'''T$, etc. Then the expression for the specific heat of the mixture is $a + bT$, in which

$$a = \frac{M'a' + M''a'' + M'''a''' + \ldots}{M' + M'' + M''' + \ldots}, \qquad b = \frac{M'b' + M''b'' + M'''b''' + \ldots}{M' + M'' + M''' + \ldots}$$

Table 49 contains values of the mean specific heat of various gases from 0 deg. to t deg. fahr. For the diatomic gases, the tabular values are to be divided by the molecular weight of the gas. Thus, the mean c_v per lb. of oxygen between 0 deg. and 800 deg. fahr. is $5.04/32 = 0.1575$.

Temperature of Combustion. In calculating the temperature attained at the end of combustion of a given fuel mixture it is assumed: 1. That there is no loss of heat through the boundary walls. 2. That there is no dissociation. 3. That the combustion is complete. 4. That the inert gases do not take part in the reactions.

The principle employed is expressed by the equation: Energy of fuel mixture above 0 deg. fahr. + heat generated = energy of products above 0 deg. fahr. Taking t_1 as the initial temperature and t_2 as the final temperature, this equation becomes

$$\left.\begin{array}{l}\text{Sum of terms } Mc_vt_1\\ \text{for constituents of fuel mixture}\end{array}\right\} + \text{heat generated} = \left\{\begin{array}{l}\text{Sum of terms } Mc_vt_2\\ \text{of products,}\end{array}\right.$$

in which c_v denotes the *mean* specific heat.

As an example, consider the blast-furnace gas having the following composition, and assume that 15 per cent. excess of air is mixed with the fuel and that the temperature at the beginning of combustion is 600 deg. fahr. Then the composition of the fuel mixture, the mean specific heats, and the energies of the constituents are as follows:

	Composition of Fuel		Lower H_v per lb.	MH_v	Composition of fuel mixture, M	Mean sp. ht. 0° to 600° $c_v]_{0°}^{600°}$	$M \cdot c_v]_0^{600}$
	By volume	By weight, M					
H_2........	0.05	0.0037	52,920	195.8	0.0037	$\frac{1}{2} \times 4.97$	0.009195
CO.......	0.27	0.2814	4,380	1232.6	0.2814	$\frac{1}{28} \times 4.97$	0.049971
CH_4.....	0.015	0.0089	21,670	192.9	0.0089	0.524	0.004664
O_2........	0.085	0.1013			0.2447	$\frac{1}{32} \times 4.97$	0.038005
N_2........	0.58	0.6046			1.0848	$\frac{1}{28} \times 4.97$	0.192550
				1621.3	1.6235		0.294385

Energy of fuel mixture = 0.294385 × 600 = 178.63 B.t.u.

The temperature t_2 must now be assumed and the energy of the products calculated. Then the preceding equation will give a value of t_2 which may be used in a second trial. Taking a trial value t_2 = 4200 deg. fahr., the following results:

	Products M	Mean specific heat $c_v]_0^{4200}$	$M \cdot c_v]_0^{4200}$
CO_2......................	0.4667	0.2900	0.135343
H_2O......................	0.0533	0.6040	0.032193
N_2......................	1.0848	$\frac{1}{28} \times 6.17$	0.239044
O_2......................	0.0187	$\frac{1}{32} \times 6.17$	0.003606
			0.408186

Hence $t_2 = (178.63 + 1621.3)/0.408186 = 4410$ deg. Now taking $t_2 = 4400$, the value of $M \cdot c_v]_0^{4400}$ becomes 0.41676, and $t_2 = (178.63 + 1621.3)/0.41676 = 4320$. Hence t_2 is approximately 4360 deg. fahr.

Comparison of Ideal and Actual Temperatures of Combustion. The observed pressure following combustion in gas-engine cylinders is found to be considerably smaller than the pressure calculated according to the preceding method. It follows that **the actual temperature** attained **is lower than** the **calculated temperature.** The causes of the discrepancy are the following:

1. Flow of Heat through Walls of Vessel. The actual process is not adiabatic, as assumed, but in the case of a water-cooled cylinder a considerable part of the heat generated during combustion flows through the walls. Levin estimates that from 5 to 10 per cent. of the heat liberated is thus lost.

2. Dissociation. The two important combustion reactions, namely:

$$2H_2 + O_2 = 2H_2O, \quad 2CO + O_2 = 2CO_2$$

are reversible. When read from left to right, the second indicates the combination of CO and O_2 to form CO_2, and when read from right to left it indicates the dissociation of CO_2 into the constituents CO and O_2. The reaction does not necessarily proceed until all the CO and O_2 are combined, but under definite conditions of pressure and temperature halts at a definite equilibrium position. Nernst and von Wartenburg give the following data concerning the dissociation of H_2O and CO_2, respectively:

DISSOCIATION OF WATER VAPOR (PER CENT.)

Temperature, deg. cent.	Pressure in atmospheres 10	1	0.1	0.01
1000	1.4×10^{-5}	3.1×10^{-5}	6.7×10^{-5}	1.4×10^{-4}
1500	1.1×10^{-2}	2.2×10^{-2}	4.8×10^{-2}	0.11
2000	0.26	0.56	1.2	2.6
2500	1.6	3.4	7.2	14.7

DISSOCIATION OF CO_2 (PER CENT.)

Temperature, deg. cent.	Pressure in atmospheres 10	1	0.1	0.01
1000	9.8×10^{-6}	2.1×10^{-5}	4.5×10^{-5}	9.8×10^{-5}
1500	1.9×10^{-2}	4×10^{-2}	8.6×10^{-2}	0.19
2000	0.74	1.6	3.5	7.3
2500	6.20	13.0	25.5	46.0

Under the conditions that obtain in the gas-engine cylinder, *i.e.*, with a temperature of perhaps 1500 deg. cent. and a pressure of 20 to 30 atm., it is apparent that the dissociation of both H_2O and CO_2 is extremely small; that is, the combustion reaction is practically completed. Hence dissociation plays a negligible rôle in reducing the temperature of combustion.

3. FORMATION OF ENDOTHERMIC COMPOUNDS. Nernst has shown that at the high temperature arising from the combustion of a gaseous fuel compounds may be formed that could not exist at lower temperatures. Thus the nitrogen brought in with air may unite with oxygen; and when an excess of oxygen is present, water vapor is partly oxidised into hydrogen peroxide, H_2O_2. Any reaction which results in a compound that becomes more stable the higher the temperature is **endothermic**, that is, it absorbs heat. Hence the presence of such endothermic reactions must cause a reduction in the final temperature attained. The extent of the reduction from this cause is at present unknown.

Combustion of Solid Fuels

For **properties of solid fuels**, heating values, etc., see p. 594.

Air Required for Combustion. Let c, h, and o, denote respectively the parts by weight of carbon, hydrogen and oxygen in 1 lb. of the fuel. Then the **minimum weight of oxygen** required for complete combustion is $2.67c + 8h - o$ lb. and the **minimum weight of air** required is $a = (2.67c + 8h - o)/0.23 = 11.6\,[c + 3\,(h - o/8)]$ lb.

With air at 62 deg. fahr. and at atmospheric pressure, the minimum volume of air required is $v_m = 147\,[c + 3(h - o/8)]$ cu. ft. In practice an excess of air over that required for combustion is admitted to the furnace. The actual weight admitted per lb. of fuel may be denoted by xa. Then x = weight admitted ÷ minimum weight.

Combustion Products. If v_m is the minimum volume of air required for complete combustion and xv_m the actual volume supplied, then the products will contain per lb. of fuel $O_2 = 0.21\,v_m(x - 1)$ cu. ft., $N_2 = 0.79\,xv_m$ cu. ft.

From the reaction equation $C + O_2 = CO_2$, the volume of CO_2 formed is equal to the volume of oxygen required for the carbon constituent alone; hence volume of $CO_2 = 0.21v_m\,c/[c + 3\,(h - 0.125o)]$.

Of the *dry* gaseous products (*i.e.*, without water) the CO_2 content by volume is therefore given by the expression

$$CO_2 = 0.21c/[xc + (x - 0.21)3(h - 0.125o)].$$

The combined CO_2 and O_2 content is

$$CO_2 + O_2 = 0.21\{1 - 0.79/[x + cx/3\,(h - 0.125o) - 0.21]\}.$$

If the fuel is all carbon the combined CO_2 and O_2 is by volume 21 per cent. of the gaseous products. The more hydrogen contained in the fuel, the smaller is the $CO_2 + O_2$ content. The CO_2 content depends in the first instance on the excess of air. Thus, for pure carbon, it is $CO_2 = 0.21/x$.

The excess of air may be calculated from the composition of the gases and that of the fuel. Thus $x = 0.21\left[\frac{c}{[CO_2]} + 3(h - 0.125o)\right]\Big/[c + 3\,(h - 0.125o)]$, in which $[CO_2]$ denotes the per cent. by volume of the CO_2 in the dry gas.

The temperature of combustion is calculated by the same method as was employed with gaseous fuels. (See p. 367.) However, as the process usually occurs at constant pressure, c_p instead of c_v should be used.

Gas Producers

(See also pp. 1053 to 1059).

Simple CO Producer. The gas producer is used to convert a solid fuel into a gaseous fuel. In its simplest form the producer is a closed retort in which carbon is burned with a limited supply of oxygen. In the lower level of the producer air introduced through the grate comes in contact with carbon and combustion proceeds in accordance with the reaction

$$C + O_2 = CO_2$$

The heat liberated is 14,650 B.t.u. per lb. of carbon burned. The CO_2 thus formed passes through a bed of incandescent carbon and combines with it. The reaction is

$$CO_2 + C = 2CO$$

and in this reaction 10,220 B.t.u. are absorbed for each lb. of carbon burned. This quantity of heat is the heat of combustion of the CO formed; the efficiency of the process is $10{,}220 \div 14{,}650 = 0.698$. The remaining heat $14{,}650 - 10{,}220 = 4430$ B.t.u. is in part carried off as sensible heat in the gas leaving the producer, in part radiated from the producer.

The gas derived from this simple producer will consist of CO and N_2.

Producer Using Steam. The loss of heat inherent in the simple CO producer may be obviated in part by the introduction of steam into the fuel bed. The steam may be supplied by an external boiler heated by the gases leaving the producer, or it may be formed in a water jacket surrounding the fuel bed. The union of steam with carbon may be expressed by the reactions

$$2H_2O + C = 2H_2 + CO_2, \qquad H_2O + C = H_2 + CO$$

For temperatures between 1000 deg. and 1600 deg. fahr. the first reaction predominates, while for temperatures above 1600 deg. the reverse is the case. In general, high temperature of fuel bed is necessary for the production of CO, while with a low temperature the gas will show an excessive CO_2 content.

Assuming that no CO_2 is formed and that the producer operates under ideal conditions, the theoretical weight of steam required per lb. of carbon is found as follows: 1 lb. C burned to CO liberates 4430 B.t.u.; 1 lb. H_2 burned to H_2O liberates 62,100 B.t.u.; $\frac{1}{9}$ lb. H_2 burned to 1 lb. H_2O liberates 6900 B.t.u.

The heat liberated by the burning of C (4430 B.t.u.) is available for the decomposition of H_2O. Since to decompose 1 lb. H_2O requires 6900 B.t.u., the weight of H_2O supplied must be $4430/6900 = 0.628$ lb.

The gas formed has for its constituents CO, H_2, and N_2. For 1 lb. carbon the weights of constituents are as follows:

	Vol. at 62 deg. and 14.7 lb.	Theoretical composition by volume	Lower heating value (B.t.u. per cu. ft. at 62 deg. fahr.)
$CO = 28/12 = 2.33$ lb.	31.8 cu. ft.	0.396	127.5
$H_2 = 1/9 \times 0.628 = 0.07$ lb.	13.2 cu. ft.	0.165	46.4
O_2 required $= 1.333$ lb.		.....	......
O_2 from $H_2O = 0.628 - 0.07 = 0.558$ lb.		.....	......
O_2 from air $= 1.333 - 0.558 = 0.775$ lb.		.....	......
$N_2 = 0.775$ lb. $\times 77/23 = 2.595$ lb.	35.2 cu. ft.	0.439	0.0
Total volume of gas	80.2 cu. ft.		173.9

Heat Balance. Regarding the producer as a unit, heat is supplied to it from outside, heat is generated and absorbed within it by the various chemical processes, and heat passes out with the gaseous product withdrawn. The fuel, air, and steam furnished the producer bring in a certain amount of sensible heat above some assumed standard temperature, say 62 deg. fahr. Within the producer heat is generated by the combustion of C to CO and to CO_2, and heat is absorbed by the decomposition of H_2O into H_2 and O_2. Heat is also absorbed in raising the temperature of the fresh fuel to that of the producer. Some heat is lost by radiation, and some is carried out of the producer as sensible heat of the gaseous product. Assuming the producer to be maintained at a constant temperature,

$$\left\{\begin{array}{l}\text{heat received}\\ \text{by producer}\end{array}\right\} + \left\{\begin{array}{l}\text{heat generated}\\ \text{in producer}\end{array}\right\} = \left\{\begin{array}{l}\text{heat absorbed}\\ \text{in producer}\end{array}\right\} + \left\{\begin{array}{l}\text{heat carried out}\\ \text{of producer.}\end{array}\right.$$

It is convenient to refer these heat quantities to 1 lb. of carbon burned in the producer.

Let x = part of 1 lb. C that burns to CO_2. $1 - x$ = part of 1 lb. C that burns to CO. y = weight of steam introduced per lb. C. Q_s = heat furnished by entering steam. Q_a = heat furnished by entering air. Q_r = heat lost by radiation. Q_g = heat carried out by gas as sensible heat. Q_f = heat required to raise temp. of fuel to that of producer. The heat generated by the combustion of carbon to CO_2 is $14{,}650x$, that generated by the combustion of C to CO is $4430\,(1 - x)$. If y lb. of steam is decomposed, $\frac{1}{9}y$ lb. of H_2 is formed and the heat absorbed in the decomposition is $\frac{1}{9}y \times 62{,}100 = 6900y$. Hence the heat balance is expressed by the following equation:

$$Q_s + Q_a + 14{,}650x + 4430(1 - x) = 6900y + Q_r + Q_f + Q_g$$

From this equation the CO_2 content of the producer gas is determined when the weight of steam y is fixed.

Efficiency. For 1 lb. of carbon burned in the producer, $2\frac{1}{3}\,(1 - x)$ lb. of CO and $y/9$ lb. of H_2 are formed. The heating value of the gas is $10{,}220\,(1 - x) + 6900y$. Add to this the sensible heat Q_g and the sum is the heat output of the producer per lb. of C. The heat supplied per lb. of C is $Q_s + Q_a + 14{,}650$; hence the efficiency of the producer is

$$e = [10{,}220(1 - x) + 6900y + Q_g]/(Q_s + Q_a + 14{,}650)$$

When the gas is used in furnaces the sensible heat Q_g may be usefully employed and the preceding definition of efficiency holds. If the gas is used in a motor, it must be cooled, and the heat Q_g is wholly or in large part lost. The efficiency in this case, the so-called "cold-gas efficiency," is

$$e' = [10{,}220(1 - x) + 6900y]/(Q_s + Q_a + 14{,}650)$$

In best practice the value of e' may reach 0.85.

Weight of Steam Supplied. The heat quantities Q_s, Q_a, Q_g, etc., in the heat-balance equation depend upon the conditions of operation. The following may be taken as reasonable values under usual conditions:

$$Q_s + Q_a = 1000 \text{ B.t.u.} \quad Q_r = 900. \quad Q_f = 350. \quad Q_g = 950$$

Substituting these values in the equation,

$$14{,}650x + 4430(1 - x) = 6900y + 1200$$

For various values of x (part of carbon burned to CO_2) the weights of water decomposed per lb. of carbon are therefore as follows:

x =	0	0.10	0.20	0.30	0.40
y(lb.) =	0.468	0.616	0.764	0.913	1.061

If the weight of steam supplied exceeds 0.47 lb., there must necessarily be CO_2 in the gas formed.

The temperature of the fuel bed, however, determines largely the per cent. of CO_2 formed. According to the experiment of Clement (*Bulletin* No. 30, Engineering Exper. Station, Univ. of Illinois), the reaction $CO_2 + C = 2CO$ requires a temperature of 2372 deg. fahr. for the formation of 90 per cent. of CO from CO_2 and anthracite coal. With lower temperatures the per cent. of CO falls rapidly. If a small amount of steam is supplied the temperature of the fuel bed is high, thus permitting the formation of maximum CO. If more steam is admitted the temperature is lowered, the reaction between CO_2 and C is incomplete, and CO_2 is formed.

The effect of the introduction of steam is discussed by Clement and Adams (*Bulletin* No. 7, U. S. Bureau of Mines). The following is a condensation of this discussion.

The object of adding steam is threefold—to reduce the temperature of the fuel bed and thus avoid or hinder the fusion of the ash and the formation of clinker; to prevent the destruction of the furnace walls from fusion or slagging, and to reduce the heat losses in the gases leaving the producer. With increasing weight of steam there is a gradual decrease of efficiency.

A considerable amount of steam is necessary, with coals high in ash and where the ash is readily fusible, to prevent the formation of large clinkers.

The rate of gasification increases rapidly with rise in temperature. This suggests the possibility of operating producers at very high temperatures —2700 deg. fahr. or above—by providing for the removal of slag in a liquid state, as in blast-furnace practice. A producer embodying this principle would be adapted to coals which, because they clinker badly, have no market at present.

The higher the temperature, the better will be the quality of the gas and the greater the capacity of the producer.

Composition of Producer Gas. Taking x as the part of the carbon burned to CO_2 and y as the weight of steam supplied per lb. of carbon, the following expressions give, respectively, the weight in lb. and the volume in cu. ft. (at 62 deg. fahr. and 14.7 lb.) of the constituents of the gas formed from 1 lb. of carbon:

Constituent	Weight (lb.)	Volume (cu. ft.)
CO	$\frac{7}{3}(1 - x)$	$31.8(1 - x)$
CO_2	$1\frac{1}{3}x$	$31.7x$
H_2	$\frac{1}{9}y$	$21y$
N_2	$3.35\,[\frac{4}{3}(1 + x) - \frac{8}{9}y]$	$60.6(1 + x) - 40.4y$
	Total weight, $6.8 + 5.8x - 2.87y$.	Total volume, $92.4 + 60.5x - 19.4y$.

Table 50 gives the composition of producer gas for various values of x and the corresponding values of y as calculated in a preceding paragraph.

Table 50. Composition of Producer Gas

For **actual analyses of producer gas,** see pp. 1057 to 1059.

Surface Combustion. If, after forcing combustible gas through a porous mass of refractory material, igniting, and allowing it to burn in the air with the usual flame, air is forced in with the gas so that the resulting explosive mixture flows with too great velocity for backfiring to occur, the flame becomes non-luminous and, as the surface of the refractory mass is heated up, gradually disappears from the surface of the material, which glows under the action of the surface combustion. The combustion, which is supported by the oxygen admitted with the gas and is not influenced by the oxygen in front of the refractory mass, is perfect with a minimum of excess air. In the case of a porous slab or diaphragm, the combustion takes place within a distance of from ⅛ to ¼ in. from the surface. This method of heating has been applied to muffles and crucibles, where the porous refractory material, in the form of small lumps, is closely packed in the interspaces. Liquids may be evaporated from their surfaces by an inverted diaphragm placed directly over the containing vessel. Muffles can be kept steadily at a temperature of 2700 deg. fahr. (3600 deg. attainable) with the use of only one-half the amount of gas required in the older method of firing. The advantages of this method of combustion, according to Prof. W. A. Bone (*Engg.*, Apr. 14, 1911), are that combustion is accelerated by the incandescent surface, the heat developed can be concentrated just where it is required, very high temperatures are attainable without the use of regenerators, and that the energy is converted into radiant form which is transmitted very rapidly to the object exposed to it.

Surface combustion has been applied to boilers, the tubes being packed throughout their length with pieces of firebrick, the air-gas mixture entering each tube through a ¼-in. hole in a fireclay plug or nozzle (which serves to protect the joints in the tube sheet) at the front end. For gas firing, 3- to 6-in. tubes are used, and 9 to 12 in. for oil firing, the oil being first vaporized in a chamber at the firing end of the tube. Tests on a 10-ft. boiler (4 ft. long, with 110 3-in. tubes) at the Skinningrove Iron Works, in connection with an economiser, using coke-oven gas, after 5 months' use showed that of the heat supplied 92.7 per cent. was utilized, 3 per cent. escaping with the waste gases, and the remainder being lost through radiation, etc., but none in unburnt gas. Allowing for the power required to drive the draft fan, the overall efficiency was practically 90 per cent. The evaporation from and at 212 deg. was about 19 lb. per hour per sq. ft. of heating surface. The combustion was confined to about 4 in. next to the admission nozzles, the rest of the refractory material serving merely to baffle the gases; the heat was greatest in the cores of the material, the parts in contact with the tube walls not being very hot. In this boiler it was found that 70 (22) [8] per cent. of the total evaporation took place over the first (2nd) [3rd] third of the length of the tubes (*Engg.*, May 10, 1912). The length of the boiler is not increased for greater capacities, the increased capacity being obtained by an increase in the diameter of the boiler and the use of a greater number of tubes. Therefore in large units the distortion strains would be negligible because of the short length. In an experimental boiler with ten 3-in. tubes 3 ft. long the following results were obtained: 100 lb. per sq. in. gage was obtained in 20 min. after starting from cold; the evaporation from and at 212 was 21.6 per sq. ft. per hour; the gases left at only 126 deg. fahr. above the steam temperature without the use of an economiser; the CO_2 in the exhaust was 10.6 per cent. as against a theoretical percentage of 11; the free oxygen in the exhaust amounted to only 1.6 per cent. An evaporation of 17 lb. from and at 212 deg. has been obtained per pound of liquid fuel.

DEFINITIONS AND SIMPLE STRESSES

Deformations are changes in form produced by external forces or loads that act on non-rigid bodies. Deformations are **longitudinal,** e, a lengthening (+) or shortening (−) of the body; and **angular,** d, a change of angle between the faces.

Unit Deformation (abstract number) is the deformation in unit distance. Unit longitudinal deformation, $s = e/l$ (Fig. 1). Unit angular deformation, tan d, equals d approx. (Fig. 2).

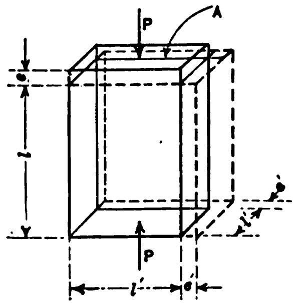

FIG. 1.

Accompanying a longitudinal deformation e, is a **lateral** deformation e', (Fig. 1). The ratio of s'/s is **Poisson's ratio,** m. Values of m are: Glass, 0.244; brass, 0.333; copper, 0.333; cast iron, 0.270; wrought iron, 0.278; steel, 0.303; lead, 0.430; concrete, 0.10 to 0.20 at working stresses and 0.25 at higher stresses.

The weight of a bar and also centrifugal forces are often important deforming forces. If the sides of a bar are restrained, important modifications result (see p. 391).

Stress is an internal distributed force; it is the internal mechanical reaction of the material accompanying deformation. Stresses always occur in pairs. Stresses are: **longitudinal**, S [tensile stress (+) and compressive stress (−)]; and **tangential**, or **shearing**, S_v.

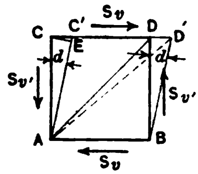

FIG 2.

Uniformly Distributed Longitudinal Stress is produced by a load acting along the geometric axis of a bar.

Intensity of Stress, or **Unit Stress**, S (lb. per sq. in.) is the amount of force per unit of area of surface (Fig. 3). P is the load acting through the center of gravity of the bar. The uniformly distributed normal stress is

$$S = P/A$$

When the stress is not uniformly distributed, $S = dP/dA$.

A **long rod** will stretch under its own weight G and a terminal load P. (See Fig. 4.) The total elongation e is that due to terminal load plus that due to one-half the weight of the rod considered as acting at the end.

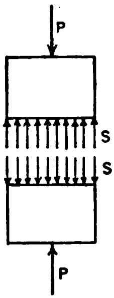

FIG. 3.

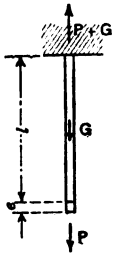

FIG. 4.

$$e = [Pl + (Gl/2)]/AE$$

The maximum stress is at the upper end.

A **solid of uniform strength in tension** or **compression** has curved boundaries (Fig. 5). Let A = area at any section at the distance x from the end; A_0 = area of base; P = load on base; E = base of Napierian logarithmic system; y = weight of material per unit volume; and S = uniform stress. The stress S on the increase of area dA, in height dx, carries the weight dG. $dG = yAdx = SdA$. Then $ydx/S = dA/A$, or

$$A = A_0E^{yx/S}$$

The weight of any portion of height x is $P_0E^{yx/S}$.

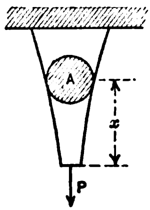

FIG. 5.

When the deformation arising from change of temperature is prevented, **temperature stresses** arise that are proportional to the amount of deformation that is prevented. Let a = coefficient of expansion per degree of temperature, l_1 = length of bar at temperature t_1, and l_2 = length at temperature t_2. Then

$$l_2 = l_1[1 + a(t_2 - t_1)]$$

If, subsequently, the bar is cooled to a temperature t_1, the proportionate deformation is $s = a(t_2 - t_1)$, and the corresponding unit stress $S = Ea \times (t_2 - t_1)$. For **coefficients of expansion**, see p. 293. In the case of steel, a change of temperature of 12 deg. fahr. will cause a unit stress of 2240 lb. per sq. in.

Shearing Stresses, S_v (Fig. 2), act tangentially to the surface of contact and do not change length of sides of elementary volume; they **change the**

angle between faces, and the **length of diagonal.** Two pairs of shearing

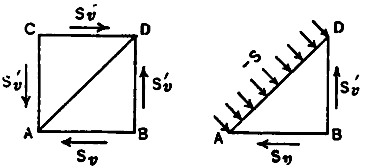

FIG. 6.

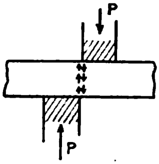

FIG. 7.

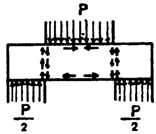

FIG. 8.

stresses must act together. **Shearing stresses are of equal magnitude on all four faces of an element.** $S_v = S_v'$ (Fig. 6).

In the presence of **pure shear** on external faces (Fig. 6), the **resultant stress** S on one diagonal plane at 45 deg. is pure tension, and on the other diagonal plane pure compression; $S = S_v = S'_v$. S on diagonal plane is called "diagonal tension" by writers on reinforced concrete. Failure under pure shear is difficult to produce experimentally. Fig. 7 shows an ideal case, and Fig. 8 a common form of test piece that introduces bending stresses.

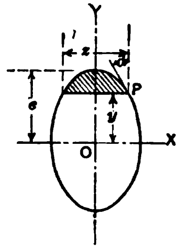

FIG. 9.

Let Fig. 9 represent the section of area A on which a shearing force Q acts. Then, if pure shear should exist, $S_v = Q/A$. This would be uniformly distributed over the area A. When **shear is accompanied by bending (horizontal shear in beams)** the unit shear S_v increases from the extreme fiber to the neutral axis OX, where it is a maximum. The unit shear parallel to axis OY at any point y distant from the neutral axis as at P (Fig. 9), is

$$S_v = \left(Q\int_y^e yzdy\right)/Iz$$

where I is the moment of inertia of the cross-section.

For a **rectangular cross-section** (Fig. 10a),

$$S_v = \frac{3}{2}\frac{Q}{bh}\left[1 - \left(\frac{2y}{h}\right)^2\right]; \qquad S_v\,(\text{max.}) = \frac{3}{2}\frac{Q}{bh} = \frac{3}{2}\frac{Q}{A}, \text{ for } y = 0.$$

For a **circular cross-section** (Fig. 10b),

$$S_v = \frac{4}{3}\frac{Q}{\pi r^2}\left[1 - \left(\frac{y}{r}\right)^2\right]; \qquad S_v\,(\text{max.}) = \frac{4}{3}\frac{Q}{\pi r^2} = \frac{4}{3}\frac{Q}{A}, \text{ for } y = 0.$$

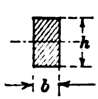

FIG. 10.—a.

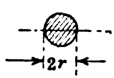

FIG. 10.—b.

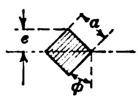

FIG. 10.—c.

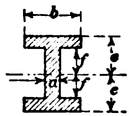

FIG. 10.—d.

For a **circular ring** (thickness small in comparison with the major diameter), S_v (max.) $= 2\,Q/A$, for $y = 0$.

For a **square cross-section** (diagonal vertical, Fig. 10c),

$$S_v = \frac{Q\sqrt{2}}{a^2}\left[1 + \frac{y\sqrt{2}}{a} - 4\left(\frac{y}{a}\right)^2\right]. \qquad S_v\,(\text{max.}) = 1.591\frac{Q}{A}, \text{ for } y = \frac{e}{4}.$$

For an **I-shaped cross-section** (Fig. 10*d*),

$$S_v \text{ (max.)} = \frac{3}{4}\frac{Q}{a}\frac{be^2 - (b-a)f^2}{be^3 - (b-a)f^3}, \text{ for } y = 0.$$

Stress-Strain Diagrams are drawn from results of tests of materials. Gradually increasing loads are applied and the resulting deformations are measured. In Figs. 11 and 12, unit deformations are shown as abscissæ and stresses as ordinates [tension (+) and compression (−)]. The word **strain,** as used here, means deformation.

Figs. 13 and 14 shows several such diagrams. The stresses are not actual but nominal, because the load is divided by the *original,* and not the actual deformed, cross-sectional area.

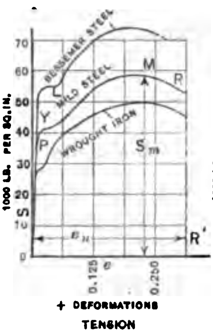

FIG. 11.

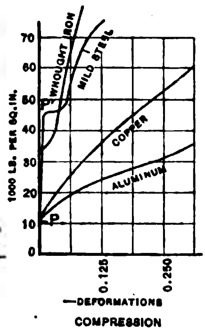

FIG. 12.

Elasticity is the tendency of deformed bodies to resume their former shape. The **elastic limit** is the limit of stress within which the deformation completely disappears after the removal of the stress; that is, no set remains. As measured in tests and used in design this term refers to the **proportional elastic limit,** S_p (Fig. 13), which is the stress within which stresses and deformations are directly proportional. At the **commercial elastic limit** or **yield point,** S_y, some materials experience a sudden and large increase of deformation without increase of stress. S_p ranges from 0.75 S_y (hot rolled steel) to 0.90 S_y (annealed steel). Location of S_p depends upon speed of application of stress.

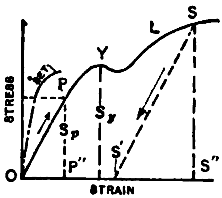

FIG. 13.

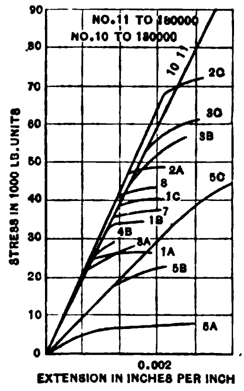

FIG. 14.—Typical Stress-strain Diagrams for Various Metals, Up To the Elastic Limit.

1A, 1B and 1C are for soft O.H. steel; 2A and 2C for axle steel; 3A, 3B and 3C for O.H. steel, forged; 4B for heavy steel casting; 5A, 5B and 5C for copper; 7 for wrought iron; 8 for light steel casting; 10 for chrome tungsten steel; 11 for vanadium steel.

Hooke's Law states that, within the elastic limit, the deformation produced is proportional to the stress. (Unless modified, the deduced formulæ of mechanics apply only within the elastic limit. Beyond this they are modified by experimental coefficients, as, for instance, the modulus of rupture.)

The Modulus of Elasticity (lb. per sq. in.) is the ratio of the increment of unit stress to increment of unit deformation within the elastic limit.

The Modulus of Elasticity in Tension, or Young's Modulus, E, is measured graphically by the slope of OP (Fig. 13). The compression modulus is similarly measured (Fig. 12). The reciprocals of the values of E for several materials express the relative deformations of these materials under the same stress. **E is a measure of stiffness.**

$$E = S/s = Pl/Ae$$

Modulus of Elasticity in Shear (lb. per sq. in.), or coefficient of rigidity, G (Fig. 2):

$$G = S_v/d$$

where d is expressed in radians. Theoretically, $G = En/2(n + 1)$, where n is the reciprocal of Poisson's ratio.

The Bulk Modulus of Elasticity, K, is the ratio of longitudinal stress, applied to all six faces of a cube, to the change of volume. Theoretically, $K = (1/3)En/(n - 2)$. When $n = 3$, $K = E$.

Change of Volume Under Longitudinal Stress. Let l, d, and b represent length, width, and thickness; m = Poisson's ratio; s = unit deformation. Then deformed volume $= (1 + s)l(1 - ms)b(1 - ms)d = (1 + s - 2ms)lbd$. Fractional change of volume $= (1 - 2m)s$. When m is less than ½, the volume is increased in tension and decreased in compression. For steel ($m = 1/3$), change of volume is about 1/3000-part at the elastic limit.

A bar of steel under stress does not at once assume the length due to its stress. Deformation proceeds for days and weeks. These phenomena of **residual elasticity** or **elastic afterworking** do not seem to be of practical importance.

When a load is carried by several paths to a support, the different paths take portions of the load in proportion to their stiffness, which is controlled by material (E) and by design.

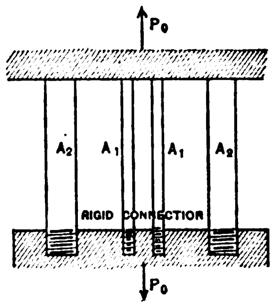

FIG. 15.

Example. Two pairs of bars rigidly connected (with the same elongation) carry a load P_0 (Fig. 15). A_1, A_2 and E_1, E_2 and P_1, P_2 and S_1, S_2 are cross-sections, moduli of elasticity, loads and stresses of the bars, respectively; e = elongation.

$$e = P_1l/(E_1A_1) = P_2l/(E_2A_2); \qquad P_0 = 2P_1 + 2P_2;$$

$$S_2 = P_2/A_2 = \tfrac{1}{2}[P_0E_2/(E_1A_1 + E_2A_2)] \text{ and } S_1 = \tfrac{1}{2}[P_0E_1/(E_1A_1 + E_2A_2)].$$

Resilience, U (in.-lb.), is the potential energy stored up in a deformed body. The amount of resilience is equal to the work required to deform the body from zero stress to stress S, when S does not exceed the elastic limit. For longitudinal stress, P = load; e = deformation; S = stress; A = cross-section; V = volume. Then Resilience = Work of deformation = Average force times deformation $= \tfrac{1}{2}Pe = \tfrac{1}{2}AS \times Sl/E = \tfrac{1}{2}S^2V/E$.

Modulus of Resilience, U_p (in.-lb. per cu. in.), or **Unit Resilience,** is the elastic energy stored up in a cubic inch of material at the elastic limit. For longitudinal stress U_p is graphically expressed by the area OPP'', Fig. 13.

$$U_p = \tfrac{1}{2}\, S_p^2/E$$

The unit resilience for any other kind of stress, as shearing, bending, torsion, is a constant times one-half the square of the stress divided by the appropriate modulus of elasticity. For values, see Table 1.

The **resilience** stored up at a stress **beyond** the **elastic limit** is measured by the area of the triangle $S''S\,S'$ (Fig. 13). The line SS' represents the release of a stress from S to zero load at S', leaving a set OS'.

Table 1. Resilience per Unit of Volume, U_p

(S = Longitudinal stress; S_s = Shearing stress; E = Tension modulus of elasticity; G = Shearing modulus of elasticity)

		TORSION	
Tension or compression....	$\frac{1}{2}S^2/E$	Solid, circular...........	$\frac{1}{4}S_s^2/G$
Shear....................	$\frac{1}{2}S_s^2/G$	Hollow, radii R_1 and R_2..	$\frac{(R_1^2 + R_2^2)}{R_1^2}\frac{1}{4}\frac{S_s^2}{G}$
BEAMS (free ends)		SPRINGS	
Rectangular section, bent in arc of circle no shear.....	$\frac{1}{6}S^2/E$	Carriage...............	$\frac{1}{6}S^2/E$
Ditto, circular section.....	$\frac{1}{8}S^2/E$	Flat spiral, rect. section.	$\frac{1}{24}S^2/E$
Concentrated center load; rectangular cross-section..	$\frac{1}{18}S^2/E$	Helical: axial load, circular wire................	$\frac{1}{4}S_s^2/G$
Ditto, circular cross-section.	$\frac{1}{24}S^2/E$	Ditto, axial twist........	$\frac{1}{8}S^2/E$
Uniform load, rectangular cross-section.............	$\frac{4}{45}S^2/E$	Ditto, axial twist, rect. section................	$\frac{1}{6}S^2/E$
I-beam section, concentrated center load.........	$\frac{3}{32}S^2/E$		

Unit Rupture-work, U_R, sometimes called **ultimate resilience,** is measured by the area of the stress-deformation diagram to rupture, $0PYMRR'$ (Fig. 11). For steel

$$U_R = \tfrac{1}{3}e_u(S_y + 2S_M), \text{ approximately}$$

For structural steel, for instance, $U_R = \frac{1}{3} \times \frac{27}{100} \times [35{,}000 + (2 \times 60{,}000)] = 13{,}950$ in.-lb. per cu. in.

Example 1. A load $P = 40{,}000$ (lb.) compresses a wooden block of cross-sectional area $A = 10$ (sq. in.) and length $= 10$ (in.), an amount $e = \frac{5}{100}$ (in.). Stress $S = \frac{1}{10} \times 40{,}000 = 4000$ (lb. per sq. in.). Unit elongation $s = \frac{5}{100} \div 10 = \frac{1}{250}$ (abstract number). Modulus of elasticity $E = 4000 \div \frac{1}{250} = 1{,}000{,}000$ (lb. per sq. in.). Unit resilience $U_p = \frac{1}{2} \times 4000 \times 4000/1{,}000{,}000 = 8$ (in.-lb. per cu. in.)

Example 2. A weight $G = 5000$ (lb.) falls through a height $h = 2$ (ft.); V = number of cubic inches required to absorb the shock without exceeding a stress of 4000 (lb. per sq. in.). Neglect compression of block. Work done by falling weight $= Gh = 5000 \times 2 \times 12$ (in.-lb.). Resilience of block $= V \times 8$ (in.-lb.) $= 5000 \times 2 \times 12$. Therefore, $V = 15{,}000$ (cu. in.).

MATERIAL STRESSED BEYOND THE ELASTIC LIMIT

Beyond the elastic limit in tension S_p (Fig. 13), ductile materials like steel enter a semi-plastic stage. The material stretches at Y without increase of stress, and the scale beam of the testing machine "drops" and the hard mill scale falls from bar. Steel shows both S_p and S_y; cast iron, S_y but no S_p; wood and hardened steel, S_p, but no S_y.

The shape of the diagram from S_p to S_y depends upon *speed of stress* (Fig. 11). After L, semi-plastic and semi-elastic deformations proceed. One or several contractions of cross-section occur, depending upon homogeneity of metal. The **maximum load** is reached at M (Fig. 11), when the metal at one of these contractions begins to flow. The contraction or "neck" proceeds until bar ruptures at R. The character of the metal changes under this excessive deformation, and therefore the actual stress on the ruptured section is not of practical importance, and is not observed.

Ultimate Strength S_M = maximum load divided by original area. **Per cent. of ultimate elongation** $e'_u = (l' - l)100/l$. **Per cent. of contraction** $c'_u = (A - A')100/A$. Here l and l' are original and deformed lengths, and A and A' are original and deformed areas, respectively. In testing wire, it is common to measure the elongation just before rupture. On account of elasticity the latter is notably greater than elongation after rupture. If the load is released at intervals to observe the set, a **set curve** may be constructed (Fig. 13).

The Character of the Fracture Under Tension indicates quality of material, but is influenced by the speed and the method of producing fracture, and by the shape of the test piece. A metal that is tough and fibrous may appear crystalline if broken quickly at a nicked section. Contraction is greatest in tough and ductile, and least in brittle, materials. The **shape** of fracture is usually a central flat surface of failure in tension, surrounded by a rim on which the metal shears. The extent of the rim is more pronounced when the ratio of shearing to tensile strength is less; is more developed in soft steels; becomes a complete cone in very soft materials; and vanishes in cast iron. The color, grain and shear of the fracture are significant. **Forms of fracture** are shown in Fig. 16. Terms describing fracture are: silky, dull, granular, crystalline, fibrous.

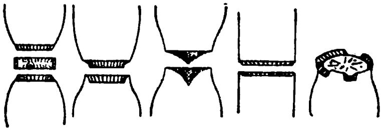

FIG. 16.—Typical Metal Fractures in Tension.

Failure Under Compression (Fig. 17) depends on material, slenderness of specimen, and restraint at ends or sides. **Short blocks of brittle materials** in compression like cast iron, stone, cement, when unconfined at the sides, fail by sliding along inclined planes. The angle of these planes is a function of the shearing stress and of the coefficient of friction of the material. Internal cones with their bases at the pressure heads of the testing machines, and pyramids, form in cylindrical and rectangular specimens, respectively.

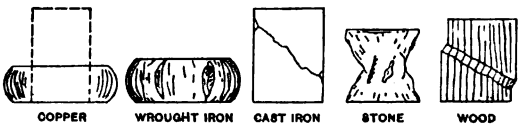

FIG. 17.—Typical Compression Fractures.

Ductile or Soft Materials, like lead, copper and soft steel, cannot be ruptured in compression. They bulge, increase in diameter under increasing stress, and finally become plastic at the **stress of fluidity**. Unwin quotes following values for **pressure of fluidity** in lb. per sq. in.: Mild steel, 112,000; copper, 54,000; lead, 1700. Experiments by Hatt give 76,000 for wrought iron.

The available strength in compression of short blocks **of materials of medium ductility**, like steel or wrought iron, is generally to be taken as the **yield point** of the material. The strength of longer columns depends on the ratio of length to diameter of specimen. The compressive strength of stone and concrete is about 10 times the tensile strength. Fracture forms for several materials in compression are shown in Fig. 17.

Permanent Deformation of metals beyond the elastic limit is accompanied by an increased hardness, an **increased strength** and a **decreased ductility.**

If steel is strained to or beyond the yield point, unloaded, and again immediately loaded, (*a*) the ultimate elongation is diminished, and the ultimate strength increased; and (*b*) the elastic limit is lowered, sometimes to zero, and the modulus of elasticity is diminished, there no longer being a rectilinear relation between stress and strain; and (*c*) the yield point is raised to a stress corresponding to the previous load. If, after the first loading, a period of quiescence is allowed before the second loading, (*a*) the elastic limit will rise above its original value, and (*b*) the yield point rises gradually above the stress corresponding to the previous load. The recovery of the elastic limit, reduced by overstrain, can be hastened by heating the bar for 3 to 4 min. in boiling water. Annealing an overstrained bar at 750 deg. cent., restores its original properties.

The primitive elastic limit of steel observed under first loading, is a limit artificially raised by processes of manufacture. By applying reversals of stress from tension to compression, and *vice versa*, through a range of stress less than the primitive elastic limit, a new and lowered elastic limit in tension is established. There is a range of reversal of stress within which the material is perfectly elastic, and the limiting stress in this case has been called the **natural elastic limit.** This is evidence that this elastic range is the same range to which a bar can be subjected an indefinite number of times without breaking under fatigue. (Abstracted from Unwin.)

Fatigue and Repetitive Stress. Numerous researches by Wöhler, Spangenberg and Martens, Bauschinger and others have shown that when a metal is subjected to cycles of varying stress, not applied in impact but gradually, it breaks at loads varying from one-half to two-thirds the ultimate breaking strength. The greater the range through which the stress varies and the greater the number of repetitions, the lower is the breaking strength. Fig. 18, from Unwin's "Testing the Materials of Construction," illustrates the laws of fatigue. The shaded area represents the range of stress which, applied an indefinite number of times, will not cause failure. For instance, a range of reversed stress less than one-third the ultimate strength for soft steel and one-fourth for high carbon steel will not cause failure when applied an unlimited number of times. An unlimited number of repetitions of a range of stress in tension from *nd* to *ne* will not cause failure. *am* = reversal limit of stress. Two cases arise: 1. The stress is repetitive, of same sign. 2. The stress varies from compression to tension, a reversal of stress.

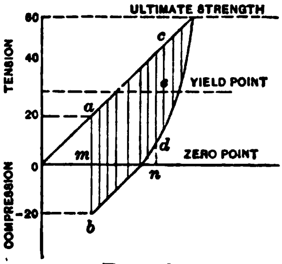

FIG. 18.

Gerber's Formula is an expression of experimental laws. Let S_R = the range of stress = $S_{max} \mp S_{min}$. The upper sign is taken when the stresses are of same sign; and the lower where they are of different sign. Let S_M = statical breaking strength. Then

$$S_{max} = \tfrac{1}{2} S_R + \sqrt{S_M^2 - nS_RS_M}$$

where n is a constant for a given material, ranging from 1.5 in ductile iron and steel to 2 in harder qualities. This equation fixes the maximum strength S_{max} against unlimited repetition when the range of stress S_R and the statical strength S_M are known.

Bars breaking under repetitive and reversed stresses exhibit no ductility. Microscopic examination shows that slippage along the cleavage planes of the crystalline constituents of the metal under repetitive stress ultimately develops into a crack.

STRENGTH OF MATERIALS

Technical Qualities of Materials may be grouped as: **Technological,** having to do with manufacturing requirements, such as malleability, fusibility, forgeability, bending to shape; **physical,** such as specific gravity, homogeneity, structural characteristics; **mechanical** properties examined in tests. The latter, together with criteria commonly used, are as follows:

QUALITY	SERVICE	CRITERIA	EXAMPLE
Strength.	To carry dead load.	Ultimate strength.	Piano wire.
Elasticity.	To undergo deformation and return to shape.	Amount of deformation.	Rubber.
Resilience.	To absorb shock without permanent deformation.	Modulus of resilience.	Hickory.
Stiffness.	To carry load without deformation.	Modulus of elasticity.	Steel.
Hardness.	To (a) withstand wear; (b) to resist penetration.	Scratch test; abrasion test; ball test.	Manganese steel.
Toughness.	Various conceptions; to endure large permanent deformations; to withstand large energy without rupture.	Various.	Rivet steel, hickory.
Endurance.	To withstand repetition of stress and small shocks.	....	Vanadium steel.

General Strength Values. The following tables exhibit the general range of values to be expected in various materials when subjected to various kinds of loading. For more detailed data, see Section 6.

Table 2. Tensile Strength of Iron and Steel*
(Range of Averages)

Material	Specific gravity	Ultimate strength, lb. per sq. in.	Elastic limit, lb. per sq. in.	Yield point, lb. per sq. in.	Ultimate elongation, per cent.	Modulus of elasticity, 1000 lb. per sq. in.
Cast iron	7.207					
Gray iron		15,000–18,000	5,000–6,000		0.1–1.0 in 2 in.	12,000 14,000
Better grade		20,000–30,000	10,000–24,000			
Malleable cast iron		25,000–48,000	12,000–22,000	12,500–19,000	1.0–3.0 in 2 in.	
Wrought iron	7.78	42,000–52,000	21,000–26,000	28,000–34,000	22.0–30.0 in 8 in.	26,000 29,000
Steel						
Extra soft		45,000–55,000	22,500–27,500	30,000–33,000	27.0–33.0 in 8 in.	
Soft (C.–0.08–0.15)	7.833	50,000–60,000	25,000–30,000		25.0–30.0 in 8 in.	
Medium (C.–0.15–0.30)		60,000–70,000	30,000–35,000	37,000–44,000	22.0–25.0 in 8 in.	
Hard (C.–0.30 up)		70,000–80,000	35,000–40,000	38,000–45,000	18.0–22.0 in 8 in.	
Rail (C.–0.55–0.75)		101,000–115,000	50,000–57,000	50,000–57,000	12.0–15.0 in 2 in.	
Ingot iron (C.–0.01–0.15)		42,000–60,000			18.0–36.0 in 8 in.	Modulus of elasticity of all steels varies from 28,000,000 to 31,000,000; average, 30,000,000.
Steel castings	7.917					
Soft		60,000–72,000	30,000–35,000	40,000–46,000	22.0–up in 2 in.	
Medium		72,000–78,000	36,000–39,000		16.0–22.0 in 2 in.	
Hard		78,000 up	39,000 up		12.0–16.0 in 2 in.	
Steel forgings		75,000–90,000	37,000–45,000		22.0–24.0 in 2 in.	
Spring steel						
Untempered		101,000–135,000	50,000–67,000		3.0–6.5 in 8 in.	
Tempered		130,000–200,000	110,000–170,000		0.5–2.1 in 8 in.	
Nickel steel						
Structural (3.5 per cent. N)		100,000–120,000	50,000–60,000	58,000–70,000	16.0–20.0 in 8 in.	
Forging (annealed)		80,000	40,000		30.0 in 2 in.	
Forging (oil-tempered)		98,000	75,000		25.0 in 2 in.	
Vanadium steel						
Annealed		54,000–96,000	27,000–48,000		22.0–24.0 in 2 in.	
Oil-tempered		125,000–232,000	100,000–180,000		11.0–21.0 in 2 in.	

* OTHER STRENGTH FUNCTIONS. Compressive strength of cast iron = 6 × T. S. (Tensile Strength). Compressive strength of wrought iron and steel to be taken as the yield point. Shearing strength of cast iron = 1.10 × T. S.; of wrought iron = 0.85 × T. S.; of hard and soft steels = 0.75 × T. S. Bending strength or modulus of rupture of cast iron = 2 × T. S.; of wrought iron = T. S.; of steel, to be taken as the yield point. Coefficient of expansion for change of 1 deg. fahr. is 0.0000065 for steel; and 0.0000062 for cast iron.

Table 3. Mechanical Properties of Non-ferrous Metals and Their Alloys
(Range of Averages)

Metal	Specific gravity	Tensile elastic limit, lb. per sq. in.	Tensile ultimate strength, lb. per sq. in.	Tensile modulus of elasticity, in 1000 lb. per sq. in.	Compressive strength, lb. per sq. in.
Copper, cast*	8.6–8.9	11,000–15,000	22,000–28,000	10,000–15,000	39,000–48,000

Sand-lime	1.85	3,500	1,000,000	1/10	....	....
Brick masonry						
In lime mortar		0.14 × compressive strength of brick				
In cement mortar		0.23 × compressive strength of brick				

* OTHER STRENGTH FUNCTIONS. Shearing strength of brick and stone is from 10 to 20 per cent. of the compressive strength; tensile strength is 4 per cent. of compressive strength; modulus of rupture is 15 per cent. of compressive strength. Poisson's ratio is ¼.

Tensile Strength of Wire depends upon its diameter. The ultimate strength in lb. per sq. in. $= S_M = (c/d) + S_0$, for any diameter d in in. (for diameters not less than 0.01 in.) where S_0 represents the ultimate strength ($d = \infty$) and c is a constant for each material.

Table 5. Tensile Strength of Wire
(Values of c and S_0)

Kind of wire	Not annealed		Annealed	
	c	S_0 lb. per sq. in.	c	S_0 lb. per sq. in.
Best iron wire	894	90,600	213	47,080
Ordinary iron wire	1282	65,140	358	40,820
Steel wire	1495	90,600	213	81,500
Zinc wire	123	18,060	.....	.....
Copper wire	538	49,790	.....	33,570
Brass wire	571	77,940	392	40,820
Hard lead wire	.....	3,130	.....	.....
Soft lead wire	.....	2,420	.....	.....
Platinum wire	678	31,720	538	26,310
Bronze wire	1041	71,540	.....	.....

For average values of the tensile strength, see Section 6. Allowable stresses are ¼ to ⅙ the ultimate stress.

Relation Between Tensile Strength and Elongation. Tetmajer's criterion for a good quality of steel is: The product of percentage elongation and tensile strength in lb. per sq. in., equals a constant varying from 1,000,000 to 1,500,000.

Standard Tests and Test Pieces

Forms of Test Bars. In addition to those shown in Fig. 19 and on pp. 506 and 508, the following are recommended by the American Society for Testing Materials. **Compressive test of metals:** Specimen 1 in. in diameter and from 2.5 to 4 diameters high. **Transverse test of metals:** For cast metals a specimen 1¼ in. in diameter, long enough to furnish a span of at least 15 times the diameter, cast on end, and not machined before testing.

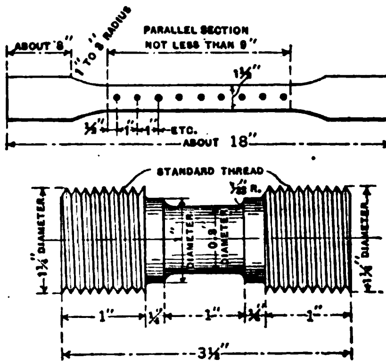

FIG. 19.—Dimensions of Standard Tension Test Pieces.

Impact Tests on notched bars, to detect **brittleness,** are favored abroad. The test piece used is a bar 30 mm. by 30 mm. in cross-section and 160 mm. long, with a notch at center of lower face 15 mm. deep, having a radius at bottom of 2 mm.; bar is tested on a 120-mm. span. Striking edge of hammer to be rounded to radius of 2 mm. Rupture to be effected by a single blow.

In the ordinary commercial tensile test the speed of application of load will not affect the results appreciably when the test ranges between 1 and 6 minutes.

The relation between strength, elongation and shape of tension test bar is expressed by **Barba's law of proportionality** thus: Test bars that are geometrically similar deform similarly and yield equal unit strengths and percentages of elongation and contraction. Thus, for cylindrical test bars the ratio of gage length to diameter is constant for similar bars; in plate specimens the ratio of gage length to square root of cross-sectional area is constant.

The change in elastic limit and other properties with a change in length of stem of test piece is shown in the following table. (See also p. 468.) The material was from the same bar in all cases, and the stem was turned to a uniform diameter of 0.798 in. (Jas. E. Howard, Engg. Congress, 1893, Sec. G.)

Description of stem	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.	Contraction of area, per cent.
1.00 in. long	64,900	94,400	49.0
0.50 in. long	65,320	97,800	43.4
0.25 in. long	68,000	102,420	39.6
Semicircular groove, 0.4 in. radius	75,000	116,380	31.6
Semicircular groove, ⅛ in. radius	86,000 (about)	134,960	23.0
V-shaped groove	90,000 (about)	117,000	Indeterminate

To obtain ductility in case bar breaks outside the middle third for an 8-in. gage, or outside gage for a 2-in. gage, a new test bar may be substituted. To calculate the *approximate* percentage of elongation when fracture is outside the middle third, assume that the ductility is symmetrical on both sides of fracture.

Hardness Tests. Hardness as resistance to permanent distortion is best measured by the Brinell ball test, in which a hardened-steel sphere 1 cm. in diameter is pressed into the surface of the material. Brinell's hardness number is the quotient of the p essure (3000 kg. for hard metals and 500 kg. for soft metals) and the area of surface of indentation. Thus N = hardness number, P = pressure, t = depth of impression, R' = radius of curvature of indentation. $N = P/2\pi tR'$.

Since the relation between load P and depth of impression t is constant for any one metal, Martens suggests the ratio of P/t as a measure of hardness; and the **hardness number** as the load P in kg. necessary to indent the material an amount t equal to 0.05 mm. Devries (*Proc. Am. Soc. Test. Mat.*, 1911, p. 725) gives the following values (Table 6):

Table 6. Hardness Numbers of Metals

Metal	Shore scleroscope	Brinell test $\frac{P}{2\pi tR'}$	Brinell test $\frac{P}{t}$
High-carbon steel	86.1	641.0	4550
Manganese steel	29.5	179.0	641
Cast iron (1)	33.3	149.0	538
Cast iron (2)	32.9	172.3	590
Bessemer steel	26.6	188.0	428
Tool steel	37.8	289.0	1230
Copper	15.0	89.5	235

A fairly close **relation** exists **between** the **hardness number and** the **ultimate tensile strength** of metals. Thus, Devries (Int. Soc. Test. Mat. Congress, 1912) gives results for alloy steels as follows: Tensile strength, S_M (lb. per sq. in.) = 20,000 + (hardness number × 103), in which the hardness

Table 7. Allowable Unit Stresses and Loads
(In Accordance with the Building Laws of Various Cities)

Allowable unit stresses for steel and iron	Revised to 1912			
	New York	Chicago	Philadelphia	Boston
	Lb. per sq. in.			
Compression: Rolled steel, mild	16,000	14,000	14,500	....

Columns: Mild steel	$15{,}200-58\frac{L}{R}$	$16{,}000-70\frac{L}{R}$	$\frac{14{,}500}{1+\frac{L^2}{13{,}500R^2}}$	$\frac{16{,}000}{1+\frac{L^2}{30{,}000\,R^2}}$
Medium steel	$15{,}200-58\frac{L}{R}$	$16{,}000-70\frac{L}{R}$	$\frac{16{,}250}{1+\frac{L^2}{11{,}000R^2}}$	$\frac{16{,}000}{1+\frac{L^2}{30{,}000\,R^2}}$
Wrought iron	$14{,}000-80\frac{L}{R}$	$12{,}000-60\frac{L}{R}$	$\frac{12{,}500}{1+\frac{L^2}{15{,}000R^2}}$	$\frac{12{,}000}{1+\frac{L^2}{20{,}000\,R^2}}$
Cast iron	$11{,}300-30\frac{L}{R}$	$10{,}000-40\frac{L}{R}$	$\frac{11{,}700}{1+\frac{L^2}{400D^2}}$	....

L = Length of column, R = length of radius of gyration, D = diameter of column, all in inches.

number is the load P (in kg.) required to indent the material to a depth of 0.1 mm.

The **Shore scleroscope** is used to indicate hardness by the rebound of a steel ball from the surface of a metal. The elasticity of the material enters into this rebound, which may be the same for a copper-tin alloy and tool steel. For any one class of material, however, the indications for hardness agree with those obtained in the Brinell tests.

Ability to resist **abrasion** involves toughness as well as hardness and cohesion, and is not necessarily indicated by the hardness number.

WORKING STRESSES

Allowable unit stresses for steel structures according to the building laws of various cities are given in Table 7. For the stresses recommended by the American Bridge Co., see p. 1285.

Working Stresses for Machine Parts, according to Bach, are given in Table 8. For stresses varying frequently but without shock from zero to a maximum, use two-thirds the tabulated working stresses. For stresses varying frequently but without shock from a negative maximum to an equal positive maximum, use one-third of the tabulated working stresses.

Table 8. Working Stresses for Machine Parts, Lb. per Sq. In.
(Dead Load)

Kind of stress	Tension S_t	Compression	Bending S_r	Shear	Torsion S
Wrought iron*	12,800	12,800	12,800	10,200	5,100
Low-carbon steel†	12,800 to 17,000	12,800 to 17,000	12,800 to 17,100	10,200 to 13,600	8,500 to 12,000
Medium-carbon steel†	17,000 to 21,300	17,000 to 21,300	17,100 to 21,300	13,600 to 17,100	12,800 to 17,100
Cast steel	8,500 to 12,800	12,800 to 17,000	10,600 to 15,000	6,800 to 12,000	6,900 to 12,000
Cast iron	4,300	12,800	‡	4,300	§
Rolled sheet copper	8,500**	....	....	....	....

(For varying load and shock, see p. 390.)

* When resulting changes in dimensions are not otherwise objectionable, for good wrought iron these values may be increased ⅓.

† Higher values are applicable only for absolutely reliable material. For wire the allowable tensile strength may be increased ⅙ to ⅓. Greater stress is allowable in special steels.

‡ For malleable cast iron the allowable stress in bending $S_r = nS_t\sqrt{e/z_0}$, where $n = 1.2$ to 1.33, S_t is the allowable tensile strength, e is the distance from the neutral axis to the extreme fiber in tension and z_0 is the distance from the neutral axis to the center of gravity of the area subjected to tension. Tests on various sections give the following: Rectangular, $S_r = 1.7S_t$; circular, $S_r = 2.05S_t$; I-sections, $S_r = 1.45S_t$. For plain cast iron these become: Rectangular, $S_r = 1.4S_t$, circular, $S_r = 1.7S_t$, and I-sections, $S_r = 1.2S_t$.

§ For malleable cast iron the allowable torsional shear for the various sections is as follows: Circular, $S =$ (amply) S_t; hollow circular and elliptical, $S = 0.8$ to 1.0 S_t; elliptical, $S = 1.0$ to 1.25 S_t; rectangular, $S = 1.4$ S_t; triangular and trapezoidal, $S = 1.4$ to 1.6 S_t; hollow rectangular, $S = 1.0$ to 1.25 S_t; I-, channel, cruciform and angle sections, $S = 1.4$ to 1.6 S_t. The influence of the hardened surface of the casting is less here than in bending.

** Air chambers of large fire engines, $S_t \leq 11{,}400$. For centrifugal machinery, $S_t = 7100$.

Hardened spring steel for bending: $S_r = 106{,}000$ and torsional shear $= 85{,}300$. **Special steel for cylindrical helical springs:** $S_r = 142{,}200$, and torsional shear $= 92{,}500$.

Factors of Safety for various materials and methods of loading, according to Unwin, are given in Table 9.

Table 9. Factors of Safety for Different Materials and Loadings

Material	Factors of safety for			
	Dead load	Live or varying load		Structures subject to shock
		Stress of one kind	Reversed stress	
Cast iron	4	6	10	15
Wrought iron and steel	3	5	8	12
Timber	7	10	15	20

IMPACT ON BARS

A static load is one at rest. **Dynamic loads** arise from impact. A **suddenly applied load** arises when a load that is just touching a bar is suddenly released. The velocity of approach is zero, the load is constant throughout the entire deformation, and the internal force in the bar increases from zero to some value AS. The stresses and deformations are double those due to an equal static load. G = weight producing a suddenly applied load. e = maximum elongation. P = internal force accompanying e. Work of weight Ge equals internal resilience $\frac{1}{2}Pe$. Therefore $P = 2G$. The bar springs back and oscillates.

An **impact loading** occurs when a moving weight strikes the end of a bar. The velocity of impact is v. If the elastic limit is not exceeded, the external work of the moving weight falling from height h equals Gh, and also equals the resilience developed. P, S, and e are respectively dynamic force, stress and elongation in bar. $G(h + e) = \frac{1}{2}Pe$. Let e' and S' be the elongation and stress which would accompany G if it acted as a static load. $G/e' = P/e$. Then

$$S = S' + S'[1 + (2h/e')]^{\frac{1}{2}}$$
$$e = e' + e'[1 + (2h/e')]^{\frac{1}{2}}$$

The value of e' is small, and dynamic stresses and deformations are usually large and may exceed the elastic limit. It is here assumed that the entire energy of the weight produces elastic deformation in the bar only, that is, that the supports are rigid and there is no friction.

Materials show a higher elastic limit of deformation under impact than under static loads. E appears to be unchanged (*Proc. Roy. Soc.*, Feb., 1905).

As on axial bars, **impact on beams** causes severe dynamic stresses. A weight W falling from height h on the center of a simple beam, produces a maximum dynamic deflection f, and a dynamic fiber stress S. Let f' and S' be the deflection and stress caused by W acting as a static load. By similar reasoning,

$$S = S' + S'[1 + (2h/f')]^{\frac{1}{2}} \quad (1)$$
$$f = f' + f'[1 + (2h/f')]^{\frac{1}{2}} \quad (2)$$

W must be large compared to the weight of the beam; otherwise, on account of inertia of beam, the energy will be used in local damage. Supports are rigid, and there is no friction.

The Effect of Inertia may be computed by the laws of collision of bodies. Assume impact **entirely inelastic.** nWh is the fractional part of the energy producing elastic deformation in the beam or bar. W' = weight of beam or bar; W = weight of falling body; $m = W'/W$.

For **longitudinal impact** on a bar, $n = (1 + \frac{1}{3}m)/(1 + \frac{1}{2}m)^2$.

For **center impact** on a simple beam, $n = (1 + \frac{17}{35}m)/(1 + \frac{5}{8}m)^2$. If beam is fixed at the ends, use $\frac{13}{35}$ instead of $\frac{17}{35}$ and $\frac{1}{2}$ instead of $\frac{5}{8}$. For a cantilever struck at the end, use $\frac{33}{140}$ instead of $\frac{17}{35}$, and $\frac{3}{8}$ instead of $\frac{5}{8}$. **To compute stresses and deflections,** the value of h in (1) and (2) should be multiplied by n.

COMBINED STRESSES

The stresses treated here are *in one plane.* N is the unit normal stress, T the unit tangential stress on an internal inclined plane, S the unit stress on a plane normal to the geometric axis, P the external force, and R the resultant unit stress.

Stresses acting on different planes cannot be resolved or compounded like forces. The area upon which the stress acts must appear in the equation.

The resultant of several stresses acting together **on the same plane** is the geometric sum of their individual actions

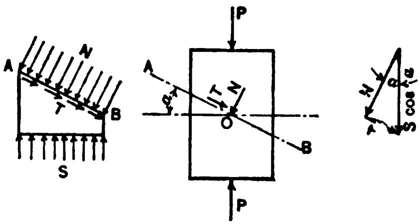

FIG. 20.

Case I. Force Along One Axis (Fig. 20). The force P acts alone. The resultant stress on diagonal plane AB is resolved into a **normal stress** N, and a **tangential stress** T.

$$N = S\cos^2 a \qquad T = S\sin a\cos a$$

The maximum value of T equals $\frac{1}{2}S$ when a equals 45 deg. The stresses on the diagonal plane CD (see Fig. 21) when $a + a' = \pi/2$, are $N' = S\sin^2 a$ and $T' = S\sin a\cos a$.

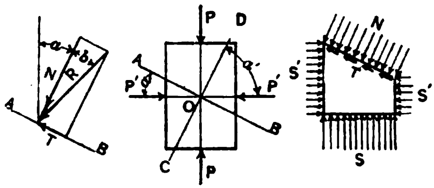

FIG. 21.

Case II. Forces Along Two Right-angled Axes (Fig. 21). Here the forces P and P' act.

$$N = S\cos^2 a + S'\sin^2 a \qquad (1)$$

$$T = (S - S')\sin a\cos a \qquad (2)$$

$N_{max} = S$ or S' and $T_{max} = \frac{1}{2}(S - S')$ when $a = 45$ deg. If $a + a' = 90$ deg., $N + N' = S + S'$ and $T = T'$. The **resultant stress** R is the resultant of N and T. $R = \sqrt{N^2 + T^2}$. The direction angle of R is b, where $\sin b = \sin 2a\,(S - S')/2R$.

Special Cases under Case II. (*a*) If $+S = +S'$ (Fig. 22), $T = 0$, $R = S = S'$, and direction of R is normal. (*b*) If $+S = -S'$ (Fig. 23), $R = S = S'$, and direction angle of $R = 2a$. S bisects the angle nOr.

Example. The metal in a steam boiler is subjected to a unit stress of 8000 lb. per sq. in. in a circumferential direction, and 4000 lb. per sq. in. in a longitudinal direction. Find the stresses on a plane the normal to which makes an angle of 30 deg. with the direction of the 8000-lb. stress. From (1) and (2)

Normal stress $N = 8000 \cos^2 30° + 4000 \sin^2 30° = 7000$ lb. per sq. in.
Tangential stress $T = (8000 - 4000) \sin 30° \cos 30° = 1730$ lb. per sq. in.
Resultant stress $R = \sqrt{7000^2 + 1730^2} = 7210$ lb. per sq. in.

Sin $b = \sin (2 \times 30°) (8000 - 4000)/(2 \times 7210) = 0.24023$, whence angle b, or the direction angle of R, is 13° 54′. For graphical solution, see Fig. 24.

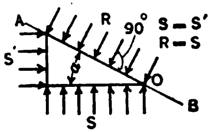

FIG. 22.

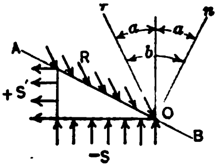

FIG. 23.

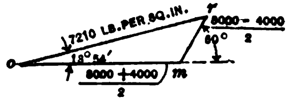

FIG. 24.

A block (Fig. 25) is acted upon by three pairs of normal stresses S_x, S_y, and S_z. The deformation e_x along axis X is due to S_x modified by the lateral effects of S_y and S_z (see p. 376). When the stresses are all of the same sign, $e_x = (S_x/E) - [(S_y + S_z)/nE]$, where n = reciprocal of Poisson's ratio, whence

$$Ee_x = S_x - [(S_y + S_z)/n]$$
$$Ee_y = S_y - [(S_x + S_z)/n]$$
$$Ee_z = S_z - [(S_x + S_y)/n]$$

When the stresses are of different sign, corresponding changes occur in the formulæ. The product Ee is regarded as a stress. The **apparent stress** is S, but the **true stress** $T = Ee$.

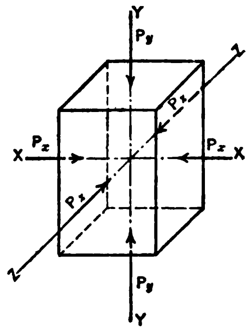

FIG. 25.

Elastic Strength Under Compound Stress is fixed, by three separate theories, as a certain value of either (*a*) the maximum principal apparent stress; (*b*) the true stress accompanying maximum principal deformation; or (*c*) the maximum shearing stress.

For example, metal in a boiler shell is under a hoop tension S_x and a longitudinal tension $S_y = \frac{1}{2}S_x$. According to (*a*), metal will begin to fail when S_x equals the elastic limit of the metal, regardless of the presence of S_y. According to (*b*), the necessary stress at failure is the true stress $T_x = Ee_x = S_x - S_x/n$. When $n = 3$, $T_x = \frac{5}{6}S_x$. That is, a hoop tension one-fifth greater than the elastic limit under simple stress, as shown in a testing machine, is required to cause failure. This method (*b*) is commonly used. According to (*c*), failure will begin when shearing stress $= \frac{1}{2}(S_x - S_y)$ is reached. Recent researches (1904–1908) by Hancock, Guest and Coker point to truth of theory (*c*). This discussion is for elastic stresses and must not be extended to ultimate strength.

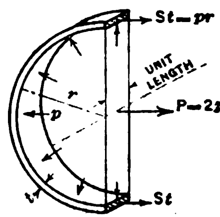

FIG. 26.

CYLINDERS AND SPHERES; TUBES

Thin Cylinders. In a thin envelope or ring (Fig. 26) subjected to an internal unit pressure p, the force of tension in ring P (hoop tension) in a unit length is constant and equal to pr. The uniform tensile stress S in the ring equals pr/t, or $t = pr/S$. An increase in t must be made to compensate for rivet holes in joints.

A portion of any circular curved ring under normal pressure carries a force $P = pr$. Internal pressure yields tension; external pressure yields compression.

If the **cylinder** is **closed at its ends**, a longitudinal stress S' acts. $S' = \frac{1}{2}rp/t = \frac{1}{2}S$. When $n = 3$ (see Poisson's ratio) the true stress $T = S - \frac{1}{3}S' = \frac{5}{6}S$.

Collapsing Pressure of Tubes. Tubes under external load may collapse. The following notation is used in the various formulæ given for collapsing pressure:

P = collapsing pressure, lb. per sq. in.
E = modulus of elasticity.
m = Poisson's ratio.
t = thickness of tube, in.
D = outside diam. of tube, in.
d = inside diam. of tube, in.
l = length of tube, in.

For collapsing pressure, where l is not greater than $6D$, **Fairbairn's empirical formula** (1858) is: $P = 9{,}672{,}000(t^{2.19}/lD)$, or, more simply, $P = 9{,}675{,}600(t^2/lD)$.

For **large iron pipe flues,** diameters 30 in. to 50 in., **D. K. Clark's formula** is: $P = 200{,}000\ t^2/D^{1.75}$.

In 1906, two series of experiments were made by Prof. Reid T. Stewart on Bessemer steel lap-welded tubes (see *Trans. A. S. M. E.*, vol. 27, p. 730). In one series the tubes tested were 8 5/8 in. in outside diameter and of varying thickness and length, while in the other series they were 20 ft. long and of varying thickness and diameter. The tests showed that **all** of the **old formulæ** were **inapplicable** to the wide range of conditions found **in modern practice.** Prof. Stewart found that the length of tube between transverse joints tending to hold it to a circular form, has no practical influence upon the collapsing pressure of a commercial lap-welded steel tube, so long as this length is not less than about six diameters of tube.

As based upon his researches, **Stewart's formulæ for** the **collapsing pressure of** modern **lap-welded Bessemer steel tubes** are as follows:

$$P = 1000[1 - \sqrt{1 - 1600(t^2/D^2)}] \qquad (a)$$
$$P = 86{,}670(t/D) - 1386 \qquad (b)$$

Formula (*a*) is for values of P less than 581 lb., or for values of (t/D) less than 0.023, while formula (*b*) is for values greater than these.

These formulæ are correct for tubes that are 20 ft. in length between transverse joints tending to hold them to a circular form, and at the same time are substantially correct for all lengths greater than about six diameters. They have been tested for seven diameters, ranging from 3 to 10 in., in all obtainable thicknesses of wall. The apparent fiber stress under which the different tubes failed varied from about 7000 lb. per sq. in. for the relatively thinnest to 35,000 lb. per sq. in. for the relatively thickest walls. Since the average yield point of the material was 37,000 and the tensile strength 58,000 lb. per sq. in., it would appear that the strength of a tube subjected to a collapsing fluid pressure is not dependent alone upon either the elastic limit or ultimate strength of the material constituting it. Prof. Stewart therefore suggests as a substitute for formula (*a*) the following:

$$P = 50{,}210{,}000(t/D)^3 \qquad (c)$$

The Experiments by Stewart are considered to be the most reliable.

Carman (University of Illinois Engineering Experiment Station *Bulletin* No. 5, June 1, 1906) states that the portion affected by collapse from hydraulic pressure is generally not greater in length than $12D$, that for greater lengths the collapsing pressure is independent of the length, and that the often-quoted law of Fairbairn type, in which the collapsing pressure varies inversely as the length, is only true for short tubes from $4D$ to $6D$ in length.

Carman's formulæ are as follows:

For thin cold-drawn seamless steel tubes: $P = 50{,}200{,}000\ (t/D)^3$.
For thin brass tubes: $P = 25{,}150{,}000\ (t/D)^3$.
For thick cold-drawn seamless steel tubes: $P = 95{,}520\ (t/D) - 2090$.
For thick lap-welded steel tubes: $P = 83{,}270\ (t/D) - 1025$.
For thick brass tubes: $P = 93{,}365\ (t/D) - 2474$.
Limits of (t/D) are below 0.025 for thin tubes and above 0.03 for thick tubes.
When (t/D) is less than 0.06, **Carman's approximate formulæ** are;
For cold-drawn seamless steel tubing, $P = 1{,}000{,}000(t/D)^2$.
For lap-welded steel, $P = 1{,}125{,}000(t/D)^2$.

These approximate formulæ are stated to give satisfactory rough values for tubes of the most common commercial thicknesses.

A. E. H. Love gives the following **rational formulæ**: $P = [2E/(1 - m^2)] \times (t/D)^3$ **for thin tubes,** and $P = 2S_c[(t/D) - (t/D)^2]$ (special case of Lamé's general formula—see below) **for thick tubes,** where S_c is the ultimate compressive strength (yield point) in lb. per sq. in. The average values of these constants for steel are: $E = 30{,}000{,}000$; $m = 0.295$; $S_c = 40{,}000$; and for brass: $E = 14{,}000{,}000$; $m = 0.357$; $S_c = 11{,}000$. Hence,

For thin steel tubes: $P = 65{,}720{,}000(t/D)^3$.
For thick steel tubes: $P = 80{,}000\,[(t/D) - (t/D)^2]$.
For thin brass tubes: $P = 32{,}090{,}000(t/D)^3$.
For thick brass tubes: $P = 22{,}000\,[(t/D) - (t/D)^2]$.

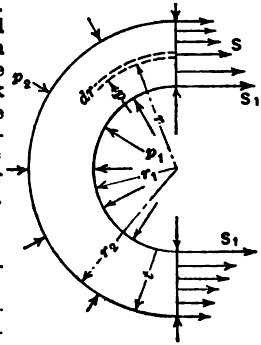

FIG. 27.

The **correction factor** for ellipticity and variation in thickness is $C = (D_{\min}/D_{\max})^3(t_{\min}/t_{\max})^3$. **Love's formula** becomes $P = [2CE/(1 - m^2)](t/D)^3$ **for thin tubes,** in which $C = 0.69$ for Stewart's lap-welded steel flues, t = average thickness and D = maximum outside diam., both in inches. **Lamé's formula** becomes $P = 2CS_c(t/D)[1 - C(t/D)^2]$ **for thick tubes,** in which $C = 0.8$.

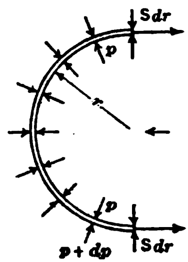

FIG. 28.

Hollow Sphere with normal pressure P. Pressure on meridian plane $= \pi r^2 P$. Tension or compression per lineal unit of shell $= \pi r^2 P/2\pi r = Pr/2$. Unit stress $S = Pr/2t$. The material carries an equal stress at right angles. True stress $T = S - (S/n) = Pr/3t$.

In thick cylinders (Fig. 27) **the stress is not uniformly distributed.** The hoop tension in the cylinder under internal pressure is greatest at the interior and diminishes toward the exterior. An interior hoop, from Fig. 27, is shown in Fig. 28. Cylinder unit pressure at bore $= p_1$. Radial internal compressive unit stress $= p$. External unit pressure $= p_2$. Hoop unit tension $= S$. Longitudinal unit stress $= S_L$.

In **Barlow's formula** it is assumed that the volume of the metal does not change during expansion of the cylinder. Therefore S varies inversely as the radius squared. $Sr^2 = S_1r_1^2$.

The total internal pressure $2r_1p_1 = 2\int Sdr$, or $p = S_1t/(r_1 + t)$.

In **Lamé's formula** the cylinder is assumed to stretch longitudinally so that cross-sections remain plane surfaces; the longitudinal deformation e_L is therefore constant. e_L is so connected with S and p that $Ee_L = S_L - [(S - p)/n]$. Therefore

$$S - p = \text{constant} = K \qquad (a)$$

Considering equilibrium of the internal hoop (Fig. 28),

$$2rp - [(r + dr)2(p \mp dp)] = 2Sdr, \text{ or}$$

$$d(pr)/dr = S \qquad (b)$$

Algebraic development of (a) and (b) leads to Lamé's formula

$$S = [r_1^2p_1 - r_2^2p_2 + (p_1 - p_2)r_1^2r_2^2/r^2]/(r_2^2 - r_1^2)$$

When $r = r_1$ and $p_2 = 0$, $S = S_1$ the hoop tension at the bore, or

$$S_1 = p_1(r_2^2 + r_1^2)/(r_2^2 - r_1^2) \qquad (1)$$

or

$$r_2 = r_1[(S_1 + p_1)/(S_1 - p_1)]^{1/2}$$

When $r = r_2$ and $p_2 = 0$, $S = S_2$ the hoop tension at exterior, or $S_2 = 2p_1r_1^2/(r_2^2 - r_1^2)$. If $r_2 = 2r_1$, $S_1 = 5p_1/3$ and $S_2 = 2/3 p_1$.

These stresses are apparent stresses. The true unit hoop stresses T are found by methods of p. 391.

Example. The variation of stresses in a numerical case is shown in Fig. 29 (from Morley's "Strength of Materials"). In a cylinder 6 in. in internal diam. with walls 2 in. thick, subjected to a pressure of 1000 lb. per sq. in. gage, the stresses [from (1)] would be $S_1 = 1000(5^2 + 3^2)/(5^2 - 3^2) = 2125$ lb. per sq. in.; and $S_2 = 2 \times 1000 \times 3^2/(5^2 - 3^2) = 1125$ lb. per sq. in.

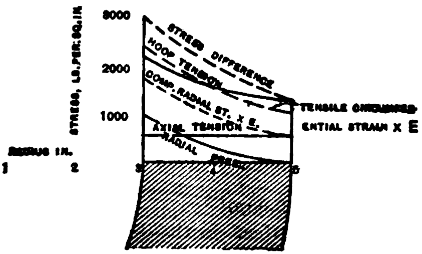

FIG. 29.

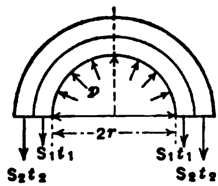

FIG. 30.

For **true stresses,** "Hütte" states that $r_2 = r_1[(T + 0.4p)/(T - 1.3p)]^{1/2}$, where T is the working tensile strength. When p is external this becomes $r_2 = r_1[T/(T - 1.7p)]^{1/2}$ when $p < T/1.7$ only. For the example just given, $T = 2256$ lb. per sq. in. is virtually the same as S_1 from Lamé's formula.

Thick Cylinders with Shrinkage Rings. In these it can be assumed that the stress under internal pressure is uniformly distributed over each ring, provided the ratio r/t is great.

Referring to Fig. 30, let t = sectional area (in sq. in.) of the cylinder for unit length in an axial direction; f = sectional area of the shrinkage rings per unit length of cylinder; S_1 = tensional hoop stress in hollow cylinder, lb. per sq. in.; S_2 = tensional hoop stress in shrinkage rings, lb. per sq. in.; p = interior pressure, lb. per sq. in., and r = interior radius of cylinder, in. Then

$$f = rp/[S_1(t/f) + S_2]$$

If the rings are shrunk on and R = outer radius of the inner cylinder; $R(1 - K)$ = inner radius of the rings before shrinking; $C_1 = 1/E_1$ for the inner cylinder; $C_2 = 1/E_2$ for the shrinkage rings; e_1 and e_2 = unit strains respectively in the inner cylinder and shrinkage rings when cold, then $K = e_1 + e_2 = C_2S_2 - C_1S_1$, and $e_1 = K/[1 + (C_2t/C_1f)]$.

The compressive stress in the cylinder before the pressure p is applied is $S' = e_1/C_1$; and the tensional stress in the shrinkage ring before the pressure p is applied is $S'' = e_2/C_2$. The pressure p causes a tensional stress of $S_1 + S'$ in the cylinder and of $S_2 - S''$ in the shrinkage rings.

The difference K found in this way is a minimum. This difference has to be increased, however, depending upon the condition of the surfaces of the cylinder and rings. If the rings are made of tough material K may be increased considerably, as the effect is only to produce permanent expansion in the rings, while the inner cylinder will be compressed, thereby diminishing its working tensional stress.

The difference in temperature when the rings are forced on should be $d = K/c_w$, where c_w is the coefficient of expansion of the shrinkage ring.

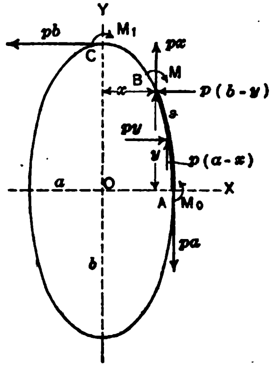

FIG. 31.

Oval Hollow Cylinders. In Fig. 31 let a and b be the semi-minor and semi-major axes. The bending moments at A and C will then be

$$M_0 = (pa^2/2) - (pI_x/2S) - (pI_y/2S)$$
$$M_1 = M_0 - p(a^2 - b^2)/2$$

where I_x and I_y are the moments of inertia of the arc AC about the x and y axes, respectively. The **bending moment at any point** will be

$$M = M_0 - (pa^2/2) + (px^2/2) + (py^2/2).$$

Thick Hollow Spheres. With an **internal pressure** p, where $p < T/0.65$,

$$r_2 = r_1[(T + 0.4p)/(T - 0.65p)]^{1/3}$$

The maximum tensile stress is on the inner surface, in the direction of the circumference. With an **external pressure** p, where $p < T/1.05$,

$$r_2 = r_1[T/(T - 1.05p)]^{1/3}$$

In both cases T is the true stress (see p. 392).

PRESSURE BETWEEN BODIES WITH CURVED SURFACES

Two Spheres. The radius A (in in.) of the compressed area is obtained from the formula $A^3 = 0.68P(c_1 + c_2)/[(1/r_1) + (1/r_2)]$, in which P is the compressing force in lb., c_1 and c_2 ($= 1/E_1$ and $1/E_2$) are reciprocals of the respective moduli of elasticity, and r_1 and r_2 are the radii in in. (Reciprocal of Poisson's ratio assumed to be $n = 10/3$.) The **greatest compressive stress** (lb. per sq. in.) in the middle of the compressed surface will be $S_{max} = 1.5(P/\pi A^2)$, and

$$S_{max}^3 = 0.235P[(1/r_1) + (1/r_2)]^2/(c_1 + c_2)^2$$

The **total deformation** of the two spheres (in in.) will be Y, which is obtained from

$$Y^3 = 0.46P^2(c_1 + c_2)^2[(1/r_1) + (1/r_2)]$$

For $c_1 = c_2 = 1/E$, *i.e.*, two spheres with the same modulus of elasticity, it follows that $A^3 = 1.36\,P/E[(1/r_1) + (1/r_2)]$, $S_{max}^3 = 0.059PE^2[(1/r_1) + (1/r_2)]^2$, and $Y^3 = 1.84P^2[(1/r_1) + (1/r_2)]/E^2$. If the radii of these spheres are also equal, $A^3 = 0.68Pr/E = 0.34Pd/E$; $S_{max}^3 = 0.235PE^2/r^4 = 0.94PE^2/d^2$; and $Y^3 = 3.68P^2/E^2r = 7.36P^2/E^2d$.

Sphere and Flat Plate. In this case $r_1 = r$ and $r_2 = \infty$, and the above formulæ become $A^3 = 0.68Pr(c_1 + c_2) = 1.36Pr/E$, and

$$S_{max}^3 = 0.235P/r^2(c_1 + c_2)^2 = 0.059PE^2/r^2$$

Also $$Y^3 = 0.46P^2(c_1 + c_2)^2/r = 1.84P^2/Er.$$

Two Cylinders. The width b (in in.) of the rectangular pressure surface is obtained from $(b/4)^2 = 0.29P(c_1 + c_2)/l[(1/r_1) + (1/r_2)]$, where r_1 and r_2 are the radii, and l the length, all in in.

$$S_{max}^2 = (4P/\pi bl)^2 = 0.35P[(1/r_1) + (1/r_2)]/l(c_1 + c_2)$$

For cylinders with the same moduli of elasticity, $c_1 = c_2 = 1/E$, and $(b/4)^2 = 0.58P/El[(1/r_1) + (1/r_2)]$; and $S_{max}^2 = 0.175PE[(1/r_1) + (1/r_2)]/l$. When $r_1 = r_2 = r$, $(b/4)^2 = 0.29Pr/El$, and $S_{max}^2 = 0.35PE/lr$.

Cylinder and Flat Plate. Here $r_1 = r$, $r_2 = \infty$, and the above formulæ reduce to $(b/4)^2 = 0.29Pr(c_1 + c_2)/l = 0.58Pr/El$, and

$$S_{max}^2 = 0.35P/lr(c_1 + c_2) = 0.175PE/lr$$

BEAMS

For Properties of Commercial Wooden Beams, see p. 1274.
For Properties of Structural Steel, see pp. 1288–1304.

Notation

R	= Reaction	S_v	= Vertical shearing unit stress
M	= Moment	Z	= Horizontal shearing unit stress
W	= Total distributed load	I	= Rectangular moment of inertia
w	= Unit load	I_p	= Polar moment of inertia
P	= Concentrated load	r	= Radius of curvature
V or Q	= Total vertical shear	i	= Slope
S	= Unit normal apparent stress	f	= Deflection

A **simple beam** is a bar resting on supports near its ends. A **cantilever beam** projects out beyond a support. To compute reactions and moments, a distributed load may be replaced by its resultant acting at the center of gravity (c. of g.) of the load area.

Simple Beams

The **reactions** (in lb.) at the support are computed by the principle of moments. Thus, in Fig. 32, $\frac{1}{2}Wl = R_1l$, or $R_1 = \frac{1}{2}W$; $R_2 = W - R_1 = \frac{1}{2}W$. In Fig. 33, $\frac{1}{3}Wl = R_1l$, or $R_1 = \frac{1}{3}W$; $R_2 = W - R_1 = \frac{2}{3}W$. In general, the weight of the beam must be considered.

The **external moment** (in ft.-lb. or in.-lb.) **at any section** is the algebraic sum of the moments of the external forces on one side only of the section, or $M = \Sigma\,(Px)$

Examples: Uniform Load (Fig. 32). $M_A = \Sigma\,(Px)$ to left of point A at which moment is to be found. $M_A = \frac{1}{2}Wx - (wx \times \frac{1}{2}x)$. **Uniformly Varying Load** (Fig. 33). (Weight of beam neglected.) $M = \Sigma(Px) = \frac{1}{3}Wx - \frac{1}{2}kwx^2\frac{1}{3}x$, where k is a constant $(= h/l)$ and w is the weight of the loading per unit of volume.

A **moment** that bends a beam convex downward is **positive** (+), and convex upward **is negative** (−).

The **external shear** V (in lb.) is the algebraic sum of the forces on one side only of the section, or $V = \Sigma P$. In Fig. 32, $V = \frac{1}{2}W - wx$. In Fig. 33, $V = \frac{1}{3}W - \frac{1}{2}kwx^2$.

The moment and shear may be expressed by an ordinate drawn to scale at the section of the beam under consideration. A **moment diagram** is a series of such ordinates throughout the beam showing the variation of moment. A **shear diagram** is similarly constructed. Table 10 shows moment and shear diagrams for common cases of flexure, and gives values of reactions (R), moments (M), shears (Q) and deflections (f).

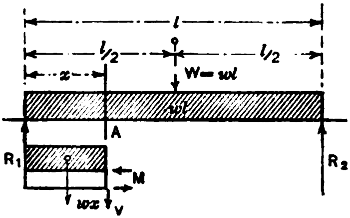

FIG. 32.

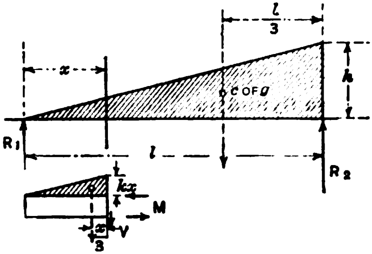

FIG. 33.

The external moment, M, is in equilibrium with the **internal moment** which is supplied by the stresses acting over the cross-section of the beam. The external shear is likewise in equilibrium with the internal shearing stresses.

* This table is convenient for wooden beams. For any other fiber stress, S', multiply the values in table by $S'/1000$. See p. 1274 for properties of wooden beams of commercial sizes.

Maximum Safe Load on Steel Beams. To obtain maximum safe load (or maximum deflection under maximum safe load) for any of the conditions of loading given in Table 12*b*, multiply the corresponding coefficient in that table by the greatest safe load (or deflection) for distributed load for the particular section under consideration as given in Table 12*a*.

Table 12a. Approximate Greatest Safe Loads in Pounds on Steel Beams

(Pencoyd Iron Works)

Allowable fiber stress for steel, 16,000 lb per sq. in. (basis of table); for iron, 14,000 per sq. in., *i.e.*, reduce values given in table by one-eighth. Beams supported at both ends.

L = Distance between supports in ft.
A = Sectional area of beam in sq. in.
D = Depth of beam in in.
a = Interior area in sq. in.
d = Interior depth in in.
w = Total working load in net tons.

Shape of section	Greatest safe load, pounds		Deflection, inches	
	Load in middle	Load distributed	Load in middle	Load distributed
Solid rectangle......	$\frac{890AD}{L}$	$\frac{1780AD}{L}$	$\frac{wL^3}{32AD^2}$	$\frac{wL^3}{52AD^2}$
Hollow rectangle...	$\frac{890(AD-ad)}{L}$	$\frac{1780(AD-ad)}{L}$	$\frac{wL^3}{32(AD^2-ad^2)}$	$\frac{wL^3}{52(AD^2-ad^2)}$
Solid cylinder.......	$\frac{667AD}{L}$	$\frac{1333AD}{L}$	$\frac{wL^3}{24AD^2}$	$\frac{wL^3}{38AD^2}$
Hollow cylinder.....	$\frac{667(AD-ad)}{L}$	$\frac{1333(AD-ad)}{L}$	$\frac{wL^3}{24(AD^2-ad^2)}$	$\frac{wL^3}{38(AD^2-ad^2)}$

Factors for Reducing Load When Beams Are Long in Comparison to Breadth. (Supported)

Ratio of unsupported (lateral) length in in. to flange width or breadth in in.........	20	30	40	50	60	70
Ratio of greatest safe load to calculated load	10:10	9:10	8:10	7:10	6:10	5:10

Table 12b. Coefficients for Correcting Values in Table 12a for Various Methods of Support and of Loading

Conditions of loading	Maximum relative safe load	Maximum relative deflection under max. relative safe load
Beam Supported at Ends		
Load uniformly distributed over span..........	1.0	1.0
Load concentrated at center of span...........	½	0.80
Two equal loads symmetrically concentrated....	$l/4c$	.....
Load increasing uniformly to one end..........	0.974	0.976
Load increasing uniformly to center...........	¾	0.96
Load decreasing uniformly to center...........	3/2	1.08
Beam Fixed at One End, Cantilever		
Load uniformly distributed over span..........	¼	2.40
Load concentrated at end......................	⅛	3.20
Load increasing uniformly to fixed end.........	⅜	1.92
Beam Continuous over Two Supports Equidistant from Ends		
Load uniformly distributed over span:		
1. If distance $a > 0.2071l$..................	$l^2/4a^2$	.....
2. If distance $a < 0.2071l$..................	$\frac{l}{l-4a}$	.....
3. If distance $a = 0.2071l$..................	5.83	.....
Two equal loads concentrated at ends..........	$l/4a$	.....

l = length of beam; c = distance from support to nearest concentrated load; a = distance from support to end of beam.

Theory of Flexure

A bent beam is shown in Fig. 34. The concave side is in compression and the convex side in tension. These are divided by the **neutral plane** of zero stress $A'B'BA$. The intersection of the neutral plane with the face of the beam is the **neutral line** or **elastic curve** AB. The intersection of the neutral plane with the cross-section is the **neutral axis** NN'.

It is assumed that a beam is prismatic, of a length at least 10 times its depth, and that the external forces are all at right angles to the axis of the beam and in a plane of symmetry, and that flexure is slight. Other assumptions are: (1) That the material is homogeneous, and obeys Hooke's law.

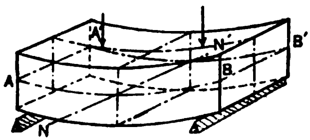

FIG. 34.

(2) That **stresses are within the elastic limit.** (3) That every layer of material is free to expand and contract longitudinally and laterally under stress as if separate from other layers. (4) That the tensile and compressive moduli of elasticity are equal. (5) That the cross-section remains a plane surface. (The assumption of plane cross-sections is only strictly true when the shear is constant or zero over the cross-section, and when the shear is constant throughout the length of the beam.)

It follows then that: (1) The internal forces are in horizontal balance. (2) The **neutral axis contains the center of gravity** of the cross-section. (3) The stress intensity varies directly with the distance from the neutral axis.

The moment of the elastic forces about the neutral axis, that is, the **internal stress-moment** or **moment of resistance,** is $M = SI/c$, where S is an elastic unit stress at outer fiber whose distance from the neutral axis is c; and I is the rectangular moment of inertia about the neutral axis.

$$M = SI/c$$

This formula is for the **strength of beams.** For rectangular beams, $M = \frac{1}{6}Sbh^2$, where b = breadth, and h = depth. That is, the elastic **strength of beam sections** varies as follows:

(*a*) For equal width, as the square of the depth. (*b*) For equal depth, directly as the width. (*c*) For equal depth and width, directly as the strength of the material. (*d*) If span varies, then for equal depth, width and material, inversely as the span.

If a beam is cut in halves horizontally, the two halves laid side by side will carry only one-half as much as the original beam.

The term **section modulus** is given to the value of I/c, where c is the distance to the fiber carrying greatest stress. Area of cross-section = A.

Tables 13, 14 and 15 give the properties of various beam cross-sections For properties of structural-steel shapes, see pp. 1288 to 1304.

Table 13. Properties of Various Beam Cross-sections

(I = Moment of inertia; I/c = section modulus; $r = \sqrt{I/A}$ = radius of gyration)

				$I =$	$\frac{bh^3}{12}$	$\frac{bh^3}{3}$	$\frac{b^3h^3}{6(b^2+h^2)}$	$\frac{bh}{12}(h^2\cos^2 a + b^2\sin^2 a)$
$\frac{I}{c} =$	$\frac{bh^2}{6}$	$\frac{bh^2}{3}$	$\frac{b^2h^2}{6\sqrt{b^2+h^2}}$	$\frac{bh}{6}\left(\frac{h^2\cos^2 a + b^2\sin^2 a}{h\cos a + b\sin a}\right)$
$r =$	$\frac{h}{\sqrt{12}} = 0.289h$	$\frac{h}{\sqrt{3}} = 0.577h$	$\frac{bh}{\sqrt{6(b^2+h^2)}}$	$\sqrt{\frac{h^2\cos^2 a + b^2\sin^2 a}{12}}$
				$I =$	$\frac{b}{12}(H^3 - h^3)$	$\frac{H^4-h^4}{12}$	$\frac{H^4-h^4}{12}$	$\frac{bh^3}{36}$; $c = \frac{2}{3}h$
$\frac{I}{c} =$	$\frac{b}{6}\,\frac{H^3-h^3}{H}$	$\frac{1}{6}\,\frac{H^4-h^4}{H}$	$\frac{\sqrt{2}}{12}\,\frac{H^4-h^4}{H} = 0.1179\frac{H^4-h^4}{H}$	$\frac{bh^2}{24}$
$r =$	$\sqrt{\frac{H^3-h^3}{12(H-h)}}$	$\sqrt{\frac{H^2+h^2}{12}}$	$\sqrt{\frac{H^2+h^2}{12}}$	$\frac{h}{\sqrt{18}} = 0.236h$
				$I =$	$\frac{bh^3}{12}$	$\left(\frac{5\sqrt{3}}{16}R^4 = 0.5413R^4\right)$		$\frac{1+\sqrt{2}}{6}R^4 = 0.6381R^4$
$\frac{I}{c} =$	$\frac{bh^2}{12}$	$\frac{5}{8}R^3$;	$0.5413R^3$	$0.6906R^3$
$r =$	$\frac{h}{\sqrt{6}} = 0.408h$	$\left(\sqrt{\frac{5}{24}}R = 0.456R\right)$		$0.475R$

Square, axis same as first rectangle, side $= h$: $I = h^4/12$; $I/c = h^3/6$; $r = 0.289h$.
Square, diagonal taken as axis: $I = h^4/12$; $I/c = 0.1179h^3$; $r = 0.289h$.

Internal Moment Beyond the Elastic Limit

Ordinarily, the expression $M = SI/c$ is used for stresses above the elastic limit, in which case S becomes an experimental coefficient S_R, the **modulus of rupture,** and the formula is empirical. The true relation is obtained by applying to the cross-section a stress-strain diagram from a tension and compression test, as in Fig. 35. Fig. 35 shows the side of a beam of depth d under flexure beyond its elastic limit; line 1–1 shows the distorted cross-section; line 3–3, the usual rectilinear relation of stress to strain; and line 2–2, an actual stress-strain diagram (see Figs. 11 and 12) applied to the cross-section of the beam, compression above and tension below. The neutral axis is then below the gravity axis. The **outer material** may be expected to develop **greater ultimate strength** than in simple stress, on account of the reinforcing action of material nearer the neutral axis that is not yet overstrained. This leads to **an equalization of stress** over the cross-section. For values of S_R, see Table 2. S_R exceeds the ultimate strength S_M in tension as follows: For cast

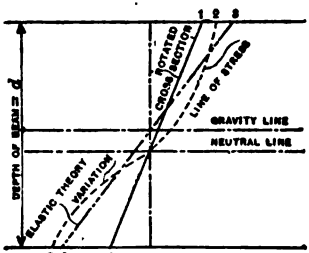

FIG. 35.

iron, $S_R = 2S_M$; for sandstone, $S_R = 3S_M$; for concrete, $S_R = 2.2S_M$; for wood (green), $S_R = 2.3S_M$.

In the case of steel I-beams, failure practically begins when the elastic limit in the compression flange is reached.

On account of support of adjoining material, the **elastic limit in flexure** S_p is also greater than in tension, depending upon the relation of breadth to depth of section. For the same breadth the difference decreases with increase of height. No difference will occur in the case of an I-beam, nor with hard materials. Bauschinger quotes for soft steel plates, 1.27; Considère, 1.37; Hatt, 1.5 (*R. R. Gas.*, 1899).

Wide plates will not expand and contract freely, and the value of E will be increased on account of side constraint. As a consequence of lateral contraction of the fibers of the tension side of a beam and lateral swelling of fibers at the compression side, the cross-section becomes distorted to a trapezoidal shape, and the neutral axis is at the c. of g. of the trapezoid. Strictly, this shape is one with a curved perimeter, the radius being r/m, where r is the radius of the neutral line of the beam, and m is Poisson's ratio.

Deflection of Beams

When a beam is subjected to an external moment, the fibers on one side elongate, while the fibers on the other side shorten (Fig. 36). These changes in length cause the beam to deflect. All points on the beam except those directly over the support fall below their original position, as shown by Fig. 34.

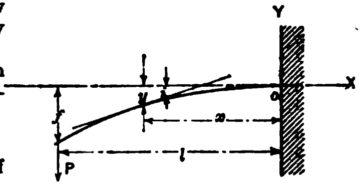

FIG. 36.

The **elastic curve** is the curve taken by the neutral axis. The radius of curvature at any point is

$$r = EI/M$$

A beam bent to a **circular curve** of constant radius has a constant moment and a constant stress.

Replacing r in the equation by its approximate geometrical value, $1/r = d^2f/(dx)^2$, the fundamental equation from which the elastic curve of a bent beam can be developed and the deflection of any beam can be obtained is,

$$M = EId^2f/(dx)^2 \text{ (approximate)}$$

This is a formula for **stiffness of beams.**

Substituting the value of M, in terms of x, and integrating once, gives the value of the angle i of the tangent to the elastic curve of the beam at point x, y; $i = df/dx = \int_0^x Mdx/EI$. A second integration gives the vertical deflection of any point of the elastic curve from its original position.

Example. In the cantilever beam shown in Fig. 36, the bending moment at any section $= -P(l - x) = EId^2f/(dx)^2$. Integrate and determine constant by the condition that when $x = 0$, $df/dx = 0$. Then $EIdf/dx = -Plx + \frac{1}{2}Px^2$. Integrate again and determine constant by the condition that when $x = 0$, $f = 0$. Then $EIf = -\frac{1}{2}Plx^2 + Px^3/6$. This is the equation of the elastic curve. When $x = l$, $f = -Pl^3/3EI$.

Deflection in general, f, may be expressed by the equation $f = Pl^3/mEI$, where m is a coefficient. See Tables 10 and 12 for values of f for beams of various sections and loadings. For coefficients of deflection of wooden beams, see pp. 1274 and 1276; for structural steel shapes, see pp. 1288 and 1289.

Since I varies as the cube of the depth, the **stiffness,** or inverse deflection, of various **beams** varies, other factors remaining constant, inversely as the load, inversely as the cube of the span, and directly as the cube of the depth.

This deflection is due to bending, but is increased by that due to vertical shear, especially in deep beams. For a **rectangular beam** with a center load P, the deflection due to vertical shear is $f' = Pl/4GA$, where G is the modulus of rigidity and A the area of cross-section. The shear is assumed to be uniformly distributed. If the shear S_v is distributed according to the parabolic law, $f' = 3Pl/10GA$. If the **load is distributed**, the deflection due to vertical shear is one-third that due to same load concentrated at the center.

Usually, deflection due to shear is unimportant, but in case of **I-beam girders**, where the vertical shear in the web is large, f' may become important. Here the deflection due to shear $= Pl/4GA$, when the shear due to P is considered to act entirely on the web of area A.

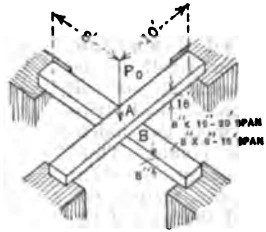

FIG. 37.

Design of beams may be fixed either by consideration of **strength**, or of **stiffness**, when deformations must be low. Stiffness is controlled by design or by material (E).

When a load may pass by two paths to a support, the different paths take parts of the load in proportion to their stiffness.

Example (Fig. 37). Two wooden stringers—one (A) 8 × 16 in. in cross-section and 20 ft. in span, the other (B) 8 in. × 8 in. × 16 ft.—carry the center load $P_0 =$ 22,000 lb. Required, the load carried by each stringer. The deflections, f, of the two stringers must be equal. Load on $A = P_1$, and on $B = P_2$. $f = P_1l_1^3/48EI_1 = P_2l_2^3/48EI_2$. Then $P_1/P_2 = l_2^3I_1/l_1^3I_2 = 4$. $P_0 = P_1 + P_2 = 4P_2 + P_2$, whence $P_2 =$ 22,000/5 = 4400 lb. and $P_1 = 4 \times 4400 =$ 17,600 lb.

Relation Between Deflection and Stress

Combine the formula $M = SI/c = Pl/n$, where n is a constant, P = load, and l = span, with formula $f = Pl^3/mEI$, where m is a constant. Then

$$f = C''Sl^2/Ec$$

where C'' is a new constant $= n/m$. Other factors remaining the same, the **deflection varies directly as the stress and inversely as E.** If the span is constant, a shallow beam will submit to greater deformations than a deeper beam without exceeding a safe stress. If depth is constant, a beam of double span will attain a given deflection with only one-quarter the stress. Values of n, m and C'' are as follows (for other values, see Table 10):

Beam	Load	n	m	C''
Cantilever	Concentrated at end	1	3	1/3
Cantilever	Uniform	2	8	1/4
Simple	Concentrated at center	4	48	1/12
Simple	Uniform	8	384/5	5/48
Fixed ends	Concentrated at center	8	192	1/24
Fixed ends	Uniform	12	384	1/32
One end fixed, One end supported	Concentrated at center	16/3	768/7	7/144
One end fixed, One end supported	Uniform	128/9	185	1/8
Simple	Uniformly varying, maximum at center	6	60	1/10

Graphical Relations

Referring to Fig. 38, the shear V acting at any section is equal to the total load on the right of the section, or

$$V = \int w dx$$

Since wdx is the product of w, a loading intensity (which is expressed as a vertical height in the load diagram), by dx, an elementary length along the horizontal, evidently wdx is the area of a small vertical strip of the **load diagram.** Then $\int wdx$ is the summation of all such vertical strips between two indefinite points. Thus, to obtain the shear in any section mn, find the area of the load diagram up to that section, and draw a second diagram called the **shear diagram,** any ordinate of which is proportional to the shear, or to the area in the load diagram to the right of mn. Since $V = dM/dx$,

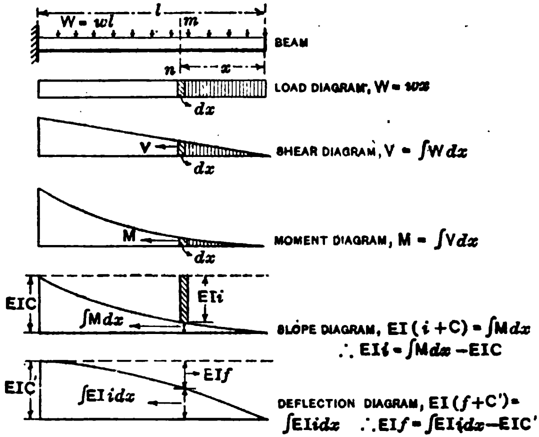

Fig. 38.

$$\int V dx = M$$

By similar reasoning, a **moment diagram** may be drawn, such that the ordinate at any point is proportional to the area of the shear diagram to the right of that point. Since $M = EId^2f/(dx)^2$,

$$\int M dx = EI[(df/dx) + C] = EI(i + C)$$

if I is constant. Here C is a constant of integration. Thus i, the slope or grade of the elastic curve at any point, is proportional to the area of the moment diagram $\int M dx$ up to that point; and a **slope diagram** may be derived from the moment diagram in the same manner as the moment diagram was derived from the shear diagram.

If I is not constant, draw a new curve whose ordinates are M/I and use these M/I ordinates just as the M ordinates were used in the case where I was constant; that is, $\int (M/I)dx = E(i + C)$. The ordinate at any point of the slope curve is thus proportional to the area of the M/I curve to the right of that point. Again, since $iE = Edf/dx$,

$$\int iE dx = \int E df = E(f + C')$$

and thus the ordinate f to the elastic curve at any point is proportional to the area of the slope diagram, $\int i dx$, up to that point. The equilibrium polygon may be used in drawing the **deflection curve** directly from the M/I diagram.

Thus, the five curves of load, shear, moment, slope, and deflection are so related that each curve is derived from the previous one by a process of graphical integration, and with proper regard to scales the deflection is thereby obtained.

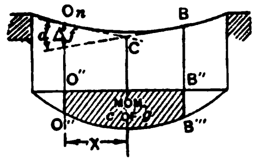

FIG. 39.

The vertical displacement of any point O_n (Fig. 39) in the elastic curve of a bent beam from the tangent line at any other point B, is Δf, and equals the area of the moment diagram between O'' and B'' times the distance X of the center of gravity of the area from O''. Or,

$$\Delta f = \text{Area } O''B''B'''O'''O'' \times X/EI$$

The angle d between the tangents at O_n and B equals the area of the moment diagram between O'' and B'' divided by EI. The intersection of the tangents at O_n and B is in the same vertical line as the center of gravity of the moment area between O'' and B''.

Resilience of Beams

The external work of a load gradually applied to a beam, and which increases from zero to P, is $\frac{1}{2}Pf$, and equals the **resilience** U. But, from formulæ under "Relation Between Deflection and Stress," p. 411, $P = nSI/cl$, and $f = nSl^2/mcE$, where n and m are constants that depend upon loading and supports, S = fiber stress, c = distance from neutral axis to outer fiber, and l = length of span. Substitute for P and f, and

$$U = \frac{n^2}{m}\left(\frac{k}{c}\right)^2 \cdot \frac{S^2V}{2E}$$

where k is the radius of gyration, and V the volume of the beam. For values of U, see Table 1.

The resilience of beams of similar cross-section at a given stress is proportional to their volumes. The **internal resilience**, or the elastic deformation energy in the material of a beam in a length x, is dU, and

$$U = \tfrac{1}{2}\int M^2dx/EI = \tfrac{1}{2}\int Mdi$$

where M is the moment at any point x, and di is the angle between the tangents to the elastic curve at the ends of dx. The values of resilience and deflection in special cases are easily developed from this equation.

Rolling Loads

Rolling or Moving Loads are those loads which may change their position on a beam. Fig. 40 represents a beam with two equal concentrated moving loads, such as two wheels on a crane girder, or the wheels of a wagon on a bridge. Since the maximum moment occurs where the shear is zero, it is evident from the shear diagram that the maximum moment will occur under a wheel. $x < a/2$:

$$R_1 = P\left(1 - \frac{2x}{l} + \frac{a}{l}\right) \qquad M_2 = \frac{Pl}{2}\left(1 - \frac{a}{l} + \frac{2x}{l}\frac{a}{l} - \frac{4x^2}{l^2}\right)$$

$$R_2 = P\left(1 + \frac{2x}{l} - \frac{a}{l}\right) \qquad M_1 = \frac{Pl}{2}\left(1 - \frac{a}{l} - \frac{2a^2}{l^2} + \frac{2x}{l}\frac{3a}{l} - \frac{4x^2}{l^2}\right)$$

M_2 max. when $x = \frac{1}{4}a$, $\qquad M_1$ max. when $x = \frac{3}{4}a$.

$$M_{\max} = \frac{Pl}{2}\left(1 - \frac{a}{2l}\right)^2 = \frac{P}{2l}\left(l - \frac{a}{2}\right)^2$$

Example. Two wheel loads of 3000 lb. each, spaced on 5-ft. centers, move on a span of $l = 15$ ft.; $x = 1.25$ ft. and $R_2 = 2500$ lb. ∴ Moment $= 6.25 \times 2500 = 15{,}600$ ft.-lb.

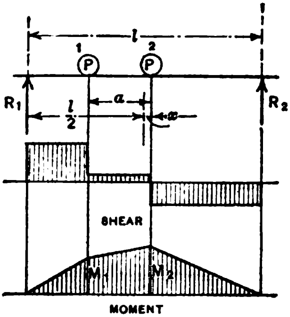

Fig. 40.

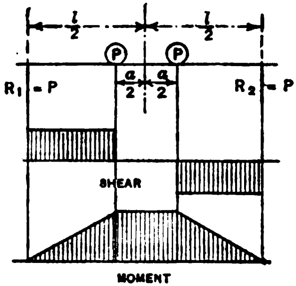

Fig. 41.

Fig. 41 shows the condition when two equal loads are equally distant on opposite sides of the center. The moment is equal under the two loads.

If the **two moving loads are of unequal weight,** the condition for **maximum moment** is that the maximum moment will occur under the heavy wheel when the center of the beam bisects the distance between the center of gravity and the heavy wheel. Fig. 42 shows this position and the shear and moment diagrams.

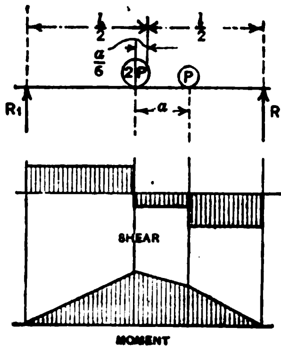

Fig. 42.

When **several wheel loads** constituting a system occur, the several suspected wheels must be examined in turn to determine which will cause the greatest moment. The **position for the greatest moment** that can occur under a given wheel is, as stated, when the center of the span bisects the distance between the wheel in question and the resultant of all the loads then on the span. The **position for maximum shear** at the support will be when one wheel is passing off the span.

Constrained Beams

Constrained beams are those so held or "built in" at one or both ends that the tangent to the elastic curve remains fixed in direction. These beams are held at the ends in such a manner as to allow free horizontal motion, as illustrated by Fig. 43. A constrained beam is stiffer than a simple beam of the same material, on account of the modification of the moment by an end resisting moment. Fig. 44 shows the two most common cases of constrained beams. See also Table 10.

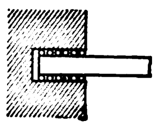

Fig. 43.

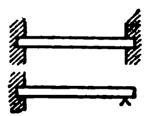

Fig. 44.

Continuous Beams

A continuous beam is one resting upon several supports which may or may not be in the same horizontal plane. The general discussion for beams holds for continuous beams. $S_sA = V$, $SI/c = M$, and $d^2f/dx^2 = M/EI$. The **shear** at any section is equal to the sum of all the reactions on one side of the section minus all the loads on the same side of the section. The internal moment at any section is equal to the moment of all reactions on one

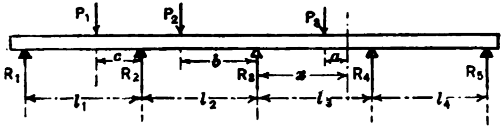

Fig. 45.

side of the section minus the moment of all the loads on the same side of the section. The relations stated above between shear and moment diagrams hold true for continuous beams. The internal bending moment at any section is equal to the bending moment at any other section, plus the shear at that section times its arm, plus the product of all the intervening external forces times their respective arms. To illustrate (Fig. 45):

$$V_x = R_1 + R_2 + R_3 - P_1 - P_2 - P_3$$
$$M_x = R_1(l_1 + l_2 + x) + R_2(l_2 + x) + R_3x - P_1(l_2 + c + x) - P_2(b + x) - P_3a$$
$$M_x = M_3 + V_3x - P_3a$$

Table 16 gives the value of the moment at the various supports of a uniformly loaded continuous beam over equal spans, and it also gives the values of the shears on each side of the supports. Note that the shear is of opposite sign on either side of the supports, and that the sum of the two shears is equal to the reaction.

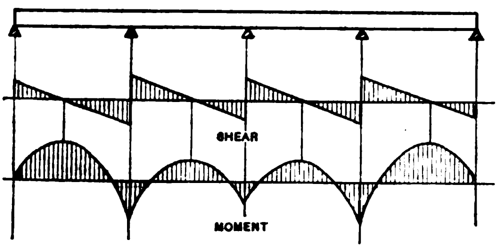

Fig. 46.

Fig. 46 shows the relation between the moment and shear diagrams for a uniformly loaded continuous beam of four equal spans (see Table 16). Table 16 also gives the **maximum bending moment** which will occur **between supports**, and in addition the position of this moment and the points of inflection (see Fig. 47).

Fig. 47 shows the values of the functions for a uniformly loaded continuous beam resting on three equal spans with four supports.

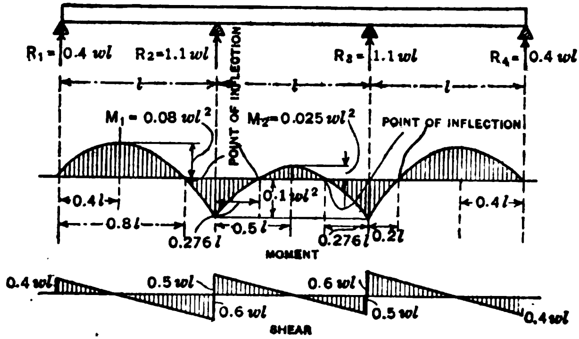

FIG. 47.

* The numerical values given are coefficients of the expressions at the foot of each column.

Continuous beams are stronger and much stiffer than simple beams. However, a small, unequal subsidence of piers will cause serious changes in sign and magnitude of the bending stresses, reactions and shears.

Maxwell's Theorem. When a number of loads rest upon a beam, the deflection at any point is equal to the sum of the deflections at this point due to each of the loads taken separately. Maxwell's Theorem states that if unit loads rest upon a beam at two points, A and B, the deflection at A due to the unit load at B equals the deflection at B due to the unit load at A.

Castigliano's Theorem states that the deflection of the point of application of an external force acting on a beam is equal to the partial derivative of the work of deformation with respect to this force. Thus, if P be the force, f the deflection, and U the work of deformation, which equals the resilience,

$$dU/dP = f$$

According to the **principle of least work,** the deformation of any structure takes place in such a manner that the work of deformation is a minimum.

Beams of Uniform Strength

Beams of uniform strength so vary in section that the unit stress S remains constant, and I/c varies as M. For **rectangular beams,** of breadth b and depth d, $I/c = bd^2/6$; and $M = Sbd^2/6$. Thus, for a cantilever beam of rectangular cross-section, under a load P, $Px = Sbd^2/6$. If b is constant, d^2 varies with x, and the profile of the shape of the beam will be a parabola, as Fig. 48. If d is constant, b will vary as x and the beam will be triangular in plan, as shown in Fig. 49.

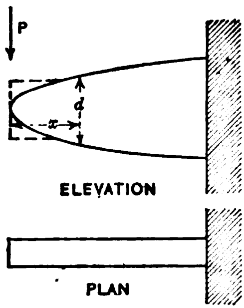

FIG. 48.

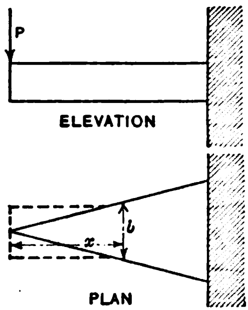

FIG. 49.

Shear at the end of a beam necessitates a modification of the forms determined above. The area required to resist shear will be P/S_v in a cantilever, and R/S_v in a simple beam. The dotted extensions in Figs. 48 and 49 show the changes necessary to enable these cantilevers to resist shear. The waste in material and extra cost in fabricating, however, make many of the forms impractical, except for cast iron.

Table 17 shows some of the simple **sections of uniform strength.** In none of these, however, is shear taken into account.

Table 17. Beams of Uniform Strength (in Bending)

1. Fixed at One End, Load P Concentrated at Other End

Beam	Cross-section	Elevation and plan	Formulæ
	Rectangle: width (b) constant, depth (y) variable.	Elevation: 1, top, straight line; bottom, parabola. 2, complete parabola. Plan: Rectangle	$y^2=\frac{6P}{bS_s}x$ $h=\sqrt{\frac{6Pl}{bS_s}}$ Deflection at A: $f=\frac{8P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Triangle	$y=\frac{6P}{h^2S_s}x$ $b=\frac{6Pl}{h^2S_s}$ Deflection at A: $f=\frac{6P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (z) variable, depth (y) variable: $\frac{z}{y}=k$ (const.)	Elevation: Cubic parabola Plan: Cubic parabola	$y^3=\frac{6P}{kS_s}x$ $z=ky$ $h=\sqrt[3]{\frac{6Pl}{kS_s}}$ $b=kh$
	Circle: diam. (y) variable	Elevation: Cubic parabola Plan: Cubic parabola	$y^3=\frac{32P}{\pi S_s}x$ $d=\sqrt[3]{\frac{32Pl}{\pi S_s}}$

2. Fixed at One End, Load P Uniformly Distributed over l

	Rectangle: width (b) constant, depth (y) variable	Elevation: Triangle Plan: Rectangle	$y=x\sqrt{\frac{3P}{blS_s}}$ $h=\sqrt{\frac{3Pl}{bS_s}}$ $f=6\frac{P}{bE}\left(\frac{l}{h}\right)^3$

Table 17. Beams of Uniform Strength (in Bending)—(*continued*)

2. FIXED AT ONE END, LOAD P UNIFORMLY DISTRIBUTED OVER l

Beam	Cross-section	Elevation and plan	Formulæ
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Two parabolic curves with vertices at free end	$y = \frac{3P}{lS_s}\frac{x^2}{h^2}$ $b = \frac{3Pl}{S_s h^2}$ Deflection at A: $f = \frac{3P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (z) variable, depth (y) variable, $\frac{z}{y} = k$	Elevation: Semi-cubic parabola Plan: Semi-cubic parabola	$y^3 = \frac{3P}{kS_s}\frac{x^2}{l}$ $z = ky$ $h = \sqrt[3]{\frac{3Pl}{kS_s}}$ $b = kh$
	Circle: diam. (y) variable	Elevation: Semi-cubic parabola Plan: Semi-cubic parabola	$y^3 = \frac{16P}{\pi l S_s}x^2$ $d = \sqrt[3]{\frac{16Pl}{\pi S_s}}$

3. SUPPORTED AT BOTH ENDS, LOAD P CONCENTRATED AT POINT C

	Rectangle: width (b) constant, depth (y) variable	Elevation: Two parabolas, vertices at points of support Plan: Rectangle	$y = \sqrt{\frac{3P}{S_s b}x}$ $h = \sqrt{\frac{3Pl}{2bS_s}}$ $f = \frac{P}{2Eb}\left(\frac{l}{h}\right)^3$
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Two triangles, vertices at points of support	$y = \frac{3P}{S_s h^2}x$ $b = \frac{3Pl}{2S_s h^2}$ $f = \frac{3Pl^3}{8Ebh^3}$

Table 17. Beams of Uniform Strength (in Bending)—(*continued*)

3. Supported at Both Ends, Load P Concentrated at Point C

Beam	Cross-section	Elevation and plan	Formulæ
	Rectangle: width (b) constant, depth (y or y_1) variable	Elevation: Two parabolas, vertices at points of support Plan: Rectangle	$y^2 = \frac{6P(l-p)}{blS_s}x$ $y_1^2 = \frac{6Pp}{blS_s}x_1$ $h = \sqrt{\frac{6P(l-p)p}{blS_s}}$

Load P Moving Across Span

	Rectangle; width (b) constant, depth (y) variable	Elevation: Ellipse, Major axis $= l$ Minor axis $= 2h$ Plan: Rectangle	$\frac{x^2}{\left(\frac{l}{2}\right)^2} + \frac{y^2}{\frac{3Pl}{2bS_s}} = 1$ $h = \sqrt{\frac{3Pl}{2bS_s}}$

4. Supported at Both Ends, Load P Uniformly Distributed over l

	Rectangle: width (b) constant, depth (y) variable	Elevation: Ellipse Plan: Rectangle	$\frac{x^2}{\left(\frac{l}{2}\right)^2} + \frac{y^2}{\frac{3Pl}{4bS_s}} = 1$ $h = \sqrt{\frac{3Pl}{4bS_s}}$ Deflection at O: $f = \frac{1}{64}\frac{Pl^3}{EI}$ $= \frac{3}{16}\frac{P}{bE}\left(\frac{l}{h}\right)^3$
	Rectangle: width (y) variable, depth (h) constant	Elevation: Rectangle Plan: Two parabolas with vertices at center of span	$y = \frac{3P}{S_s h^2}\left(x - \frac{x^2}{l}\right)$ $b = \frac{3Pl}{4S_s h^2}$

STRENGTH OF PLATES

Notation.

P = Total load, lb.
p = load per unit area, lb. per sq. in.
t = thickness of plate, in.
S_{max} = maximum stress, lb. per sq. in.
S_s = safe stress, lb. per sq. in.
E = modulus of elasticity.
f = deflection, in.
K_1 and K_2 = coefficients.

The values of K_1 and K_2 are dependent upon the method of support and upon the initial force required to give a tight joint (to prevent leakage) before the load is applied. Cases 3 and 6 follow Grashof; the others, C. Bach. The formulæ apply only within the elastic limit. For tests of flat plates by Prof. Bryson, see *Rensselaer Polytechnic Bulletin.*

Flat Plates

(1) Circular Plate Subjected to Uniformly Distributed Load.

$$S_{max} = K_1 r^2 p/t^2 \leqq S_s, \text{ and } f = K_2 r^4 p/t^3 E.$$

For cast iron, $K_1 = 0.8$ (fixed edge) to 1.2 (freely supported); $K_2 = 0.17$ (fixed edge) to 0.60 (freely supported). For mild steel, $K_1 = 0.50$ (not < 0.45) with fixed edge to 0.75 (not < 0.67) when freely supported.

FIG. 50.

In Fig. 50, S_{max} is at edge. In Fig. 51, S_{max} is at center. If the fixed ends deflect sufficiently to make the center and circumferential stresses equal, $K_1 = 0.38$, or not < 0.33.

FIG. 51.

(2) Circular Plate Loaded at the Center and Freely Supported at the Circumference (Fig. 52); P uniformly distributed over area πr_0^2.

$$S_{max} = \frac{3}{\pi} K_1 \left(1 - \frac{2}{3}\frac{r_0}{r}\right)\frac{P}{t^2} \leqq S_s; \quad f = K_2 \frac{r^2}{t^3}\frac{P}{E}.$$

For cast iron, $K_1 = 1.5$; $K_2 = 0.4$ to 0.5.

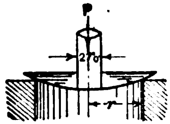

FIG. 52.

(3) Circular Plate Loaded as in (2) but Fixed at the Circumference (Fig. 53).

$$S_{max} = \frac{1.365}{\pi}\frac{P}{t^2}\log_e \frac{r}{r_0} \leqq S_s;$$

$$f = \frac{0.6825}{\pi}\frac{r^2}{t^3}\frac{P}{E} = 0.22\frac{r^2}{t^3}\frac{P}{E}.$$

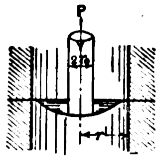

FIG. 53.

(4) Elliptical Plate Subjected to a Uniformly Distributed Load p. (See Figs. 50 and 51).

Major axis $= 2a$; minor axis $= 2b$; ratio of axes $= b/a = c$.

$$S_{max} = K_1 \frac{b^2}{t^2}\frac{2p}{(1+c^2)} \leqq S_s$$

For cast iron, $K_1 = 0.67$ (fixed) to 1.13 (freely supported).

For mild steel, $K_1 = 0.42$ (fixed) to 0.71 (freely supported).

For $c = 1$ (circle), $S_{max} = K_1 b^2 p/t^2$.

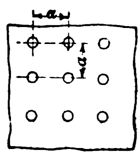

FIG. 54.

(5) Elliptical Plate with Load P **at the Center.** Notation as in (4).

$$S_{max} = \frac{8}{5\pi} K_1 \frac{8 + 4c^2 + 3c^4}{3 + 2c^2 + 3c^4} c \frac{P}{t^2} \leqq S_s.$$

For cast iron, $K_1 = 1.50$ (fixed) to 1.67 (freely supported).

For $c = 1$ (circle), $S_{max} = 3K_1 P/\pi t^2$.

(6) Infinitely Large Plate Subjected to a Uniformly Distributed Load and supported at points distant a from each other (Fig. 54). For each single square,

$$S_{max} = 0.2275\, a^2 p/t^2 \leqq S_s, \quad \text{and} \quad f = 0.0284\, a^4 p/t^3 E.$$

(7) Rectangular Plate Supported at the Periphery and Subjected to a Uniformly Distributed Load. (a and b = length and breadth of plate; $b/a = c$.) For the calculation of stress along the diagonal, as in case (4) of an ellipse,

$$S_{max} = K_1 \frac{(b/2)^2}{t^2} \frac{2p}{(1 + c^2)} \lesseqgtr S_s$$

When $b = a$, $c = 1$ (square plate), and $S_{max} = 0.25K_1a^2p/t^2 \lesseqgtr S_t$.

For cast iron, $K_1 = 0.75$ (fixed) to 1.13 (freely supported).

For mild steel, $K_1 = 0.48$ (fixed) to 0.72 (freely supported).

If the plate is supported on two sides ($b = \infty$), the coefficient of a^2p/t^2 will be 0.50 (fixed) to 0.75 (freely supported).

Note. In cases (4) and (7), values of K_1 for mild steel are: for elliptical plates, 0.43 to 0.55 (max. = 0.86); rectangular plates, 0.56 to 0.75 (max. = 1.13). The maxima, which correspond to values for free support, are to be rarely used. The minimum value of K_1 corresponds to the case where the moment at the center equals the moment at the support, $M_{max} = pl^2/16$.

Tests on rectangular cast-iron plates at Case School of Applied Science (1896–97), with load applied at center, give the following values for the breaking load W. For plates supported at the edges, $W = 276St^2/(l^2 + b^2)$; for plates with fixed edges, $W = 442\,St^2/(l^2 + b^2)$. The plates tested were 10 × 15 in., ½ to 1⅛ in. thick; modulus of rupture of the cast iron, 33,000 lb. per sq. in.

(8) Rectangular Plate Supported at the Periphery and Subjected to a Concentrated Load at the Center. (a and b = length and breadth, and $b/a = c$.) With the assumption made in (7),

$$S_{max} = 1.5K_1 \frac{c}{(1 + c^2)} \frac{P}{t^2} \lesseqgtr S_s.$$

K = 1.75 to 2.00 for cast iron. For $b = a$, $c = 1$ (square plate), and $S_{max} = 0.75Kp/t^2 \lesseqgtr S_s$.

Deflection of Square Plates with Different Methods of Support. Deflection under uniformly distributed load $= f = 15b^4pK/\pi^5t^3E$. Values of K are as follows:

Method of supporting plate	Center of plate K	Middle of unsupported edge K
2 edges supported, 2 rigidly fixed	0.134	.....
3 edges supported, 1 rigidly fixed	0.212	.....
4 edges supported, 0 rigidly fixed	0.310	.....
2 edges supported, 1 rigidly fixed, 1 not supported	0.430	0.825
3 edges supported, 1 not supported	0.602	0.915
2 edges supported, 2 not supported	0.994	1.110

Trapezoidal Plates. Calculations for these are made by assuming equivalent rectangular plates.

Flat Cylinder Heads with Flanged Edges (Fig. 55).

$$S_{max} = p\left\{K_1\frac{R}{t} + K_2\left[\frac{r - 0.5R\left(1 + \frac{R}{r}\right)}{t}\right]^2\right\}$$

in which R = radius of curvature of the flange and r = radius of head or attached cylinder, both in in.; p = internal pressure, in lb. per sq. in.

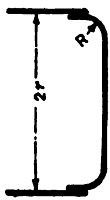

FIG. 55.

For steel heads riveted to the cylinder $K_1 = 0.5$, and $K_2 = 0.33$ to 0.38; for cast-iron heads integral with the cylinder, $K_1 = K_2 = 0.8$.

Curved Plates with Openings (Bach and Pfleiderer). With a single flue (Figs. 56 and 57) riveted into the plate, the greatest stress due to bending will be found at the flanges, and

$$S_{\max} = 0.45\,p\,\frac{r_a - r_i}{t^2}\left(r_a - r_i - 2e + \frac{5e^2}{h + 2e}\right).$$

With two flues (Figs. 58 and 59),

$$S_{\max} = 22p\,\frac{r_a - 1.5r_i}{t^2}\left(r_a - r_i - 2e + \frac{5e^2}{h + 2e}\right).$$

In computing h (Fig. 57), assume $v = 1.5$ to $2t$.

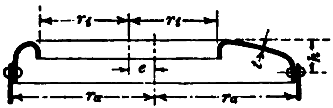

FIG. 56.

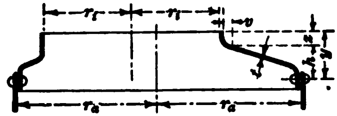

FIG. 57.

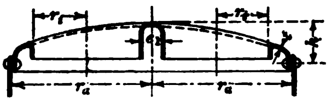

FIG. 58.

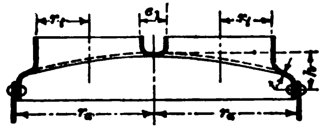

FIG. 59.

TORSION

Under torsion, a bar (Fig. 60) is twisted by a couple of the value Pp. Elements of the surface become helices of angle d, and a radius rotates through an angle a in a length l, both d and a being expressed in radians. S_v = shearing unit stress at distance r from center; I_P = polar moment of inertia; G = shearing modulus of elasticity. It is assumed that the cross-sections remain plane surfaces. The strain on the cross-section is wholly tangential, and is zero at the center of the section. $ld = ra$.

In the case of a circular cross-section, the stress S_v increases directly as the distance of the strained element from the center.

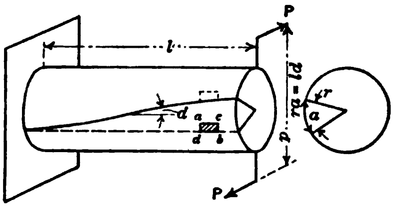

FIG. 60.

The polar moment of inertia I_P for any section may be obtained from $I_P = I_1 + I_2$, where I_1 and I_2 are the rectangular moments of inertia of the section about any two lines at right angles to each other, through the center of gravity.

The external twisting moment M_t is balanced by the internal resisting moment.

For strength, $M_t = S_v I_P / r$.

For stiffness, $M_t = aGI_P / l$.

The torsional resilience $U = \frac{1}{2} Ppa = S_v^2 I_P l / 2r^2 G = a^2 G I_P / 2l$.

The state of stress on an element taken from the surface of the shaft, as in Fig. 61, is pure shear. Pure tension exists at right angles to one 45-deg. helix and pure compression at right angles to the opposite helix.

Reduced **formulæ for shafts of various sections** are given in Table 18.

Table 18. Torsion of Shafts of Various Cross-sections

(For allowable stresses, see Table 8, p. 389. For strength and stiffness of shafts, see pp. 439 and 688)

Cross-section	Torsional resisting moment M_t	Angular deflection, a_1 (length = 1 in., radius = 1 in.)		Work of torsion (V = volume)
		In terms of torsional moment	In terms of max. shear	
	$\frac{\pi}{16} d^3 S_s$	$\frac{M_t}{GI_P} = \frac{32}{\pi d^4}\frac{M_t}{G}$	$2\frac{S_s \max}{G}\frac{1}{d}$	$\frac{1}{4}\frac{S_s^2 \max}{G}V$ (Note 1)
	$\frac{\pi}{16}\frac{D^4-d^4}{D}S_s$	$\frac{32}{\pi(D^4-d^4)}\frac{M_t}{G}$	$2\frac{S_s \max}{G}\frac{1}{D}$	$\frac{1}{4}\frac{S_s^2 \max}{G}\frac{D^2+d^2}{D^2}V$ (Note 2)
	$\frac{\pi}{16}b^2hS_s$ ($h > b$)	$\frac{16}{\pi}\frac{b^2+h^2}{b^3h^3}\frac{M_t}{G}$	$\frac{S_s \max}{G}\frac{b^2+h^2}{bh^2}$	$\frac{1}{8}\frac{S_s^2 \max}{G}\frac{b^2+h^2}{h^2}V$ (Note 3)
	$\frac{2}{9}b^2hS_s$ ($h > b$)	$3.6\frac{b^2+h^2}{b^3h^3}\frac{M_t}{G}$*	$0.8\frac{S_s \max}{G}\frac{b^2+h^2}{bh^2}$*	$\frac{4}{45}\frac{S_s^2 \max}{G}\frac{b^2+h^2}{h^2}V$ (Note 4)
	$\frac{2}{9}h^3S_s$	$7.2\frac{1}{h^4}\frac{M_t}{G}$	$1.6\frac{S_s \max}{G}\frac{1}{h}$	$\frac{8}{45}\frac{S_s^2 \max}{G}V$ (Note 5)
	$\frac{b^3}{20}S_s$	$46.2\frac{1}{b^4}\frac{M_t}{G}$	$2.31\frac{S_s \max}{G}\frac{1}{b}$	
	$\frac{b^3}{1.09}S_s$	$0.967\frac{1}{b^4}\frac{M_t}{G}$	$0.9\frac{S_s \max}{G}\frac{1}{b}$	

* When h/b =	1	2	4	8
Coefficient 3.6 becomes	= 3.56	3.50	3.35	3.21 and
Coefficient 0.8 becomes	= 0.79	0.78	0.74	0.71

NOTES.—1. S_s max at circumference. 2. S_s max at outer circumference. 3. S_s max at A; $S_{sB} = 16M_t/\pi bh^2$. 4. S_s max at middle of side h; in middle of b, $S_s = 9M_t/2bh^2$. 5. S_s max at middle of side.

Failure under torsion in brittle materials is a tensile failure at right angles to a helical element of the surface. Plastic materials twist off squarely. Fibrous materials separate in long strips.

Torsion of Non-circular Sections. When a section is not circular, the unit stress no longer varies directly as the distance from the center. Cross-sections become warped, and the greatest unit stress usually occurs at a point on the perimeter of the cross-section *nearest* the axis of twist. There is no stress at the corners of square and rectangular sections, and the analyses become complex.

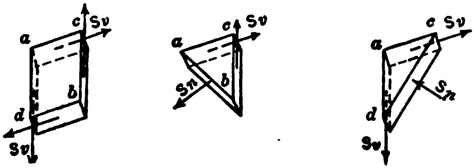

FIG. 61.

SPRINGS

It is assumed in the following formulæ that the springs are in no case stressed beyond the elastic limit (*i.e.*, that they are perfectly elastic), and that they are subject to Hooke's Law.

Notation:

P = Safe load, lb.
f = Deflection for a given load, P, in.
l = Length of spring, in.
V = Volume of spring, cu. in.
S_s = Safe stress (due to bending), lb. per sq. in.
S_v = Safe shearing stress, lb. per sq. in.
U = Resilience in in.-lb.

For values of E and G, see p. 384. Benjamin and Hoffman (in "Machine Design") recommend the following values for S_v, G and E: For spring brass wire, S_v = 45,000 to 60,000; G = 6,000,000; E = 9,000,000. For spring steel, tempered, S_v = 75,000 to 115,000; G = 12,000,000 to 15,000,000; E = 30,000,000.

The **work** in in.-lb. performed **in deflecting a spring** from 0 to f (spring duty) is $U = Pf/2 = S_s^2V/CE$. This is based upon the assumption that the deflection is proportional to the load. C is a constant dependent upon the shape of the springs.

The **time of vibration** T (in seconds) **of a spring** (weight not considered) is equal to that of a simple circular pendulum whose length l_0 equals the deflection f (in ft.) that is produced in the spring by the load P. $T = \pi\sqrt{l_0/g}$, where g = acceleration of gravity in ft. per sec.^2

Springs Subjected to Bending

(See first case in Table 10, p. 398)

1. **Rectangular Plate Spring** (Fig. 62).
$P = bh^2S_s/6l$; $I = bh^3/12$; $U = Pf/2 = VS_s^2/18E$;
$f = Pl^3/3EI = 4Pl^3/bh^3E = 2l^2S_s/3hE$.

2. **Triangular Plate Spring** (Fig. 63). The elastic curve is a circular arc.
$P = bh^2S_s/6l$; $I = bh^3/12$; $U = Pf/2 = S_s^2V/6E$;
$f = Pl^3/2EI = 6Pl^3/bh^3E = l^2S_s/hE$.

3. **Rectangular Plate Spring with End Tapered** in the form of a cubical parabola (Fig. 64). The elastic curve is a circular arc. P, I and f same as for triangular plate spring (Fig. 63). $U = Pf/2 = S_s^2V/9E$.

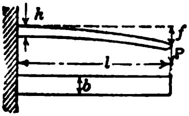

FIG. 62.

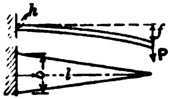

FIG. 63.

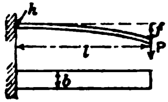

FIG. 64.

The strength and deflection of **single-leaf flat springs** of various forms are given (R. A. Bruce, *Am. Mach.*, July 19, 1900) by the formulæ $h = al^2/f$ and $b = cPl/h^2$. The volume of the spring is given by $V = vlbh$. The values of the constants a and c and the resilience in in.-lb. per cu. in. are given in Table 19, both in terms of the safe stress S_s and for stated specific values of S_s and E. Values of v are given also.

Table 19. Strength and Deflection of Single-leaf Flat Springs

Plans and elevations of springs	General				$S_s = 60{,}000$; $E = 30{,}000{,}000$		
	a	c	U	v	a	c	U

4. Compound (Leaf or Laminated) Springs. If several springs of rectangular section are combined, the resulting compound spring should (1) form a beam of uniform strength that (2) does not open between the joints while bending (*i.e.*, elastic curve must be a circular arc). Only the type immediately following meets both requirements, the others meeting only the second requirement.

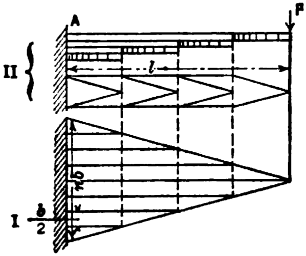

FIG. 65.

5. Laminated Triangular Plate Spring (Fig. 65). If the triangular plate spring shown at I be cut into an even number ($=2n$) of strips of equal width (in this case 8 strips of width $b/2$), and these strips be combined, a laminated spring will be formed whose carrying capacity will equal that of the original uncut spring; or $P = nbh^2S_s/6l$; $n = 6Pl/bh^2S_s$.

6. Laminated Rectangular Plate Spring with Leaf Ends Tapered in the form of a cubical parabola (Fig. 66); see (3) *ante*.

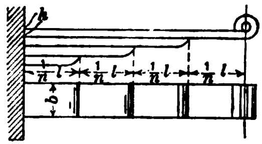

FIG. 66.

7. Laminated Trapezoidal Plate Spring with Leaf Ends Tapered. (Fig. 67.) The ends of the leaves are trapezoidal in form and are tapered according to the formula

$$z = h\Big/\left[1+\sqrt[3]{\frac{b_1}{b}\left(\frac{a}{x}-1\right)}\right]$$

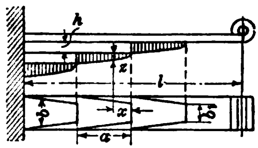

FIG. 67.

8. Semi-elliptic Springs (for locomotives, horse-drawn and automobile trucks, etc.). Referring to Fig. 68, the load $2P$ (lb.) acting on the spring center band produces a tensional stress $P/\cos a$ in each of the inclined shackle links. This is resolved into the vertical force P and the horizontal force $P \tan a$, which together produce a bending moment $M = P(l + p \tan a)$. The equations given in (1), (2) and (3) apply to curved as well as straight springs. The bearing force $= 2P = (2nbh^2/6)[S_s/(l + p \tan a)]$, and the deflection $= (6l^2/nbh^3)P(l + p \tan a)/E = l^2S_s/hE$.

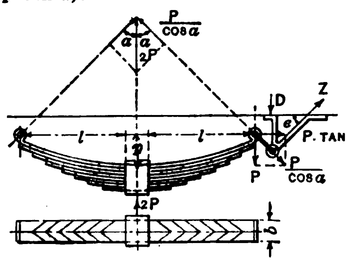

FIG. 68.

In addition to the bending moment, the leaves are subjected to the tensional force $P \tan a$ and the transverse force P, which produce in the upper leaf an additional stress $S = P \tan a/bh$, as well as a shearing stress to be calculated according to p. 412.

In determining the number of leaves n in a given spring, allowance should be made for an excess load on the spring caused by the vibration. This is usually made by decreasing the allowable stress about 15 per cent.

The foregoing does not take account of initial stresses caused by the band. For more detailed information, see "The Design of Automobile Springs," by E. R. Morrison. *Machinery*. Jan., 1910.

9. Elliptic Springs. Safe load P(lb.) $= nbh^2S_s/6l$, where l = ½ distance between bolt eyes (less ½ length of center band, where used); deflection f (in.) $= 4l^2S_sK/hE$, where

$$K = \frac{1}{(1-r)^3}\left[\frac{1-r^2}{2} - 2r(1-r) - r^2\log_e r\right]$$

r being the number of full-length leaves $\div$ total number (n) of leaves in the spring. All dimensions in in. For semi-elliptic springs the deflection is only half as great. Safe load $= nbh^2S_s/3l$. (J. B. Peddle, *Am. Mach.*, Apr. 17, 1913.)

Coiled Springs. In these the load is applied as a couple, Pr, which turns the spring while winding or holds it in place when wound up. If the spindle is not to be subjected to bending moment, P must be replaced by two equal and opposite forces ($P/2$) acting at the circumference of a circle of radius r. The formulæ are the same in both cases. The springs are assumed to be fixed at one end and free at the other. The bending moment acting on the section of least resistance is always Pr. The length of the straightened spring $= l$. See "Experiments on Helical Springs", by Benjamin and French, *Trans. A. S. M. E.*, vol. 23, p. 298.

10. Spiral Coiled Spring of Rectangular Cross-section (Fig. 69).

$P = bh^2S_s/6r$; $I = bh^3/12$; $U = Pf/2 = S_s^2V/6E$;

$f = ra = Plr^2/EI = 12Plr^2/Ebh^3 = 2rlS_s/hE$.

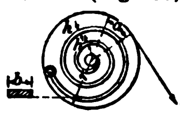

FIG. 69.

11. Cylindrical Helical Spring of Circular Cross-section (Fig. 70).

$P = \pi d^3S_s/32r$; $I = \pi d^4/64$; $U = Pf/2 = S_s^2V/8E$;

$f = ra = Plr^2/EI = 64Plr^2/\pi Ed^4 = 2rlS_s/dE$.

12. Cylindrical Helical Spring of Rectangular Cross-section (Fig. 71).

$P = bh^2S_s/6r$; $I = bh^3/12$; $U = Pf/2 = S_s^2V/6E$;

$f = ra = Plr^2/EI = 12Plr^2/Ebh^3 = 2rlS_s/hE$.

Springs Subjected to Torsion

The statements made concerning coiled springs subjected to bending apply also to (13) and (14).

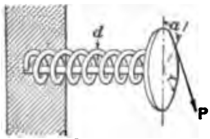

FIG. 70.

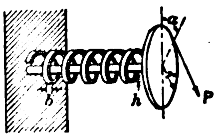

FIG. 71.

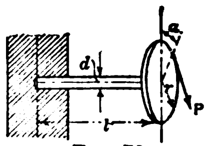

FIG. 72.

13. Straight Bar Spring of Circular Cross-section (Fig. 72).

$P = \pi d^3S_v/16r = 0.1963d^3S_v/r$; $U = Pf/2 = S_v^2V/4G$;

$f = ra = 32r^2lP/\pi d^4G = 2rlS_v/dG$.

14. Straight Bar Spring of Rectangular Cross-section (Fig. 73).

$P = 2b^2hS_v/9r$; $K = b/h$; $U = Pf/2 = 4S_v^2V(K^2+1)/45G$ (maximum when $K = 1$);

$f = ra = 3.6r^2lP(b^2+h^2)/b^3h^3G = 0.8rlS_v(b^2+h^2)/bh^2G$.

Springs Loaded Axially Either in Tension or Compression

[**Note.** For springs Nos. 15 to 18 inclusive, r = mean radius of coil; n = number of coils.]

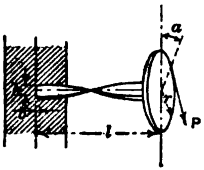
15. Cylindrical Helical Spring of Circular Cross-section (Fig. 74).

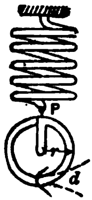
$P = \pi d^3S_v/16r = 0.1963d^3S_v/r$; $U = Pf/2 = S_v^2V/4G$;

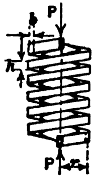
$f = 64nr^3P/d^4G = 4\pi nr^2S_v/dG$.

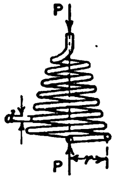
16. Cylindrical Helical Spring of Rectangular Cross-section (Fig. 75).
$P = 2b^2hS_v/9r$; $K = b/h$; $U = Pf/2 = 4S_v^2V(K^2+1)/45G$ (maximum when $K = 1$);
$f = 7.2\pi nr^3P(b^2 + h^2)/b^3h^3G = 1.6\pi nr^2S_v(b^2 + h^2)/bh^2G$.

17. Conical Helical Spring of Circular Cross-section (Fig. 76).
l = length of developed spring; d = diameter of wire; r = maximum mean radius of coil.
$P = \pi d^3S_v/16r = 0.1963d^3S_v/r$; $U = Pf/2 = S_v^2V/8G$;
$f = 16r^2lP/\pi d^4G = 16nr^3P/d^4G = rlS_v/dG = \pi nr^2S_v/dG$.









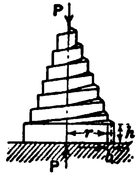


FIG. 73. FIG. 74. FIG. 75. FIG. 76. FIG. 77.

18. Conical Helical Spring of Rectangular Cross-section (Fig. 77).
$K = b/h$; $P = 2b^2hS_v/9r$; $U = Pf/2 = 2S_v^2V(K^2 + 1)/45G$ (maximum when $K = 1$);
$f = 1.8r^2lP(b^2 + h^2)/b^3h^3G = 1.8\pi nr^3P(b^2 + h^2)/b^3h^3G$.
$= 0.4rlS_v(b^2 + h^2)/bh^2G = 0.4\pi nr^2S_v(b^2 + h^2)/bh^2G$.

19. Truncated Conical Springs (Types 17 and 18). The formulæ under (17) and (18) apply for truncated springs. In calculating deflection f, however, it is necessary to substitute $(r_1^2 + r_2^2)$ for r^2, and $\pi n(r_1 + r_2)$ for πnr, r_1 and r_2 being respectively the greatest and least mean radii of the coils.

Note. The preceding formulæ for various forms of coiled springs are sufficiently accurate when the dimensions of the wire cross-section are small in comparison with the radius of the coil, and when the pitch is small. Springs (15) to (19) are for use either in tension or compression.

Safe Working Loads and Deflections of Cylindrical Helical Springs of round steel wire, in tension or compression, are given in Table 20. The values for steel of ¼ in. diam. and larger are from a table calculated by J. Begtrup (*Am. Mach.*, Aug. 18, 1892); while those for Roebling and Washburn & Moen wire-gage sizes (Nos. 000 to 28) are from a table due to F. D. Howe (*Am. Mach.*, Dec. 20, 1906). Both of these tables are based on the formulæ given in (15) *ante:*

When designing a spring for continuous work, as a car spring, a smaller value of S_s should be chosen than that used in calculating the table; for intermittent working, as in a steam-engine governor or a safety valve, the tabular values are to be used

Examples of Use of Table 20. (1) Required the safe load (P) for a spring of ⅜-in. round steel with an outside diam. (D) of 3 in. In the line headed D, under 3, is given the value of P, or 473 lb. To determine the number of coils this spring should have to deflect (say) 3 in. under a load of (say) 400 lb., take the value of f under 473, or 0.0610. This is the deflection of one coil for a load of 100 lb.; therefore $0.0610 \times 400/100 = 0.244$ in. is the deflection of one coil under a 400-lb. load, and $3/0.244 = 12.3$, say 13, = number of coils required. The spring will therefore be 4⅞ in. long when closed (13 × ⅜), counting the working coils only, and will stretch to 7⅞ in. under the 400-lb. load.

Table 20. Safe Working Loads and Deflections of Cylindrical Helical Steel Springs of Circular Cross-section

d = diameter of steel, in. P = safe working load, lb.
D = outside diameter of coil, in. f = deflection of 1 coil by load of 100 lb., in.

Table based on $S_s = 60,000$ lb. per sq. in. and $G = 12,000,000$. For any other value of G, multiply value of f in table by 12,000,000 and divide by the value of G chosen.

For square steel, multiply values of P by 1.2, and values of f by 0.59.

For brass, take $S_s = 10,000$ to 20,000, and multiply values of f by 2 (Howe).

(2) A $\frac{7}{16}$-in. steel spring of $3\frac{1}{4}$ in. outside diameter has its coils in close contact How much can it be extended without exceeding the limit of safety? The maximum safe load for this spring is found to be 702 lb. and the deflection of one coil for 100 lb. load 0.0405 in.; $(702/100) \times 0.0405 = 0.284$ in. is therefore the greatest admissible opening between any two coils. In this way it is possible to ascertain whether or not a spring is overloaded, without knowledge of the load carried.

ECCENTRIC LOADS

When **short blocks** are **loaded eccentrically** in compression or in tension, *i.e.*, not through the center of gravity (c. of g.), a combination of axial and bending stress results. The maximum unit stress S_m is the algebraic sum of these two unit stresses.

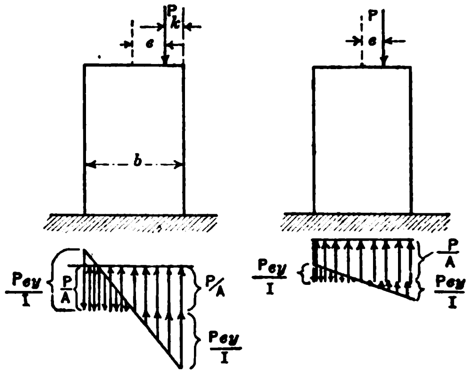

FIG. 78.

In Fig. 78 a load P acts in a line of symmetry at the distance e from c. of g.; r = radius of gyration. The unit stresses are (1) S_c, due to P, as if it acted through c. of g., and (2) S_b, due to the bending moment of P acting with a leverage of e about c. of g. Thus unit stress S at any point $y = S_c \pm S_b$

$$= P/A \pm Pey/I$$

$$= S_c(1 \pm ey/r^2).$$

y is positive for points on the same side of c. of g. as P, and negative on the opposite side. For a **rectangular cross-section** of width b, the maximum stress $S_m = S_c(1 + 6e/b)$. When P is outside the middle third of width b and is a compressive load, tensile stresses occur.

For a **circular cross-section** of diameter d, $S_m = S_c(1 + 8e/d)$. The stress due to the weight of the solid will modify these relations.

Note. In these formulæ e is measured from the gravity axis, and gives tension when e is greater than $\frac{1}{6}$ the width measured in the same direction as e.

If, as in certain classes of masonry nstruction, the **material cannot ithstand tensile stress** and thus no nsion can occur, the center of moments Fig. 79) is taken at the center of stress. For a **rectangular section,** P acts at distance k from the nearest edge. Length under compression $= 3k$, and $S_m = \frac{2}{3}P/hk$. For a **circular section,** $S_m = [0.372 + 0.056(k/r)]P/k\sqrt{rk}$, where r = radius and k = distance of P from circumference. For a **circular ring,** S = average compressive stress on cross-section produced by P; e = eccentricity of P; z = length of diameter under compression (Fig. 80). Values of z/r and of the ratio of S_{max} to average S are given in Tables 21 and 22.

Chimney Problem. Weight of chimney = 563,000 lb.; e = 1.56 ft.; outside diam. of chimney = 10 ft. 8 in.; inside diam. = 6 ft. 6½ in. Overturning moment = Pe = 878,000 ft.-lb. r_1/r = 0.6. e/r = 0.29. This gives $(z/r) > 2$. Therefore, the entire area of the base is under compression. Area under compression = 55.8 sq. ft.; I = 546; $S = (563{,}000/55.8) \pm (878{,}000 \times 5.33)/546$ = 18,700 (max.) and 1500 (min.) lb. compression per sq. ft. From Table 22, by interpolation, $S_{max}/S_{avg} = 1.85 \therefore S_{max} = (563{,}000/55.8) \times 1.85$ = 18,685 lb. per sq. ft.

28

The **kern** is the area around the c. of g. of a cross-section within which any load applied will produce stress of only one sign throughout the entire cross-section. Outside the kern a load produces stresses of different sign. Fig. 81 shows kerns (shaded) for various sections.

For a **circular ring** the radius of the kern $r = D[1 + (d/D)^2]/8$.

For a **hollow square** (H and h = lengths of outer and inner sides) the kern is a square similar to Fig. 81(a), where

$$r_{\min} = \frac{H}{6}\frac{1}{\sqrt{2}}\left[1 + \left(\frac{h}{H}\right)^2\right] = 0.1179H\left[1 + \left(\frac{h}{H}\right)^2\right]$$

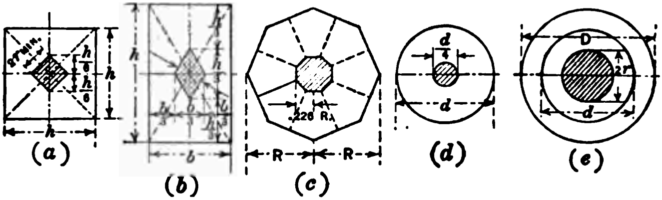

FIG. 81.

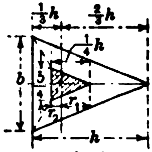

For a **hollow octagon** [R_a and R_i = radii of circles circumscribing the outer and inner sides; thickness of wall = 0.9239 ($R_a - R_i$)] the kern is an octagon similar to Fig. 81(c), where 0.2256R becomes

$$0.2256R_a[1 + (R_i/R_a)^2].$$

COLUMNS

A column differs from a tension bar in that any non-uniform yielding in the cross-section brings about further yielding. This non-uniform yielding is not serious in short blocks, but is serious in columns.

Columns are divided for analysis into **long columns** and **short columns,** in both of which initial inequalities introduce serious bending.

Long Columns fail by buckling at a load less than the elastic limit of the material. **Buckling** is the sudden collapse of a long column at or above the **critical load** at which equilibrium no longer obtains. The ratio of length to radius of gyration, or **slenderness ratio,** at which a column begins to fail by buckling, is between 100 and 120. Such columns are computed by Euler's formula. Few structural columns fail as long columns.

Short Columns with values of l/r less than 100 begin to fail when the ombination of direct stress and bending stress reaches the yield point of the aterial. The actual failure is dependent upon the homogeneity of the marial, the straightness of the column, and the eccentricity of loading, all of hich control bending stresses. Failure of built-up columns begins with a cal crippling at some part of the column. Such elements are not susceptible of calculation, and short columns of this kind are to be computed by empirical formulæ which are, however, modeled on rationally derived forms.

Failure of columns also depends upon the condition of their ends, as shown in Fig. 82: (a) **Free-ended** column, as a mast with a terminal load; (b) **round-ended,** as a spherical bearing; (c) **fixed-ended,** when rigidly connected to a rigid support; (d) **square-ended,** when a square-ended column abuts upon a support; and (e) a combination of rounded and fixed ends as a pin. The theoretical curves of flexure are shown by dotted lines. Columns of types (*c*), (*d*) and (*e*) are common. Pure conditions are only obtained practically in free-ended columns. Structural columns have various degrees of freedom. The elements controlling the strength of columns are so indeterminate and have been so little studied in detail, that refined analysis is misapplied.

Long Columns

Notation. A = Area of cross-section; P = load; l = length; r = radius of gyration = $\sqrt{I/A}$; f = deflection; I = rectangular moment of inertia; S = unit axial stress.

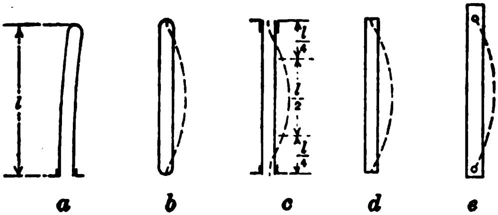

FIG. 82.

Euler's Formula. A perfect or ideal column with a straight axis, of uniform material, and loaded in the direction of its axis, would fail in direct compression like a short block. On account of imperfections, a sudden lateral deflection will occur under some critical load on a long column, which will then be no longer in equilibrium. The **critical load,** acting with a continually increasing leverage, will continue to bend the column until it fails by buckling. This critical load, P, for rounded ends, is given by Euler's formula (published in 1759) as follows:

$$P = \pi^2 EI/l^2$$

The assumptions made in deriving this formula are: (1) That the shortening of the column may be neglected; (2) that the bent length of arc is equal to the length of the vertical projection; and (3) that shearing forces may be neglected. To take account of end conditions, Euler's formula includes a coefficient n.

$$P = n\pi^2 EI/l^2$$

Table 23. Strength of Round-ended Columns According to Euler's Formula

P = allowable load, lb. l = length of column, in. b = smallest dimension of a rectangular section, in. d = diameter of a circular section, in. r = least radius of gyration of section.

Material	Cast iron	Wrought iron	Low-carbon steel	Medium-carbon steel	Wood (fir)
Ultimate compressive strength, lb. per sq. in.	107,000	53,400	62,600	89,000	4,000
Allowable compressive stress, lb. per sq. in.	7,100	15,400	17,000	20,000	850
Modulus of elasticity	14,200,000	28,400,000	30,600,000	31,300,000	1,400,000
Factor of safety	8	5	5	5	6 to 10
Smallest I allowable at worst section, in.^{4}	$\frac{Pl^2}{123{,}000}$	$\frac{Pl^2}{395{,}000}$	$\frac{Pl^2}{425{,}000}$	$\frac{Pl^2}{435{,}000}$	$\frac{Pl^2}{16{,}200 \text{ to } 9{,}700}$
Limit of ratio, $l/r <$	50.0	60.6	59.4	55.	40.5
Rectangle ($r = b\sqrt{1/12}$), $l/b <$	14.4	17.5	17.2	16.0	11.7
Circle ($r = \frac{1}{4}d$), $l/d <$	12.5	15.2	14.9	13.9	10.1
Circular ring of small thickness ($r = d\sqrt{1/8}$), $l/d <$	17.6	21.4	21.1	19.7	....

Values of n: Both ends rounded, n = 1; both ends fixed, n = 4; one rounded, one fixed, n = 2; one end fixed, one end free n = ¼. These values are theoretical. Experiments by Kirsch (*Zeit. Ver. Deutsch. Ing.*, 1905, p. 907) show that when $l/r = 100$ the relation of the first three coefficients, instead of being 1 : 4 : 2, is 1 : 1.13 : 1.05, and when $l/r = 200$, it is 1 : 3.0: 1.78 in the case of wrought-iron bars 20 mm. (0.79 in.) thick.

Euler's formula is proved to be reliable for long columns that fail by buckling within the elastic limit by Tetmajer's experiments (*Zeit. Ver. Deutsch. Ing.*, 1896, p. 1404). The value of the ratio (l/r) at which failure of round-ended columns by buckling occurred was as follows: Wrought iron, 112; soft steel, 105; medium steel, 90; cast iron, 80; wood, 100.

The use of Euler's formula is more common in Germany than elsewhere. Table 23, for columns with rounded ends $(n = 1)$, is based on this formula.

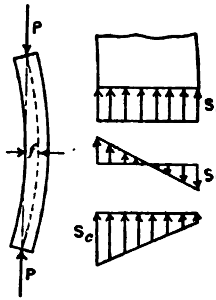

Fig. 83.

Short Columns

Rankine's Formula applies to short columns, which fail under the stress S_c (Fig. 83), this stress being the sum of (1) the stress S_0, a uniform compression due to P acting as an axial load, and (2) S_B in the outer fiber due to moment M of P acting with a lever arm f around the gravity axis of the section. $S_0 = P/A$ and $S_B = Mc/I = Pfc/Ar^2$; $P = S_cA/[1 + (fc/r^2)]$, where r is the radius of gyration and c the distance from the outer fiber to the gravity axis. Here f is unknown and is replaced by Kl^2/c, giving Rankine's formula

$$P = S_cA/[1 + K(l^2/r^2)]$$

This is largely used in design. Values of K have been derived experimentally, and those recommended by Merriman are given in Table 24. Rankine's formula is to be used for values of $l/r = 20$ to 120. The value of S_c should be the allowable unit stress for designing, and should be the ultimate compressive strength where ultimate load is required.

Table 24. Values of the Coefficient K in Rankine's Formula

Material	Both ends fixed	Fixed and rounded	Both ends rounded	Fixed and free
Timber	1/3000	1.95/3000	4/3000	16/3000
Cast iron	1/5000	1.95/5000	4/5000	16/5000
Wrought iron	1/36000	1.95/36000	4/36000	16/36000
Steel	1/25000	1.95/25000	4/25000	16/25000

Tetmajer's Experiments on round-ended columns (*Zeit. Ver. Deutsch. Ing.*, 1896, p. 1404) show that K varies with the material of the column and with the value of l/r. For wrought iron, K varied from 0.000448 to 0.000136; for steel, from 0.000370 to 0.000130. Tetmajer's recommended values for K are as follows:

	l/r	K
Cast iron	20 to 150	0.00070
Wrought iron	20 to 250	0.00016
Soft steel	20 to 250	0.00014
Wood	20 to 200	0.00023

Tetmajer's Formula for ultimate loads on round-ended columns is

$$S = S_c[1 - a(l/r) + b(l/r)^2]$$

Table 25. Values to be Used in Tetmajer's Formula for Short Columns

Materials	S_c	a	b	Limits of l/r Min.	Limits of l/r Max.
Cast iron	110,000	0.01546	0.00007	5.0	80
Wrought iron	43,000	0.00426	0.0	10.0	112
Hard steel	48,000	0.00185	0.0	.....	90
Soft steel	44,000	0.00368	0.0	10.0	105
Wood	4,200	0.00662	0.0	1.8	100

Straight-line Formula for Columns. Plotted results of tests yield a straight-line relation between the load at failure and the slenderness ratio l/r. T. H. Johnson's formula is

$$P/A = S - C(l/r)$$

where S is the unit strength of a very short column, and C is a constant obtained by drawing the straight line tangent to a curve representing Euler's formula at a point where $l/r = 150$. The values recommended for use in this formula are given in Table 26. For designing, S and C should be divided by a proper factor of safety.

Table 26. Constants for Use in Johnson's Straight-line Column Formula

Kind of column	S lb. per sq. in.	C	Limit of l/r
Wrought iron:			
Flat ends	42,000	128	218
Hinged ends	42,000	157	178
Round ends	42,000	203	138
Steel:			
Flat ends	52,500	179	195
Hinged ends	52,500	220	159
Round ends	52,500	284	123
Cast iron:			
Flat ends	80,000	438	122
Hinged ends	80,000	537	99
Round ends	80,000	693	77
Oak:			
Flat ends	5,400	28	128

Table 27. Allowable Unit Stresses (lb. per sq. in.) on Steel Columns According to Various Formulæ

$\frac{l}{r}$	American Bridge Co. $19000-100\frac{l}{r}$ 13000 max.	A. R. E. Assn. and Chicago $16000-70\frac{l}{r}$ 14000 max. 90	10,000	9,700	10,205	9,980	9,360	11,390
100	9,000	9,000	9,785	9,400	8,510	10,670
110	8,000	8,300	9,355	8,820	7,740	9,970
120	7,000	7,600	8,930	8,240	7,035	9,300

Table 27 gives the allowable unit stresses for **steel columns** as deduced from the American Bridge Co.'s formula, and also as deduced from the American Railway Engineering Association formula (A. R. E. Ass'n); the Gordon formula, and the formulæ from the building codes of the cities of Chicago, New York, Philadelphia and Boston.

For tables of structural-steel columns see pp. 1297 to 1302.
For tables of steel-pipe columns see p. 1279.

For columns carrying traveling machinery, cranes, etc., add 25 per cent. to the live load to allow for impact and vibration.

W. H. Burr's tests on **cast-iron columns** at Phoenixville (*Eng. News*, June 30, 1898) gave a wide range of results. The **average ultimate strength** (lb. per sq. in.) for round columns is expressed by $P/A = 30{,}500 - 165(l/d)$, where d and l are expressed in the same units. A large factor of safety, 4, must be used with cast-iron columns. Maximum slenderness ratio is 70. For tables of cast-iron columns, see p. 1278.

For **wood,** the formula recommended by Am. Ry. Eng. Assn., 1909, is: $S_1 = S\ (1 - l/60d)$, in which S_1 = safe working stress; S = safe stress in compression along grain (see p. 1277); l = length of column, d = least side. l and d are expressed in same unit. Table 28 is calculated from this formula. For l/d less than 15, use S. No column should have a value of l/d greater than 60.

Table 28. Safe Loads for Square Wooden Columns in Units of 1000 Lb.

(Based on safe end-bearing compression of 1000 lb. per sq. in.)

Unbraced length in feet	Size of column in inches						
	4 × 4	6 × 6	8 × 8	10 × 10	12 × 12	14 × 14	16 × 16

44						72.8	115.2
46						67.2	108.8
48							102.4
50							96.0

For values of S_1 for common woods, see pp. 590 and 591.

COMBINED STRESSES

Combined Flexure and Torsion arise when a twisted shaft is bent by belts or other forces. Elements of the shaft become helices of variable pitch. An element of the surface (Fig. 84) is subjected to a flexural unit stress S due to bending moment M, and a shearing unit stress S_v, due to torsional moment

M_t. $S = My/I = 8Pl/\pi d^3$, and $S_v = 16M_t/\pi d^3$ for a circular shaft. S and S_v combine (Fig. 84) to produce internal normal (S_n) and tangential (S_t) unit stresses on an interior plane (see p. 000). In Fig. 85, S_n and S_t vary with the

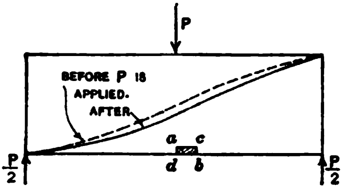

FIG. 84.

angle d. S_n is a maximum when $\cot 2d = -S/2S_v$, and S_t is a maximum when $\tan 2d = +S/2S_v$. The maximum apparent stresses are:

$$S_n = \tfrac{1}{2}S \pm \sqrt{S_v^2 + (\tfrac{1}{2}S)^2} \qquad S_t = \sqrt{S_v^2 + (\tfrac{1}{2}S)^2}$$

These formulæ also apply to any case of **normal stress combined with shear**, as when a bolt is under tension and shear, or when the material of a beam is under tension (or compression) and shear. When S is tension, use (+) sign in order to find the maximum tensile stress S_n, and use (−) sign to find the maximum compressive stress S_n. For **strength under combined stresses**, see p. 391.

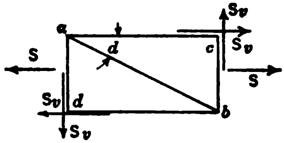

FIG. 85.

Combined Torsion and Longitudinal Force

A common case is the shaft of a vertical turbine. The longitudinal force is then compression. If W be the weight carried on the shaft in pounds, d the shaft diameter in inches, H the horse power transmitted, and n the r.p.m.,

$$S_n = \frac{2W}{\pi d^2} + \sqrt{\frac{321{,}000^2\, H^2}{n^2 d^6} + \frac{16W^2}{\pi^2 d^4}}$$

Combined Flexure and Longitudinal Force

Fig. 86 shows a bar under flexure due to transverse and longitudinal loads. The maximum fiber stress S (Fig. 86) is made up of S_0, due to the direct action of load P, and S_b, due to the entire bending moment M. M is the algebraic sum of two bending moments, M_1 due to longitudinal load (+ for compression and − for tension), and M_2 due to transverse load. $M = M_2 \pm M_1$. Here $M_1 = Pf$ and $f = C''S_0 l^2/Ec$.

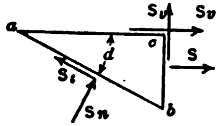

FIG. 86.

$$\frac{S_b I}{c} = M_2 \pm \frac{PC''S_0 l^2}{Ec}, \quad \text{or} \quad S_b = \frac{M_2 c}{I \pm \dfrac{Pl^2}{CE}}$$

$C = 10$ for hinged-end columns, 24 for one end hinged and other end fixed, and 32 for both ends fixed. M is the total eccentric moment. The + sign should be used when P is compression, and − when P is tension.

A common method for **computing stresses on eccentrically loaded**

columns consists in adding to the uniform stress, P/A, the additional stresses due to column action, $(P/A)(Kl^2/r^2)$, as given by Rankine's formula, and that due to eccentricity, $(P/A)(ey/r^2)$. Thus,

Total stress $= \frac{P}{A}\left(1 + \frac{ey}{r^2} + \frac{Kl^2}{r^2}\right)$ when $S_b = \frac{P}{A}\left(1 + \frac{ey}{r^2}\right)$ = stress due to flexure, and $S_c = \frac{P}{A}\left(1 + \frac{Kl^2}{r^2}\right)$ = stress due to longitudinal load.

BENDING OF CURVED BEAMS

(From Morley's "Strength of Materials")

Simple beam equations apply when the radius of curvature of a curved beam is large (8 to 10 times) compared to dimensions of its cross-section. This is not the case in hooks, links, and rings, when some modification of formulæ is necessary. Plane cross-sections, normal to the axis of curvature, are assumed. The deformation (e) is proportional to the distance from the gravity axis, but the unit deformation (s) is not proportional, since the lengths of the fibers vary. The elongation of any curved fiber is evaluated, and the stress determined. E is used. The neutral axis is not at the c. of g., but is near the center of curvature. The stress variation is not rectilinear (Fig. 87).

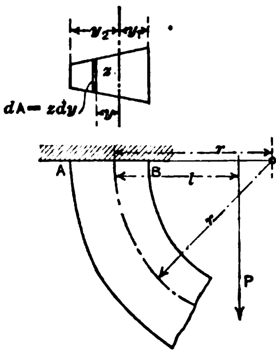

FIG. 87.

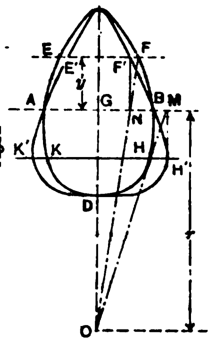

FIG. 88.

In Fig. 87, P = load; l = leverage of load about axis through c. of g. of cross-section; M = moment due to $P = Pl$; A = area of cross-section; r = radius of curvature of undeformed beam from center of curvature to c. of g. of cross-section. Stress due to combination of direct load P (taken as acting at c. of g.) and moment $M = S$, or the normal unit stress at distance y from axis through c. of g. The equations which follow are for pure bending, but apply with little error to ordinary bending, including shear.

$$S_1 \text{ (at } B) = \frac{M}{r(A' - A)}\left(\frac{r}{r - y_1} - \frac{A'}{A}\right) + \frac{P}{A} \text{ (tension)}$$

$$S_2 \text{ (at } A) = \frac{M}{r(A' - A)}\left(\frac{A'}{A} - \frac{r}{r + y_2}\right) - \frac{P}{A} \text{ (compression)}$$

where $$A' = r\Sigma\left(\frac{dA}{y + r}\right)$$

The neutral axis is at a distance y' from c. of g., where $y' = r\left(\frac{A' - A}{A'}\right)$.

A' may be considered as a "modified" area, and is obtained graphically (Fig. 88) as follows: To find $A' = r\Sigma\left(\frac{dA}{y + r}\right)$, first find the c. of g. of the original cross-section. Lay off O so that $OG = r$. Change each width in the ratio of $r/(y+r)$. For example, draw OF intersecting AB in N. Draw NF' perpendicular to AB, giving F'. Then $E'F'$ is the modified width. Similarly, KH becomes $K'H'$. The new area A' is evaluated with a planimeter.

VALUES OF A'. Rectangle (height $= h$, width $= b$): $A' = bd[1 + (h/r)^2/12 + (h/r)^4/80 + \ldots]$. Circle (radius $= R$): $A' = 2\pi r[r - \sqrt{r^2 - R^2}]$. Any Section: $A' = \Sigma\{[1 - (y/r) + (y^2/r^2) - (y^3/r^3) + (y^4/r^4) - \text{etc.}]\,dA\}$. Symmetrical Sections: $A' = A + (I/r^2) + (1/r^4)\Sigma(y^4da) + \text{etc.}$, where I is the moment of inertia of the section about the axis from which y is measured.

Example—Stress in Hooks (Fig. 89). The central horizontal section AB is a trapezoid; area $= 9.855$ sq. in. Radius of curvature $r = 2.5 + 1.843 = 4.343$ in. Eccentricity of load $= 4.343$ in. $A' = 10.673$ sq. in. $y' = 0.33$ in. $M = 20{,}000 \times 4.343$. Substituting in the above equations,

$$S_1 = \frac{20{,}000 \times 4.343}{4.343 \times 0.818}\left(\frac{4.343}{2.5} - \frac{10.673}{9.855}\right) + \frac{20{,}000}{9.855}$$

$= 17{,}700$ lb. per sq. in. tension.

$$S_2 = \frac{20{,}000 \times 4.343}{4.343 \times 0.818}\left(\frac{10.673}{9.855} - \frac{4.343}{7}\right) - \frac{20{,}000}{9.855}$$

$= 9120$ lb. per sq. in. compression.

By the ordinary theory (p. 404), tension at $B = 12{,}700$ lb. per sq. in., and compression at $A = 13{,}380$ lb. per sq. in.

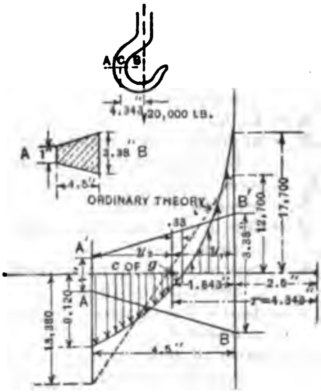

FIG. 89.

Crane Hooks. Experiments by Rautenstrauch (*Am. Mach.*, Oct. 7, 1909) yield the results given in Table 29. They show that the capacity of a hook calculated according to the ordinary theory is in excess of its real strength. See also p. 761.

Table 29. Elastic Limit of Crane Hooks

A = area, sq. in. I = moment of inertia. l = distance from load line to gravity axis, in. y = distance from inner fiber to gravity axis, in.

REINFORCED-CONCRETE DESIGN

For reinforced-concrete construction and tables of dimensions of construction units, see pp. 1305 to 1316.

Standard Notation

RECTANGULAR BEAMS:

f_s = tensile unit stress in steel.
f_c = compressive unit stress in concrete.
E_s = modulus of elasticity of steel.
E_c = modulus of elasticity of concrete.
$n = E_s/E_c$.
M = moment of resistance, or bending moment in general.
A_s = steel area.
b = breadth of beam.
d = depth of beam to center of steel.
k = ratio of depth of neutral axis to effective depth d.
z = depth of resultant compression below top.
j = ratio of lever arm of resisting couple to depth d.
$jd = d - z$ = arm of resisting couple.
p = steel ratio (not percentage).
R = coefficient in formula $M = Rbd^2$.

T-BEAMS:

b = width of flange.
b' = width of stem.
t = thickness of flange.

BEAMS REINFORCED FOR COMPRESSION:

A' = area of compressive steel.
p' = steel ratio for compressive steel.
f'_s = compressive unit stress in steel.
C = total compressive stress in concrete.
C' = total compressive stress in steel.
d' = depth to center of compressive steel.
z = depth to resultant of C and C'.

SHEAR AND BOND:

V = total shear.
v = shearing unit stress.
u = bond stress per unit area of bar.
o = circumference or perimeter of bar.
Σo = sum of the perimeters of all bars.

COLUMNS:

A = total net area.
A_s = area of longitudinal steel.
A_c = area of concrete.
P = total safe load.

Reinforced Concrete Under Axial Stress

The following formulæ may be used for (*a*) columns with longitudinal steel only and (*b*) columns with longitudinal steel and circular hoops or spirals by adopting proper values of f_c, as suggested on p. 1306.

$$P = f_c(A_c + nA_s) = f_cA[1 + (n - 1)p] \qquad (1)$$

The spirals are not figured directly, but their effect is considered by increasing the value of f_c. In figuring the total net area A and the area of concrete A_c, the outside shell composing the fireproofing must not be included. For columns with spirals, A is the area of the concrete within the spirals.

For dimensions of round and square columns, see p. 1315.

Columns with Rigid Structural Shapes, when the cross-section of steel exceeds 4 per cent., may be considered as equal in strength to those of the structural shapes (figured according to usual formula for structural steel columns) plus the strength of the concrete within the structural shapes. The unit working stress for this concrete core may be accepted at 75 per cent. of f_c used for columns with longitudinal steel only. The outer shell which is required as fireproofing should not be considered as adding to the strength of the column.

Reinforced Concrete Under Flexure

Beams of concrete are reinforced in the tension flange to prevent failure in tension; and more rarely in the compression flange; and at the ends, either by stirrups, or by bending the longitudinal reinforcement, or both, to prevent failure by diagonal tension produced by the resultant of horizontal and vertical shear. (See p. 1309.) In the following formulæ certain assumptions are made in addition to those of the theory of flexure, namely, that the concrete adheres perfectly to the steel and carries no tensile stress, that the compressive stress-strain relation is rectilinear, and that there are no initial stresses.

Rectangular Beams (Fig. 1):
Position of neutral axis,

$$k = \sqrt{2pn + (pn)^2} - pn \tag{2}$$

Arm of resisting couple,

$$j = 1 - k/3 \tag{3}$$

[For f_s = 15,000 to 16,000 and f_c = 600 to 650, k may be taken at 3/8.]
Fiber stresses,

$$f_s = M_s/A_sjd = M_s/pjbd^2,\ A_s = M_s/f_sjd,\ d = \sqrt{M_s/f_spjb} \tag{4}$$

$$f_c = 2M_c/jkbd^2 = 2pf_s/k \tag{5}$$

Steel ratio, for balanced reinforcement,

$$p = \tfrac{1}{2} \times 1 \Big/ \frac{f_s}{f_c}\left(\frac{f_s}{nf_c} + 1\right) \tag{6}$$

M_s = Moment of resistance in terms of steel stress $= f_sA_sjd$ (7)
M_c = Moment of resistance in terms of concrete stress $= \tfrac{1}{2}f_ckjbd^2$ (8)

For usual beams of 1 : 2 : 4 Portland cement concrete, the approximate value of j is 7/8, k is 3/8, and p is 0.75/100 to 1/100. The value of j varies from 0.9 at 0.5 per cent. reinforcement to 0.82 for 2 per cent. reinforcement. A given percentage of reinforcement fixes the ratio of f_s to f_c. In determining the sections, make the bending moment equal to the moments of resistance from formulæ (7) or (8). When the moments of resistance from the two formulæ are not equal, use the smaller value.

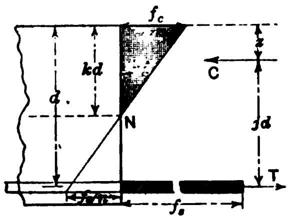

FIG. 1.

At early loads on reinforced-concrete beams rich concrete under tensile stress supplies nearly half the resisting moment. At a stress in the steel of 5000 lb. per sq. in. the concrete in tension begins to crack and throws more stress on the steel. The beam attains its ultimate strength when the yield point of the steel is reached. With weak concrete and a high percentage of steel, failure in compression may result. Deep beams with high shear may fail at ends, and show a diagonal crack.

T-beams. (Fig. 2.) When a slab joins a girder, a portion of the slab, of width not greater than one-fourth the span length of the beam and not overhanging the beam more than 4 times the thickness of the slab, is usually counted upon to withstand compression integrally with the girder, forming a "T" beam. Here $p = A_s/bd$. When the flange is thick ($t > d/4$) and the neutral axis lies in the flange, use the formulæ for rectangular beams. When the neutral axis is in the stem and the compression in stem is neglected, the following formulæ apply:

Table 1. Factors for Rectangular Reinforced-concrete Beams

(Portland cement concrete. $n = 15$)

f_c	f_s	p	k	j	$R = M/bd^2$

800	18,000	0.00889	0.400	0.867	138.7
800	20,000	0.00750	0.375	0.875	131.2

Position of neutral axis,

$$kd = (2ndA_s + bt^2)/(2nA_s + 2bt) \tag{9}$$

Position of resultant compression,

$$z = (t/3) \times (3kd - 2t)/(2kd - t) \tag{10}$$

Arm of resisting couple,

$$jd = d - z. \tag{11}$$

Fiber stresses,

$$f_s = M/A_s jd \tag{12}$$

$$f_c = Mkd/[bt(kd - \tfrac{1}{2}t)jd] = (f_s/n) \times k/(1 - k) \tag{13}$$

(For approximate results the formulæ for rectangular beams may be used.)

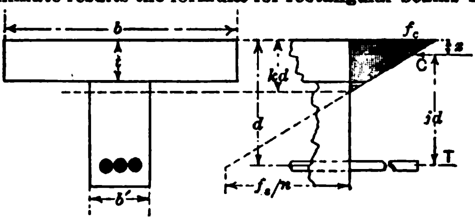

FIG. 2.

The following formulæ take into account the compression in the stem; they are recommended where the flange is small compared with the stem:

Position of neutral axis,

$$kd = \sqrt{\frac{2ndA_s + (b - b')t^2}{b'} + \left(\frac{nA_s + (b - b')t}{b'}\right)^2} - \frac{nA_s + (b - b')t}{b'} \tag{14}$$

Position of resultant compression,

$$z = \frac{(kdt^2 - \frac{2}{3}t^3)b + \{(kd - t)^2[t + \frac{1}{3}(kd - t)]\}b'}{t(2kd - t)b + (kd - t)^2b'} \tag{15}$$

Arm of resisting couple,

$$jd = d - z. \tag{16}$$

Fiber stresses,

$$f_s = M/A_sjd \tag{17}$$

$$f_c = 2Mkd/\{[(2kd - t)bt + (kd - t)^2b']jd\} \tag{18}$$

Shearing stresses must be considered in the webs of T-beams, and compressive stresses in stems of continuous T-beams.

For dimensions of T-beam for uniform loading, see p. 1311.

Beams Reinforced for Compression (Fig. 3):

Position of neutral axis,

$$k = \sqrt{2n[p + p'(d'/d)] + n^2(p + p')^2} - n(p + p') \tag{19}$$

Position of resultant compression,

$$z = \frac{\frac{1}{3}k^3d + 2p'nd'[k - (d'/d)]}{k^2 + 2p'n[k - (d'/d)]} \tag{20}$$

Arm of resisting couple,

$$jd = d - z. \tag{21}$$

Fiber stresses,

$$f_c = 6M/bd^2 \left[3k - k^2 + \frac{6p'n}{k}\left(k - \frac{d'}{d}\right)\left(1 - \frac{d'}{d}\right)\right] \tag{22}$$

$$f_s = M/pjbd^2 = nf_c(1 - k)/k \tag{23}$$

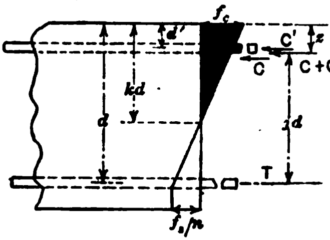

FIG. 3.

$$f'_s = nf_c[k - (d'/d)]/k \tag{24}$$

Bond Stress Between Steel and Concrete, and Shearing Stress. Let V = total vertical shear, u = bond stress per sq. in. between rod and concrete, v = maximum unit shearing stress, o = perimeter of bar, Σo = sum of perimeters of all bars constituting tension reinforcement. Then

For rectangular beams, $v = V/bjd$ (25)

For T-beams, $v = V/b'jd$ (26)

For rectangular and T-beams, $u = V/jd\Sigma o$ (27)

Stresses in Stirrups. A vertical stirrup is computed to carry a load equal to a portion of the vertical shear per sq. in. times the width of the beam times the spacing of the stirrups. The portion of the shear carried by the stirrup is taken to be the shear in excess of 40 lb. per sq. in. (for 1:2:4 concrete).

$$P = mvsb = \frac{mVsb}{\frac{7}{8}db} = \frac{mVs}{\frac{7}{8}d} \tag{28}$$

where P = total load on stirrup, s = horizontal spacing, v = unit shearing stress, V = total vertical shear in beam, and m = fractional part of shear carried on stirrup. The amount of shear carried by inclined stirrups or bent rods is

$$P = 0.7mVs/\tfrac{7}{8}d \tag{29}$$

and

$$\text{the area of cross-section of stirrup} = P/2f_s \tag{30}$$

m may be taken as ⅔, thus allowing ⅓ of the shear to be carried in the concrete.

Deflection of Reinforced-concrete Beams. Tests by Humphrey and Losse (Tech. Papers, Bureau of Standards, No. 2) show that centrally loaded and freely supported beams of 1:2:4 concrete with a stress of 16,000 lb. per sq. in. in steel deflect 1/1000 part of the span, and 1/720 part of the span for 0.5 per cent. and 1.6 per cent. reinforcement, respectively. Tests of buildings designed under the Chicago Ordinance with an imposed load of twice the load for which the buildings were designed, yielded a deflection of 1/800 span for the beams and 1/4000 span for the girders. The measured stress in the steel varied from 8000 to 11,000 lb. per sq. in. Here the concrete adjoining the member under test assists in carrying the load through arch action and slab action.

Flat-slab Floors (Fig. 4) are without beams or girders. They are continuous from one panel to another and are usually supported on enlarged column heads. The system of reinforcement may be either four-way or two-way. A **four-way reinforcement** system consists of two diagonal bands and two cross bands. **Two-way reinforcement** runs crossways from column to column, in bands in which the reinforcement varies in quantity, and in other bands which run at right angles to these. Tests of completed structures show that the greatest moment is over the column capital, and the least in the center of the panel. The circle of inflection is distant approximately ¼ of the span from center to center of columns. The greater moment over the column head is best met by increasing the thickness of the slab around the column. The following proportions for column heads will yield conservative designs (see *Eng. News*, Sept. 24, 1914):

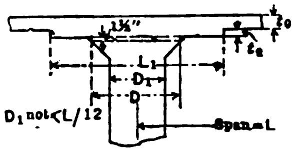

FIG. 4.

$$t_0 \geq L/32 \qquad t_2 \leq 0.4t_0$$
$$D = 0.225L \qquad L_1 \geq 0.4L$$

where L = span center to center of columns along side of panel; t_0 = thickness of slab at center; t_2 = increased thickness of slab; L_1 = width of band, D = diam. of column capital measured where its vertical thickness is at least 1½ in. (Fig. 4). The flare of the column capital should not make an angle greater than 45 deg. with the vertical.

Tests of completed buildings show that conservative design results when the following external bending moments are provided for in case of square panels of four-way systems:

Moment over column = $WL/15$; moment in center of panel = $WL/25$, where W = total live and dead load on panel, and L = span between column centers along side of panel. The reinforcing steel supplying these moments is divided into four bands. It would be theoretically possible to so increase the thickness of the slab over the column that the same steel would meet both $WL/15$ and $WL/25$. However, (1) the crossing of four layers of rods over the column cap cuts down the effective depth, and (2) it is necessary to lap some of the rods over the column. The latter rods when computed as adding to the reinforcement should lap over into the next panel to nearly the ¼ point. The rods over the column should continue in the top of the slab to nearly the ¼ point of the span. An example will explain the method of design.

For dimensions of slabs for different spans and loads see p. 1308.

Design of Flat-slab Square Panel. Example. Span $L = 20$ ft. Total load = 360 lb. per sq. ft. (= 250 lb. live load + 110 lb. dead load). Assume $f_s = 18{,}000$ and $f_c = 700$, whence $R = 113$. To obtain the approximate depth d of slab, employ the usual beam formula $M = Rbd^2$, in which $M = WL/25 = [(360 \times 20) \times 20 \times 12/25] = 69{,}120$ in.-lb. for a beam 12 in. wide and of 20 ft. span; whence $d = \sqrt{M/Rb} = \sqrt{69{,}120/(113 \times 12)} = 7.15$ in. Adding 0.75 in. for steel protection, $d = 7.9$ in., say, an 8-in. slab.

To Design Steel at Center: Load moment $= WL/25 = 360 \times 20^3 \times 12/25 = 1{,}382{,}400$ in.-lb. Area of steel [from (7)] $= A_s = M/f_s jd$, or, taking $j = 7/8$ (approx.), $A_s = 1{,}382{,}400/(18{,}000 \times 7/8 \times 7.15) = 12$ sq. in. ∴ Steel in each of the four bands $= 12/4 = 3$ sq. in., or area of sixteen ½-in. round rods (3.14 sq. in.). Width of band $= 0.4L = 8$ ft. $= 96$ in. Spacing of rods $= 96/(16 - 1) = 6.4$ in. center to center.

To Design Steel over Column. Thickness of slab over column $= t_3 = t_0 + 0.4t_0 = 8 + (0.4 \times 8) = 11.2$ in., say 11.5 in. Allowing ½ in. of concrete over the steel, the distance to the center of gravity of the four layers of rods is $11.5 - (½ + 1) = 10$ in. Load moment over column $= WL/15 = 360 \times 20^3 \times 12/15 = 2{,}304{,}000$ in.-lb. Steel required in 4 bands over column $= 2{,}304{,}000/(7/8 \times 18{,}000 \times 10) = 14.63$ sq. in. Steel at center of panel $= 4 \times 3.14 = 12.56$ sq. in. Additional steel required over column $= 14.63 - 12.56 = 2.07$ sq. in. To obtain this, lap 10 rods. The rods should be bent from bottom to top of slab near the point of inflection.

To obtain the **compressive stresses**, assume that all the steel is in one band, and that the components of two diagonal bands in this direction act on a plane tangent to the edge of the column cap. Thus, in the example, the steel acting to compress the concrete in a direction at right angles to any band has a cross-section of $3.65 + (2 \times 3.65 \cos 45 \text{ deg.}) = 3.65 + (3.65 \times 1.4) = 8.76$ sq. in., which at 18,000 lb. stress $= 157{,}680$ lb. This pull acts on an area equal to the width of the band times the depth to the neutral axis $= 96 \times 3/8 \times 10 = 360$ sq. in., and the maximum stress $f_c = 2 \times 157{,}680/360 = 876$ lb. per sq. in. In slabs of uniform thickness the width of compression area may be taken as the width of band plus three times the thickness of the slab.

Reinforcement for shrinkage placed in the top of the slab throughout the central portion of the area directly between columns inside the lines of inflection, will serve also to stiffen the slab and carry eccentric loads to adjoining panels. Rectangular panels, in which the long side is not more than ⅓ greater than the short side, may be designed by the following rule: Design a square panel whose diagonal equals that of the rectangular panel. The amount of steel in the long side of a rectangular panel equals that in the side of the square panel times L_1^3/L_0^3, and the amount of steel in short side of rectangular panel equals that in the side of square panel times L_0^3/L_2^3, where L_0 = side of equivalent square, L_1 = long side of rectangular panel, and L_2 = short side of rectangular panel. In no case should the amount of the steel in the short side be less than two-thirds of that required for the long side.

Coefficients for bending moments at the middle of **wall panels** should be increased 20 per cent. over those required for interior panels. **Shearing stresses** around column capital and other critical sections should not exceed 120 lb. per sq. in.

GENERAL PROPERTIES OF MATERIALS

BY

LOUIS A. FISCHER

CHEMISTRY

A **substance** which cannot be separated into two or more recognizably different substances by any physical means, is known as a **chemically pure substance.** A chemically pure substance is considered to consist of a great number of very small particles, all exactly alike, known as **molecules.** If a chemically pure substance cannot by any available means be separated into two or more different substances, it is known as a **chemical element.** Chemically pure substances which can be separated or decomposed into different elements by chemical means, or which can be made by combining different elements, are known as **chemical compounds.**

The molecules are aggregates of still smaller particles. These smaller particles are known as **atoms,** and the atoms of a given element are regarded as all precisely alike in every respect. The atoms are thus to be considered as the smallest mass-elements which occur separately in the structure of molecules of either compound or elementary substances, so far as can be determined by ordinary chemical analysis. The molecule of an element consists of a definite (usually small) number of its atoms. The molecule of a compound consists of one or more atoms of each of its several elements, the members of the various kinds of atoms and their arrangement being definite and fixed, and determining the character of the compound. This notion of molecules and their constituent atoms is useful for interpreting the observed fact that chemical reactions—*e.g.*, the analysis of a compound into its elements; the synthesis of a compound from the elements, or the changing of one or more compounds into one or more different compounds—take place so that the masses of the various substances concerned in a given reaction stand in definite and fixed ratios.

It appears from recent researches that some substances which cannot by any available means be decomposed into simpler substances and which must therefore be defined as elements, are continually undergoing spontaneous changes or **radioactive transformation** into other substances which can be recognized as physically and chemically different from the original substance. Radium is an element by the definition given and may be considered as made up of atoms. But it is assumed that these atoms, so called because they resist all efforts to break them up and are therefore apparently indivisible, nevertheless split up spontaneously, at a rate which chemists have not been able to influence in any way, into other atoms, thus forming other elementary substances of totally different properties.

The view generally accepted at present is that the atoms of all the chemical elements, including those not yet known to be subject to radioactive transformation, consist of aggregates of large numbers of still smaller particles known as corpuscles or **electrons;** and that these electrons are all alike, the differences between the atoms of different chemical elements being due to the different numbers and arrangements of these smaller particles composing them. An ordinary atom is conceived to be a stable system of such electrons revolving in closed orbits about their common center of mass like the planets of the solar system round the sun. The number of these electrons is, however, very great, about 2000 in one hydrogen atom and about 450,000 in one radium atom. The larger the number of electrons forming a given independent and self-contained system (atom), the greater is the probability that accidental perturbations of the orbits will result in momentary instability, the ejection of one or more electrons from the system and a con-

sequent rearrangement of the remainder into a new stable state of steady motion. This working hypothesis agrees with the fact that the heaviest known atoms—those of uranium, thorium and radium—are the most subject to radioactive transformation, and with a number of other physical observations, but should not at present be regarded as more than a convenient scheme for co-ordinating a number of phenomena about which little is known.

Chemical Elements[1]

Element	Symbol	Atomic weight	Valence	Element	Symbol	Atomic weight	Valence
Aluminum	Al	27.1	3	Molybdenum	Mo	96.0	3, 4, 5, 6, 8

[1] All the elements are metals, except as otherwise indicated.
[2] Inert gas. [3] Metalloid. [4] Liquid. [5] Gas.
[6] Most active gas. [7] Lightest gas. [8] Lightest metal. [9] Not placed.

Calculation of the Percentage Composition of Substances. Add together the atomic weights of the elements in the compound to obtain its molecular weight. Multiply the atomic weight of the element to be calculated by the number of atoms present (indicated in the formula by a subscript number) and by 100, and divide by the molecular weight of the compound. For example, hematite iron ore (Fe_2O_3) contains 69.94 per cent. of iron by weight, determined as follows: Molecular weight of $Fe_2O_3 = (55.84 \times 2) + (16 \times 3) = 159.68$. Percentage of iron in compound $= (55.84 \times 2) \times 100/159.68 = 69.94$.

Solubility of Inorganic Salts in Water

(Number of grams of the anhydrous salt soluble in 1000 grams of water)

Compressibility of Liquids

If v_1 and v_2 are the volumes of the liquids at pressures of p_1 and p_2 atmospheres respectively and at a temperature of t deg. cent., the coefficient of compressibility b is given by the equation

$$b = \frac{1}{v_1} \times \frac{v_1 - v_2}{p_1 - p_2}.$$

Values of b for water are given in the following table:

Coefficient of Compressibility of Water

(Values of $b \times 10^7$)

Temp., deg. cent.	Pressure range in atmospheres							
	1-25	1-100	1-500	500-1000	1000-1500	1500-2000	2000-2500	2500-3000
0	525	511	475	416	358	324	292	261
20	491	468	434	....	338	....	....	....
50	......	449	416	....	325	....	....	254

The value of $b \times 10^6$ for oils at low pressures at about 20 deg. cent. varies from about 55 to 80; for mercury at 0 deg. cent. it is 3.9; for chloroform at 0 deg. cent. it is 100 and increases with the temperature to 200 at 60 deg. cent.; for ethyl alcohol it increases from about 100 at 0 deg. cent. and low pressures to 125 at 40 deg.; for glycerine it is about 24 at room temperature and low pressure.

Surface Tension of Liquids

Liquid	Surface tension (in dynes per cm.) of liquid in contact with		
	Air	Water	Mercury
Water	75.0	0.0	392
Mercury	513.0	392.0	0
Bisulphide of carbon	30.5	41.7	387

CLASSIFICATION OF IRON AND STEEL

At the Brussels Congress of the International Association for Testing Materials held in 1906, the following **definitions** of the most important forms of iron and steel were adopted. The definitions of steel and of wrought iron are those proposed to the New York Congress (1912) by the International Committee on Nomenclature.

Steel of Fluid Origin is iron cast from a molten state into a mass which is usefully malleable (initially, at least) in some one range of temperature. Such metal is steel whether it can be hardened or not, whether it contains much or little or even no carbon, and for that matter even if it is chemically pure iron. These steels have been divided into: (*a*) **Ingot iron,** or steel with too little carbon to harden usefully on rapid cooling. The name is misleading but is used by some as a trade name; and (*b*) **ingot steel,** or steel with enough carbon (say, 0.30 per cent. or more) to harden usefully on rapid cooling. Steel made by melting in a crucible is called "crucible steel;" that made in an electric furnace is called "electric steel."

Steel of Plastic Origin is iron which is aggregated from pasty particles without subsequent fusion; is malleable at least in some one range of temperature; and contains enough carbon (say, 0.30 per cent. or more) to harden usefully on rapid cooling from above its critical range. Blister steel and its derivatives and a few other high-carbon steels which are unimportant to-day, are the only present steels covered by this definition.

Blister Bar, Cement Bar, Converted Bar, are names given to steel of plastic origin made by cementing wrought iron with carbonaceous matter; also, commercially, to such steel when heated and worked into merchant sizes. Most writers have used "blister steel" in the former and broader sense. In Sheffield it is used solely in the latter and narrower sense. The blister steel of commerce is made by cementing very pure wrought iron with charcoal. The term "cemented bar" may be applied in a general sense to any wrought-iron bar which has been subjected to a process of cementation.

Blister Steel (or Converted Steel) is the name given to bars rolled or forged from blister bar. Many writers have used "blister steel" in the sense of "blister bar."

Plated Bar is blister steel in the form of bars which have been rolled or hammered while hot. This treatment, which is usually applied to such bars broken to convenient lengths, flattens down their blisters and toughens the metal somewhat.

Single-shear Steel is shear steel made by welding a pile of plated bars into a fagot. The name applies also to the bars and other merchant shapes made by rolling or hammering such a fagot.

Double-shear Steel is shear steel made by piling, hammering, and thus welding bars of single-shear steel into a bloom. The name applies also to the bars and other merchant shapes made by rolling or hammering such a bloom.

Carbon Steel is steel which owes its distinctive properties chiefly to the carbon (as distinguished from the other elements) which it contains. Though among the alloy steels some are but moderately malleable, among the carbon steels industrial usage confirms the name "steel" to products malleable enough to be rolled or forged into merchant shapes.

Alloy Steel is steel which owes its distinctive properties chiefly to some element or elements other than carbon, or jointly to such other elements and carbon. Some of the alloy steels necessarily contain an important percentage of carbon, even as much as 1.25 per cent. There is no agreement as to where the line between the alloy steels and the carbon steels shall be drawn.

Semi-steel is a vague trade name for various products near the border line between steel and cast iron.

Bessemer Steel, Crucible (or Cast) Steel, and Open-hearth Steel, are steels made by the Bessemer, crucible and open-hearth processes, irrespective of carbon content.

Puddled Iron (Steel) is wrought iron (steel) made by the puddling process. Puddled steel is necessarily slag-bearing.

Wrought Iron is malleable iron which is aggregated from pasty particles of metallic iron without subsequent fusion, and contains so little carbon that it does not harden usefully when cooled rapidly. Also known formerly as **weld iron.**

Prices of Iron and Steel, 1910–1915. The accompanying table gives the range of monthly average prices for carload lots during 1910–1914, as well as prices current Aug. 1, 1915. Pig-iron prices are in dollars per ton of 2240 lb.; all others in cents per lb.

Pig Iron:	1910	1911	1912	1913	1914	Aug. 1915
Bessemer*..	15.90–19.90	15.00–15.90	14.90–18.15	15.77–18.15	14.59–15.09	15.20

No. 2 So. Fdry.†....	14.25–17.25	13.20–14.25	13.25–17.25	13.75–16.95	12.50–13.88	13.25
No. 2 Fdry.‡	16.00–19.00	14.00–15.50	14.00–18.00	14.60–17.90	12.50–14.25	13.50
No. 2X Fdry.§....	15.50–19.00	14.85–15.50	14.85–18.25	15.30–18.25	14.25–15.00	14.50
Steel bars and plates*.....	1.40–1.55	1.08–1.40	1.10–1.60	1.20–1.85	1.05–1.20	1.25
Wire nails*...	1.70–1.85	1.53–1.80	1.57–1.72	1.55–1.80	1.52–1.60	1.60
Black sheets, No. 28*.....	2.15–2.40	1.83–2.20	1.80–2.25	1.90–2.35	1.80–1.95	1.80

* Pittsburgh. † Cincinnati. ‡ Chicago. § Philadelphia. For freight rates to other points, see p. 1304.

Prices for plates are for those 6 to 100 in. wide and over ¼ in. thick. Boiler and flange steel ordinarily 0.10 cent higher in price than plates, ordinary fire-box steel 0.2 cent, locomotive fire-box steel 0.5 cent, and boiler rivets 0.5–0.6 cent. Wire-nail prices are for kegs of 100 lb.; cut nails usually 5 cents higher per keg. New York jobbers' warehouse prices for plates, bars and machinery steel are usually from 0.65 to 0.75 cent per lb. higher than the tabular prices for bars and plates.

For prices on structural shapes, see p. 1304.

SPECIFICATIONS FOR IRON AND STEEL

Tables 1 and 2 are condensed from the 1915 specifications of the American Society for Testing Materials, and Table 3 from those of the Society of Automobile Engineers.

Table 1. Strength Specifications for Steel and Iron

* Puddled or knobbled charcoal iron.
† Puddled muck bar with or without scrap.
‡ Class A, made from puddled pig and scrap from plate rolling; Class B, from puddled pig or a mixture of pig with cast and wrought scrap; widths given are inclusive.

Notes to Table 1

COLD BEND TESTS (Specimens to bend through 180 deg. without cracking on the outer bent portion):

1. Plates, shapes and bars: For material of thickness $t \leqq \frac{3}{4}$ in., flat on itself; for $t = \frac{3}{4}$ to $1\frac{1}{4}$ in., around pin of diam. t; for $t > 1\frac{1}{4}$ in., around pin of diam. $= 2t$.
2. Eyebar flats: For $t \leqq \frac{3}{4}$ in., around pin of diam. $= t$; for $t = \frac{3}{4}$ to $1\frac{1}{4}$ in., around pin of diam. $= 2t$; for $t > 1\frac{1}{4}$ in., around pin of diam. $= 3t$.
3. Pins, rollers and other bars: Around a 1-in. pin without cracking on outside bent portion.
4. Specimen to bend flat on itself without cracking on outside bent portion.
5. Plates, shapes and bars: For $t \leqq \frac{3}{4}$ in., around pin of diam. $= t$; for $t > \frac{3}{4}$ in., around pin of diam. $= 2t$.
6. Punched rivet holes pitched 2 diam. from a planed edge, to stand drifting until diam. is enlarged 50 per cent., without cracking the metal.
7. Specimen when $t \leqq 1$ in. to bend flat on itself; when $t > 1$ in., around pin of diam. $= t$.
8. Specimen to bend around a 1-in. flat mandrel having a rounded edge of $\frac{1}{2}$-in. radius.
9. Specimen to bend around a $1\frac{1}{2}$-in. flat mandrel having a rounded edge of $\frac{3}{4}$-in. radius.
10. Specimen to bend around a 1-in. pin or mandrel.
11. Around pin of diam. $= t$.
12. For $t < \frac{3}{4}$ in., 180 deg. around pin of diam. $= t$; for $t \geqq \frac{3}{4}$ in., 180 deg. around pin of diam. $= 2t$.
13. For $t < \frac{3}{4}$ in., 180 deg. around pin of diam. $= 2t$; for $t \geqq \frac{3}{4}$ in., 180 deg. around pin of diam. $= 3t$.
14. For $t < \frac{3}{4}$ in., 180 deg. around pin of diam. $= 3t$; for $t \geqq \frac{3}{4}$ in., 90 deg. around pin of diam. $= 3t$.
15. For $t < \frac{3}{4}$ in., 180 deg. around pin of diam. $= 4t$; for $t \geqq \frac{3}{4}$ in., 90 deg. around pin of diam. $= 4t$.
16. 180 deg. flat on itself in both directions without fracture of outside bent portion.
17. 180 deg. around pin of same diam. as specimen.
18. For bars < 4 sq. in. section, 180 deg. around pin of diam. $= 2t$.
19. 90 deg. around pin of diam. $= 1.5t$.
20. 90 deg. around pin of diam. $= 3t$.

QUENCH AND HOT BEND TESTS

21. When heated to light cherry red as seen in the dark ($\geqq 1200$ deg. fahr.), and quenched suddenly in water at 80–90 deg. fahr., material to stand test of Note 7.

22. When treated as in Note 21, material to stand test of Note 4. Head to flatten to diam. = 2½ × diam. of shank without cracking.

23. When heated to a yellow heat and quenched at once in water of 80–90 deg. fahr., to stand test of Note 4.

24. When heated to a bright cherry red, to stand test of Note 4.

25. When heated to 1700–1800 deg. fahr.; for round bars < 2 sq. in. in section, specimen to bend flat on itself; for larger bars, round or flat, specimen to bent 180 deg. around pin of diam. = t of specimen.

26. Strip ½ × 6 in. planed lengthwise from tube to stand bending of ends flat on itself in opposite directions after being heated to a cherry red and quenched in water at 80 deg. fahr.

Flanging Tests

27. Test specimen to stand flanging at right angles to body of tube without showing cracks or flaws; flange to be ⅜ in. wide for tubes ≦ 2½ in. O.D., and ½ in. for tubes > 2½ in.; also to stand flattening until inside walls are in contact without cracking.

Nick Bend Tests

28. Strip of Note 26 when nicked around and broken by light blows to show a wholly fibrous structure.

29. Specimen, when nicked 25 per cent. around with a 60-deg.-edge cutting tool to a depth from 8 to 16 per cent. of its diam., and broken, to show a clean fiber, entirely free from crystallization.

30. Specimen treated as in Note 29 to show a wholly fibrous structure on breaking.

31. Specimen treated as in Note 29 to show not more than 10 per cent. of fractured surface to be crystalline.

Drop Tests

32. Axles to be held on supports 3 ft. apart and struck at mid-length with a 1640-lb. tup; axle to be turned over after first and third blows; axle to stand 5 blows (7 and 9 for two largest sizes) without fracture. Maximum deflections after first blow as follows:

Axle diam. at center, in....	4¼	4⅜	4 7/16	4⅝	4¾	5⅜	5⅞	6 7/16
Height of drop, ft..........	24	26	28½	31	34	43	43	43
Deflection, in.............	8¼	8¼	8¼	8	7¾	6½	5	3½

33. Tire placed vertically on an anvil weighing at least 10 tons to stand successive blows from a 2240-lb. tup falling from heights of 10 to 20 ft. or over until a minimum deflection = $D^2/(40T^2 + 2D)$ is obtained, where D = internal diam. and T = thickness of tire at center of tread, both in inches.

Modifications in Elongation

34. For t > ¾ in., subtract 1 per cent. from col. 3 for each increase of ⅛ in. above ¾ in. to a minimum of 18. For t < 5/16 in., subtract 2½ per cent. from col. 3 for each decrease of 1/16 in. below 5/16 in.

35. For t > 1 in. subtract 1 per cent. from cols. 3 and 4 for each increase of ⅛ in. above 1 in. to a minimum of 14.

36. For t > ¾ in., subtract 1 per cent. from col. 3 for each increase of ⅛ in. above ¾ in. For t ≦ 7/16 in., subtract 1 per cent. from col. 3 for each decrease of 1/16 in. below 7/16 in.

37. For t > ¾ in., subtract 0.5 per cent. from col. 3 for each increase of ⅛ in. above ¾ in. For t ≦ ¼ in., elongation to be measured on a gage length = $24t$.

38. For section > 1¼ sq. in., subtract 2000 lb. per sq. in. from U(col. 2).

39. For flat bars to be reduced in width, subtract 1000 lb. per sq. in. from U(col. 2).

40. For t < 7/16 in., same as in Note 36.

Hydraulic Tests

41. Tubes < 5 in. diam. to stand an internal hydraulic pressure of 1000 lb. per sq. in.; tubes > 5 in., 800 lb.

42. Tubes to stand an internal hydraulic pressure of between 500 and 750 lb. per sq. in.

Notes to Table 2

USES OF STEELS LISTED

Class A, for forgings which may be welded or case-hardened.

Class B, for mild-steel forgings for structural purposes, for minor ship fittings, etc.

Class C, for mild-steel forgings for structural purposes, for ships, etc.

Classes D, E, F, G, H, and I, for various machinery forgings, choice depending upon design and upon the stresses and services to be imposed.

PERCENTAGE CHEMICAL COMPOSITION

Class A: Mn, 0.30–0.55; P, $\leqq$0.05; S, $\leqq$0.05.

Classes B, C, D, E, F, and G: Mn, 0.40–0.80; P, $\leqq$0.05; S, $\leqq$0.05.

Classes H and I: Mn, 0.40–0.80; P, $\leqq$0.04; S, $\leqq$0.05; Ni, $\geqq$3.00.

SIZES

(*a*) Not over 8 in. in outside diameter or overall thickness.

(*b*) Over 8 to 12 in., inclusive. (*c*) Over 12 to 20 in., inclusive.

(*d*) Up to 4 in., 2-in. max. wall. (*e*) Over 4 to 7 in., 3½-in. max. wall.

(*f*) Over 7 to 10 in., 5-in. max. wall. (*g*) Over 10 to 20 in., 5- to 8-in. max. wall.

Specifications for Classes A, B, C, D, E, F, H are for forgings whose max. outside diameter or overall thickness is not over 20 in. Specifications for Classes G, I, are for forgings whose max. outside diameter or thickness is not over 10 in. when solid, and not over 20 in. when bored.

S. A. E. Specifications for Steel. The chemical specifications in Table 3 were adopted by the Society of Automobile Engineers, in June, 1914. Each specification is given a four- (or five-) figure number, the first two digits of which indicate the class or quality of the steel, the last two (or three) the desired percentage carbon content. Thus, a nickel steel of 0.40 per cent. carbon content would have 2340 as its specification number, 23 being the class number assigned to nickel steels and 40 indicating the carbon percentage. The notes and data on physical characteristics, heat treatments and uses (Jan., 1915) are solely for the information of users; they form no part of the specifications and should not be included therein when ordering.

Table 3. S. A. E. Specifications for Steel

*Percentage, min.-max. (desired)		Physical characteristics					
Carbon	Manganese	Yield point,* 1000 lb. per sq. in.		Reduction of area, per cent.		Elongation in 2 in., per cent.	
		Annealed	Heat-treated	Annealed	Heat-treated	Annealed	Heat-treated
CARBON STEELS (Class 10) Max. phosphorus, 0.045 (0.04 for 0.95 carbon steel); max. sulphur, 0.05							
(a) 0.05-0.15(0.10)	0.30-0.60(0.45)	28-36	40- 60[1]	65-55	55-45[1]	40-30	....
(b) 0.15-0.25(0.20)	0.30-0.60(0.45)	30-40	40- 60[2]	60-45	60-30[2]	35-25	35-15[2]

Silico-manganese Steel (Class 92)
Phosphorus (max.), 0.04; sulphur (max.), 0.04; silicon, 1.75–2.00 (1.90)

(*p*) 0.45–0.55(0.50)	0.60–0.80(0.70)	55–65	60–180[19]	45–30	40–10[19]	25–20	20– 5[19]

* Yield point or elastic limit for all except the first nine steels listed.

Notes to Table 3

Uses of Steels Listed

(*a*) Soft basic open-hearth steel; used for seamless tubing and pressed parts; does not machine freely.
(*b*) Machine steel; used for forged, machined and case-hardened parts where strength is not paramount, also for tubes and pressed parts.
(*c*) For frames and drop forgings requiring moderate ductility but not unusually high strength
(*d*) For axles, driving shafts, steering pivots and other forgings.
(*e*) For crank, driving and propeller shafts; not to be case-hardened; machines well.
(*f*) For springs.
(*g*) Screw stock, Class 11; permits rapid removal of metal and finishes smoothly.
(*h*) For case-hardened gears and other parts requiring a very tough steel with hardened exterior; also for structural parts.
(*i*) For heat-treated structural parts requiring strength and toughness, as axles, shafts, etc.
(*k*) For case-hardened parts and for structural work.
(*l*) For structural parts requiring great strength.
(*m*) For gears where extreme strength and hardness are necessary.
(*n*) For case-hardened parts.
(*p*) For crank shafts, axles, spindles, transmission shafts, etc.
(*q*) For gears to be hardened without carbonising.
(*r*) For case-hardened shafts, gears and the like, and for structural parts.
(*s*) For structural parts; should not be case-hardened.
(*t*) For high-duty shafts and where great strength and fatigue-resisting qualities are demanded.
(*u*) For gears and springs. [For gears, to be annealed after forging by operations (1) and (2) of heat-treatment *U*.]
(*v*) For springs. Operation (5) of treatment *U* should run from 700 to 1100 deg. fahr., according as light spiral or heavy flat springs are being treated.
(*w*) For springs; used somewhat for gears and also structural parts.

Heat-treatments to be Used

[1] Quench at 1500 deg. fahr. (material cold-rolled or cold-drawn). [2] *H*. (for case-hardening, *A* or *B*). When cold-rolled or cold-drawn, yield point = 40–75; reduction of

area, 35–30 per cent. [3] *H*, or with better results, *D*. [4] *H*, *D* or *E*; for highest strength, quench in brine. [5] *H*, *D* or *E*. [6] *F* (Elastic limit values are for transverse test). [7] *H* or *K* (for case-hardening, *G*). [8] *H* or *K*. [9] *H* or *D* (For case-hardening, *G*). [10] *H* or *D*. [11] *M* or *Q*. [12] *G*. [13] *P* or *R*. [14] *R*. [15] *T* for structural parts, *S* for case-hardening. [16] *T*. [17] *U* (for high-strength structural parts, *T*). [18] *U*. [19] *V* for structural parts; for springs, operation (3) to be at 800–900 deg. fahr.

Heat-treatments for Steels

(All temperatures in deg. fahr.)

A. After forging or machining: (1) Carbonize at a temperature between 1600 and 1750 deg. (1650–1700 desired). (2) Cool slowly or quench. (3) Reheat to 1450–1500 deg. and quench.

B. After forging or machining: (1) Carbonize same as for *A*. (2) Cool slowly in carbonizing mixture. (3) Reheat to 1550–1625 deg. (4) Quench. (5) Reheat to 1400–1450 deg. (6) Quench. (7) Draw in hot oil of temperature between 300 and 450 deg., depending on degree of hardness desired.

D. After forging or machining: (1) Heat to 1500–1550 deg. (2) Quench. (3) Reheat to 1450–1500 deg. (4) Quench. (5) Reheat to 600–1200 deg. and cool slowly.

E. (1), (4) and (5) same as for *D*. (2) Cool slowly. (3) Reheat to 1400–1450 deg.

F. After shaping or coiling: (1) Heat to 1425–1475 deg. (2) Quench in oil. (3) Reheat to 400–900 deg. according to temper desired, and cool slowly.

G. After forging or machining: (1), (2), same as for *B*. (3) Reheat to 1500–1550 deg. (4) Quench. (5) Reheat to 1300–1400 deg. (6) Quench. (7) Reheat to a temperature between 250 and 500 deg. according to necessities of case, and cool slowly.

H. After forging or machining: (1) Heat to 1500–1550 deg. (2) Quench. (3) Reheat to 600–1200 deg. and cool slowly.

K. After forging or machining: (1) Heat to 1500–1550 deg. (2) Quench. (3) Reheat to 1300–1400 deg. (4) Quench. (5) Reheat to 600–1200 deg. and cool slowly.

L. After forging or machining: (1) and (2) same as for *B*. (3) Reheat to 1400–1500 deg. (4) Quench. (5) Reheat to 1300–1400 deg. (6) Quench. (7) Reheat to 250–500 deg. and cool slowly.

M. After forging or machining: Heat to 1450–1500 deg. (2) Quench. (3) Reheat to a temperature between 500 and 1250 deg. and cool slowly.

P. After forging or machining: (1) Heat to 1450–1500 deg. (2) Quench. (3) Reheat to 1375–1425 deg. (4) Quench. (5) Reheat to between 500 and 1250 deg. and cool slowly.

Q. After forging: (1) Reheat to 1475–1525 deg., and hold there for ½ hr. (2) Cool slowly. (3) Reheat to 1450–1500 deg. (4) Quench. (5) Reheat to 250–500 deg. and cool slowly.

R. After forging: (1) Heat to 1500–1550 deg. (2) Quench in oil. (3) Reheat to 1200–1300 deg. and maintain temperature 3 hr. (4) Cool slowly. (5) Machine. (6) Reheat to 1350–1450 deg. (7) Quench in oil. (8) Reheat to 250–500 deg. and cool slowly.

S. After forging or machining: (1) and (2) same as for *B*. (3) Reheat to 1650–1750 deg. (4) Quench. (5) Reheat to 1475–1550 deg. (6) Quench. (7) Reheat to 250–500 deg. and cool slowly.

T. After forging or machining: (1) Heat to 1650–1750 deg. (2) Quench. (3) Reheat to some temperature between 500 and 1300 deg. and cool slowly.

U. After forging: (1) Heat to 1525–1600 deg. and hold for about ½ hr. (2) Cool slowly. (3) Reheat to 1650–1700 deg. (4) Quench. (5) Reheat to 350–550 deg. and cool slowly.

V. After forging or machining: (1) Heat to 1650–1750 deg. (2) Quench. (3) Reheat to between 500 and 1200 deg. and cool slowly. The temperature suited to the thickness of piece, and the character of the quenching medium, must be determined experimentally.

WROUGHT IRON

Manufacture. Iron ore, consisting essentially of Fe_2O_3 or Fe_3O_4 with silica, phosphorus, sulphur, manganese, etc., as impurities, is heated in a blast furnace at a high temperature in intimate contact with coke and limestone (flux for the silica), and the resulting molten product is called **pig iron.** This iron contains about 3.5 per cent. C and considerable Si, Mn, P, and S which have been reduced with the iron. The pig iron is then heated in a puddling furnace at a temperature somewhat above its melting point, with the addition of fettling material in the form of iron ore or iron oxides (mill scale, etc.), the lining of the furnace bottom being generally composed of this material. The puddling furnace is a reverberatory furnace and the oxidising flame plays over the bath of molten metal. Air is allowed to enter the furnace, which further promotes the oxidisation. The impurities are gradually burnt out of the iron, and its melting point is thereby raised so that the resulting purer metal forms in globules which are collected together by means of long iron rods manipulated by the puddler. This purer iron is not molten, but comes from the furnace in a pasty condition in the form of balls (sometimes called **blooms**), and contains semi-molten slag (silicate of iron) mechanically included. The ball or bloom is then put through a squeezer or hammered with a steam hammer to remove a large portion of the slag. It finally passes through a rolling mill and is then known as muckbar. **Muckbar** contains too much slag to render the metal useful. The bars are therefore sheared, piled crosswise and the pile is reheated and rerolled, the purer iron product being called **merchant bar.** This is the wrought iron of commerce. When merchant bar is sheared, piled and rerolled in a similar manner, the resulting material is called **double-refined iron.** If a charge of iron scrap or of pig iron is heated in a so-called "knobbling" furnace with charcoal, and air is forced into the furnace through tuyères, the product, after being subjected to the mechanical treatment described above, is known as **charcoal knobbled iron.**

Fagoted Iron is produced by piling pieces of wrought-iron scrap, such as bolts, bars, structural material, etc., in a boxlike shape, using old boiler plates or new muckbar as sides and covers. These so-called "box piles" are then heated to a welding heat and rolled. When the scrap used is strictly wrought iron, the finished bars so made are of good quality, showing higher ductility than those made from ordinary muckbars; but it is difficult to get strictly wrought-iron scrap without an admixture of steel scrap, and, while the mixed-in soft steel does not reduce the strength or ductility of the metal, the latter frequently fails to weld, its resistance to corrosion is reduced, and it should not be used in the manufacture of such products as corrugated iron sheets, etc. **Busheled iron** is made from miscellaneous junk scrap (generally small pieces), sometimes mixed with iron and steel turnings, swarf, etc., by heating these to a welding heat in a furnace similar to a puddling furnace. The material is formed into lumps and treated like a puddled ball. Owing to the irregular composition of the scrap, which is often mixed with high-carbon and alloy steels, the material so produced is very unreliable as to its physical qualities and should never be used where either strength or longevity is an object.

Uses. Wrought iron was formerly used to a large extent for making crucible steel, and is still employed by some manufacturers for that purpose, but it is now chiefly used in the form of staybolts, rivets, corrugated siding sheets, roofing sheets, water pipes, steam pipes, boiler tubes, and by blacksmiths for horseshoes and general forging purposes, especially where welding plays a part. Bars and plates are made of single-refined iron, staybolts of double-refined iron and boiler tubes of charcoal knobbled iron.

Shapes of Finished Iron. The more usual shapes include bars having the following sections: Round, half-round, square, flat, round-edged flat, oval, half-oval, octagon, hexagon, bevel-edge, tapered, together with leveled and bulb iron, and rods; tee (or T-shaped) iron, tee with round top or edges, D-iron; angle (or L-shaped) iron, angle iron with unequal sides or round back, square-root angles; channel iron, H-iron, Z-iron; sheets, plates, bands, hoops and agricultural shapes; rails, including single-headed, double-headed, and flange; and horseshoe iron, which is rolled single-grooved, double-grooved, or concave.

Imperfections in Finished Iron. **Rough edges,** when not due to imperfections in the rolls or careless working, are a sign of red-shortness and are particularly noticeable in flat bars or strips. Red-shortness may be due to an excess of carbon or to the presence of sulphur, particularly if copper is also present. **Spilly places** are spongy or irregularly spotted parts not infrequently noticed in sheets and occasionally in all kinds of wrought iron, and are generally due to imperfect puddling, whereby one part of the iron has been oxidized more than another. **Blisters,** often met with in sheets, are attributed to a reaction between carbon and oxide of iron in wrought iron of inferior quality. **Sand holes** are pits noticed especially on the outside of pipes which have been reheated (*e.g.*, for welding) in a furnace with a sand bottom. The sand unites with some of the metal to form slag, which is more fusible than iron, and this causes the pit, which generally has considerable silicate (slag) attached to it.

Physical Properties of Wrought Iron. Table 4 (due to Turner) gives data on the physical properties of wrought irons of different qualities, which also show the great importance of ductility tests. A typical percentage **analysis** of Swedish bar iron is as follows: C, 0.05; Si, 0.037; S, 0.006; P, 0.012; Mn, 0.108; Cu, trace; As, 0.007.

Table 4. Physical Properties of Wrought Iron

Variety of iron	Quality	Form	Tensile strength, lb. per sq. in.	Elastic limit, lb. per sq. in.	Contraction of area, per cent.	Elongation, per cent. —in.
Swedish charcoal...	Very good	1 in. square....	43,904	27,440	72.18	56.0 on 3⅛
Best Yorkshire*.....		1⅛ in. round...	50,848	30,688	55.00	29.0 on 10

Effect of High and Low Temperatures on the Physical Properties. Extreme cold increases the elastic limit of wrought iron, but does not affect the tensile strength appreciably. It increases the ductility very slightly, and decreases the resistance to impact by about 3 per cent. The tensile strength increases with temperature from 0 deg. fahr. up to a maximum at from 400 to 600 deg. fahr., the increase being from 8000 to 10,000 lb. per sq. in., and then decreases steadily until the strength of only 6000 lb. per sq. in. is shown at 1500 deg. fahr. The comparative strengths, taking strength at 68 deg. fahr. as 100, are given by one observer as follows:

Temp., deg. fahr.........................	300	500	700	900	1100	1300	1500
Tensile strength (comparative)	108	116	103	79	43	34	15

Effect of Rolling Temperature. Tests on a high grade of stay-bolt iron of two sizes and finished at various rolling temperatures showed that bars rolled considerably colder than usual in both 1⅜-in. and ⅞-in. sections gave higher tensile strengths than those rolled at the usual temperature or higher, while with the larger bars the low rolling temperature gave the highest elastic limit, and also the greatest elongation and contraction. The greatest difference in elastic limit in either size, however, was only about 5 per cent., in tensile strength 2 per cent., in elongation about 4 per cent., and in contraction about 3 per cent. of the average figures. There was a marked increase in the elastic limit and tensile strength and a slight decrease in elongation, with a slight increase in contraction in the case of the smaller bars, as compared with the larger ones.

Effect of Repeated Reheating. (Turner.) Puddled iron is much improved in quality by being cut up, piled, reheated, and rolled or hammered, but indefinite repetition of this is detrimental. In practice it is advantageous only in special cases to reheat puddled iron more than once. The results given below show the effect of repeated working. The metal began to deteriorate seriously after six workings, and no advantage is seen after the third working when the extra fuel and labor expended and the waste incurred are taken into account.

Working	Original bar	2nd	4th	6th	8th	10th	12th
T. S., lb. per sq. in.	43,900	52,900	59,600	61,800	57,300	54,100	43,900

Effect of Work upon Wrought Iron (Campbell, 1907). Table 6 gives results obtained from plates rolled in a three-high train, and in a 25-in. universal mill. The better figures for the latter mill are said to be due to the continuous rolling in one direction. The width was alike for similar thicknesses and no difference was found in the universal plates whether they were 9 or 42 in. in width.

Table 6. Physical Properties of Wrought-iron Plates from Shear and Universal Mills

According to Thurston (1894), good iron, when drawn into No. 10 wire (0.134 in. diam.), has a strength of about 90,000 lb., and Nos. 15 and 20 (0.072 and 0.035 in.) have a tensile strength respectively of about 100,000 and 111,000 lb. per sq. in.

Heterogeneity of Wrought Iron. Holley found great variation in the chemical composition of materials submitted. See Table 7.

Influence of Chemical Composition upon the Welding Properties. It has been believed that slag would facilitate welding, but the work by Holley does not bear this out, his conclusion being that, while "slag should theoretically improve welding like any flux, its effect in these experiments could not be definitely traced." The iron highest in slag (2.26 per cent.) "welded less soundly than any other bar of the same iron, and below average as compared with the other irons." He concluded that, "although most of the irons under consideration are alike in composition, the hardening effects of phosphorus and silicon can be traced, and that of carbon is obvious. P up to 0.20 per cent. does not harm and probably improves iron containing Si not above 0.15 per cent. and C not above 0.03 per cent. None of the ingredients, except carbon in the proportions present, seem to very notably affect welding by ordinary methods."

Microstructure of Wrought Iron. Sections taken across or parallel to the direction of rolling show under the microscope symmetrical, polyhedral grains of ferrite (see p. 494), with slag appearing as rounded areas in the transverse section and as strings or fibers in the longitudinal section. The iron itself shows no indication whatever of being fibrous, since except for the appearance of the slag, which constitutes not more than 5 per cent. of the entire area, the microstructure is identical in transverse and longitudinal sections. If there is any appreciable amount of carbon in the iron, it shows at the junctions of the ferrite polyhedra as dark, irregular particles of pearlite (see p. 494), the amount of this constituent varying from zero to about 12 per cent. of the area as the carbon content varies from zero to 0.1 per cent.

Fracture. The fracture of wrought iron depends to a very great extent upon the method employed in breaking the metal. A sudden break causes the production of a so-called "crystalline" or "granular" fracture, while a gradual rupture produces a "fibrous" fracture.

Test for Distinguishing Wrought Iron from Steel. A section ground flat and polished with two grades of emery paper is immersed in a bath containing 9 parts of water, 3 parts of H_2SO_4 (conc.) and 1 part HCl, added in the order named. After 20 to 40 min. immersion, remove the piece and wash off the acid. If the piece is steel, the section will present a bright, solid, unbroken surface, while if made of wrought iron, it will show faint ridges (or, in a pipe section, rings like the age rings in a tree) showing the different layers of iron and streaks of cinder. This test will also show on a section of welded metal whether it has been lap-welded or butt-welded.

STEEL

Steel Manufacture

Open-hearth Process (Siemens-Martin Process). Steel made by this process is called either acid or basic. In either process the product is low in carbon and must be recarbonized by means of proper agents. The processes may be carried on in stationary or tilting furnaces. From 15 to 80 tons are made in one heat, and some special furnaces have a capacity up to 200 tons. The duration of the heat is from 6 to 12 hr.

Acid Open-hearth Steel. The charge consists of pig iron and ore or pig iron and scrap having a low phosphorus content, and is melted in an open-hearth furnace with an acid or siliceous lining. The process consists in removing the impurities in the pig iron to a great extent by means of an oxidizing flame brought about by the union of producer gas with preheated air in a reverberatory regenerative furnace. The process is similar to the puddling process for making wrought iron, but is carried on at a much higher temperature, the products, both metal and slag, being molten.

Basic Open-hearth Steel. The charge of either melted or solid pig iron or a mixture of pig iron and low-carbon scrap is heated in a furnace similar to the acid furnace. The lining in this case is of dolomite, lime, magnesite or other basic material. Ore may or may not be used.

The Bessemer Process may be acid or basic, but no basic Bessemer steel is made in the United States. The production of acid Bessemer steel is rapidly diminishing, giving way to open-hearth, electric, and duplex steel. From 8 to 20 tons of steel are made in one heat which lasts from 10 to 15 min. The furnace or converter is pear-shaped and mounted on trunnions so as to be tilted easily for charging and pouring.

Acid Bessemer Steel is made by blowing air through liquid pig iron, the heat being obtained and the impurities removed by the combustion of the silicon, manganese and carbon. Some of the iron is also oxidized and these oxides must be reduced by the addition of suitable agents. When the reaction is completed the metal is recarburized to the desired extent. The lining of the converter is of siliceous material called ganister.

Basic Bessemer Steel is made in a similar manner, but the lining of the converter is magnesite or other basic material which combines with a large proportion of the phosphorus in the pig, thus eliminating it. The process requires a pig iron very high in phosphorus, whereas the basic open-hearth process can use pig iron containing phosphorus in all but the highest amounts.

Tropenas Steel is made in a converter similar to the Bessemer vessel, but the air is blown over the surface of the metal instead of through it. The furnace generally handles not more than 2 tons to a heat and the process is restricted to making steel castings.

Table 8. Typical Percentage Analyses of Bessemer and Open-hearth Steels (Harbord)

Constituents	Acid				Basic		
	Bessemer*		Open-hearth (Siemens)		Bessemer†		Open-hearth‡

Arsenic§	0.02–0.06	0.02–0.08	0.02–0.06	0.02–0.06	0.02–0.06	0.02–0.60	0.02–0.06

* Some special steels made from selected pig iron will be as low as 0.03 per cent. in phosphorus and sulphur.

† These are simply typical analyses of average steels and it is not unusual to find the impurities exceeding the upper limits given. For exceptional purposes, however, steel is made with less than the minimum impurities given.

‡ In England high-carbon steel is rarely made in basic open-hearth furnaces working with phosphoric pig iron, but in the United States practically all O. H. steel is now basic.

§ Steel made in the United States contains no arsenic.

Electric Steel. The charge is either cold or melted, and the furnace may be of the induction or of the arc type. The induction furnace produces steel of similar quality to crucible steel from a charge of pure scrap steel and pig iron. The arc furnace produces a high-grade steel from a charge of fluid or cold steel scrap covered with a slag containing a high percentage of lime and brought to a high temperature by means of the arc from an electric current in a furnace with a basic lining. The reaction eliminates the impurities such as phosphorus, manganese and carbon, and the proper composition is obtained by the introduction of the necessary alloys.

Arc Furnaces. The **Heroult furnace** consists of a shallow bath of dolomite, similar to the open-hearth, incased in a steel shell. Two carbon electrodes project into the furnace through the roof. The electric current arcs between each of the electrodes (which are connected in series) and the charge, thus passing through the charge. The furnace may be tilted. The **Girod furnace** differs chiefly from the Heroult in having a hearth which conducts the electric current. It is especially satisfactory in the refining of cold scrap steel because of the slight fluctuations in power demand. The furnace has a shallow conducting hearth of dolomite with pieces of soft steel embedded in it near the periphery, and a carbon electrode passing through the roof. The current passes through the carbon electrode and through the steel bath, which touches the tops of the steel poles embedded in the hearth. These steel electrodes are water-cooled and project above the bottom of the hearth a short distance. The **Stassano furnace** differs from other electric steel furnaces in that the electric current does not pass through the metal or slag. All heating is by radiation from three horizontal, water-jacketed arcs. It has a circular hearth with a cylindrical melting chamber above.

Induction Furnaces. The **Kjellin furnace** is really a transformer in which the bath of molten metal forms the secondary circuit. The magnetic circuit is built up of laminated sheet iron like the core of a transformer. The primary circuit is a coil consisting of a number of turns of insulated copper wire or tubing surrounding the magnetic circuit. A ring-shaped crucible, made of suitable refractory materials, also surrounds the magnetic circuit and when filled with molten metal forms the secondary circuit of the transformer. The current passing through the coils excites a variable magnetic flux in the iron core and the variation in the magnetic flux induces a current in the closed circuit formed by the molten metal in the crucible. Before starting the furnace an iron ring must be placed in the crucible and melted down to form a bath, or the crucible must be filled with molten metal taken from another source. The **Röchling-Rodenhauser furnace** is adapted to heat the metal in a hearth of the form of a figure 8 in place of an annular crucible, and differs from the Kjellin in the use of extra secondary coils surrounding the primary coils. These secondary coils are connected to metallic plates covered by an electrically conducting mixture of lining material and the circuit is completed through the metal bath. It combines two methods of heating: (*a*) By currents induced in the bath; (*b*) by currents passed through the bath.

Table 9. Physical Properties of Electric Steel

The number of **electric furnaces in use** and in construction (1914) and their capacities are as follows (those in construction being in parentheses): Heroult, 31 (20), up to 25 tons; Girod, 16 (5), 2½ to 12 tons; Stassano, 16 (1), up to 2 tons; Kjellin, 9 (0), up to 8½ tons; Röchling-Rodenhauser, 18 (4), up to 10 tons.

The average ultimate strength and elongation of electric and open-hearth plate steels are given in Bulletin 67, U. S. Bureau of Mines, as follows:

Carbon content, per cent	0.08	0.12	0.16	0.20	0.24
Electric, ult. strength, lb. per sq. in.	59,194	64,080	69,220	72,853	69,540
O. H., ult. strength, lb. per sq. in.	51,690	56,510	52,901	58,294	63,560
Electric, elongation, in 2 in., per cent	27.25	26.05	25.25	22.82	23.12
O. H., elongation in 2 in., per cent	32.00	29.70	28.61	28.82	26.25

Defects in Steel Ingots. When steel cools in the mold, **piping** takes place, a cavity or "pipe" being usually found at the central upper portion. Large ingots are usually cast in "bottle-neck" shape, the large lower portion being formed in an iron mold, and the upper in sand. The pipe formed in the rapid-cooling bottom is fed by the hot metal from the upper portion; the volume of waste is thus reduced. Ingots cast wholly in sand pipe more extensively but are not so susceptible to external cracks. Molds are sometimes poured from the bottom by means of suitable ducts; this aids in preventing piping by forcing the lower portion of the ingot to solidify last. Casting ingots large end up will reduce the depth of the pipe, but this method requires special mechanical devices for lifting the ingot from the mold.

In low-carbon steel, deep-seated **blow holes,** if not too numerous, can be welded together during rolling; such blow holes are sometimes purposely allowed to form, since they tend to prevent piping. In most cases the blow holes are eliminated by the addition of silicon or aluminum or both. Manganese and titanium probably aid this elimination, but all of them increase the tendency to pipe. The **segregation** or concentration of impurities in the central upper portion of the ingot produces a porous or spongy mass, resulting in lack of homogeneity. It can be retarded by quick cooling, or remedied by discarding the portion of the ingot most affected, which can be discovered in a finished product by etching a section in hot acids. During rolling and shearing off ends, the worst is discarded, but even then the central portion is not always uniform with the outside of the ingot. Plates rolled directly from ingots are the most troublesome. The top surface of an ingot is usually solid, with the pipe existing beneath it. When rolled, it is possible to shear the plate so that the inner cavity or pipe is not reopened after apparent welding during the rolling, and the finished plate then has an area of lamination and an area of segregation, which defects are near one end of the plate. In plates rolled from slabs streaks of segregation often run through the central axis, but there is no centralization of impurities such as occurs in the older method of manufacture. Segregation and piping can be more easily controlled in the case of large guns and shafting, the latter generally being hollow to allow more even heat-treatment. The pipe and segregated portions are then bored out when the gun or shaft is hollowed.

Influence of Chemical Composition on the Physical Properties of Steel—Alloy Steels

Alloy steels composed of iron, carbon, and one other special element are known as **ternary steels.** This class includes nickel steel, manganese steel, chrome steel, tungsten steel, molybdenum steel, and silicon steel. Several other ternary steels have been investigated and used to a small extent, such as boron steels, cobalt steels, etc. **Quaternary,** or four-part, **steels** consist of iron, carbon, and two other special elements. The commonest and most important of these are nickel-chromium steels, tungsten-manganese, tungsten-chromium, nickel-manganese, manganese-silicon, tungsten-molybdenum, tungsten-nickel, nickel-vanadium steels, etc. The manufacture of alloy steels is usually very simple, as a general thing the alloying element being added like the recarburizer.

Carbon. The influence of carbon upon the physical properties cannot be stated with accuracy on account of the extreme sensitiveness of steel to heat-treatment and the failure of published tests to record the heat-treatment. Carbon increases the hardness and elastic limit of steel. Up to 0.85 per cent. (annealed steel; about 1.20 per cent. in forged steel) it increases the tensile strength and the ability to harden. Beyond that it decreases those properties. Carbon decreases the ductility, toughness, and weldability. It increases the resistance to fatigue, but decreases resistance to shock. Table 10 indicates the uses of carbon steels of varying carbon content.

It is extremely difficult to state the **tensile strength** corresponding to different percentages of carbon in commercial steels, as the strength of the material for the same carbon content will vary according to the process of manufacture, the size of the finished section, and the percentages of other

Table 10. Uses of Steel According to Carbon Content

Carbon, per cent.	Uses
0.05–0.10	Wire, drawn tubing, pressed work, nails.
0.10–0.15	Rivets, screws, machine parts to be case-hardened.
0.15–0.20	Same as for 0.10–0.15; ordinary forgings.
0.20–0.25	Ordinary forgings, boiler plate, structural steel, crane steel.
0.25–0.35	Forgings, structural steel, wearing parts as valves, crank pins, and gears.
0.35–0.45	Strong forgings, shafts and axles, crucible machinery steel.
0.45–0.55	Crank pins and other parts subjected to shocks and heavy stress reversals.
0.60–0.70	Bolt-heading and drop-forging dies, set screws.
0.70–0.80	Anvil facings, band saws, cold chisels, smithing hammers, pickaxes, shear blades, vise jaws, wrenches.
0.80-0.90	Punches and dies, rock drills, machinists' chisels, circular saws.
0.90–1.00	Springs, machinists' hammers, punches and dies.
1.00–1.10	Springs, lathe centers; lathe, planer, shaper and slotter tools; taps, mandrels, granite chisels.
1.10–1.20	Woodworking machine knives, ball-bearing races, taps, thread-cutting dies, reamers, wood chisels, milling cutters, twist drills, metal-cutting dies, stone-channeling bits.
1.20–1.30	Files.
1.30–1.40	Wire-drawing dies, granite-turning tools, paper knives, engravers' tools.
1.40–1.50	Wire-drawing dies, tools for turning chilled iron rolls.
1.50–1.60	Saws for cutting steel.

impurities present. The following table, compiled by Harbord from a large number of results, shows roughly what may be expected from open-hearth steel of good quality in which the manganese does not exceed 0.8 per cent. When the manganese is above 0.8, the tensile strength will be considerably higher. Acid Bessemer and basic Bessemer steels will not differ greatly from open-hearth steel in tensile strength, especially in the low-carbon steels, and comparatively little high-carbon steel is made by these processes, except for rails.

Carbon, per cent.........	0.05–0.10	0.10–0.20	0.20–0.30	0.30–0.40	0.40–0.50	0.50–0.60	0.60–0.70	0.70–0.80	0.80–0.90

Basic O. H..	45–56	52–65	58–72	65–78	76–96				

Following are **formulæ connecting chemical composition with the tensile strength of steel** (T. S., lb. per sq. in.):

T. S. = 50,000 + 90,000 C......(1) T. S. = 142,000 − 20,600 C.....(2)

where C = percentage of carbon. For $C < 0.83$ per cent., use formula (1), for $C > 0.83$ per cent., use (2). These formulæ (by Sauveur) hold good only for annealed or pearlitic steels. Campbell gives the following formulæ for acid and basic open-hearth steels:

$$\text{T.S. (acid)} = 40{,}000 + 1000C + 1000P + x\text{Mn} + R$$
$$\text{T.S. (basic)} = 41{,}500 + 770C + 1000P + y\text{Mn} + R$$

where C, P and Mn are respectively the contents of carbon (determined by combustion), phosphorus and manganese in hundredths of 1 per cent., R is a variable depending upon the heat treatment the steel has received, and x and y have the following values:

Carbon, per cent....................	0.05	0.10	0.20	0.30	0.40	0.50	0.60
x (0.4 per cent. Mn)*................		80	160	240	320	400	480
y (0.3 per cent. Mn)*................	110	130	170	210	250		

* Beginning only with the percentage of manganese stated.

Sulphur causes **red-shortness,** especially when insufficient manganese is present, or when there is copper in the steel. With manganese it forms manganese sulphide, which if present in large amounts is detrimental, producing sulphide flaws. It is especially deleterious in welding steel. Sulphur is usually limited to 0.05 per cent. in good grades of steel. High sulphur in structural steel is dangerous because it is likely to cause minute cracks in rolling, which are not discovered and make the material break under shock or alternate stresses in service. High-sulphur steel containing 0.10 per cent. sulphur is largely employed for parts to be threaded, especially those made in automatic screw-making machines, since the chips crumble and do not curl.

Phosphorus produces brittleness (**cold-shortness**), particularly under shock. High-carbon steel is affected more distinctly in this way than softer steel. Phosphorus, up to 0.1 per cent., increases the tensile strength and then decreases it, its effect in this respect being about equal to that of carbon, but it renders steel brittle in the case of vibratory stresses and sudden shocks. It also reduces the ductility much more rapidly than carbon. For structural purposes phosphorus should be not over 0.06 per cent. and it is customary to limit it to 0.05 per cent. for important details.

Manganese is always added to Bessemer and open-hearth steel in the proportion of from 0.3 to 0.5 per cent. to prevent the red-shortness generally considered to be due to iron oxides or iron sulphides. More than this is detrimental, although sometimes as much as 0.8 per cent. is used. It increases the strength but not so markedly as carbon. High-carbon steel, however, is affected more distinctly than low-carbon. Additions of 2 to 7 per cent. of manganese make steel very brittle, at least when the carbon content is high, but with larger amounts the ductility again returns. Commercial **manganese steel** containing from 1.25 to 2 per cent. carbon and from 12 to 13 per cent. manganese has a high tensile strength and is very hard in the sense of resistance to wear. It has a low elastic ratio, but possesses great ductility and toughness.

Forged or rolled manganese steel contains less carbon. Until recently it has been difficult to forge or roll manganese steel, but this is now being done, rails especially being manufactured in this manner. The high carbon content has been necessary hitherto, because ferro-manganese contains much carbon, which therefore unavoidably finds its way into the steel. A low-carbon manganese steel due to recently available low-carbon manganese metal is now being developed and is giving evidence of having new and useful properties, being more easily treated and worked.

Cast manganese steel is almost as brittle as glass and practically impossible to machine except with grinding wheels. Heating it to a temperature of more than 1832 deg. fahr. and rapidly cooling by plunging it into water renders it tough and ductile. Its wear-hardness is remarkable, although its resistance to indentation (as in the Brinell test) is no greater than that of ordinary annealed tool steel of the same carbon content.

The chief **uses** of manganese steel are for jaws and wearing parts of rock-crushing machinery and similar apparatus, for railroad frogs and crossings, for railroad rails on curves, mine-car wheels, dredger-bucket teeth, and burglar-proof safes. Its crystalline structure is austenitic when heat-treated, but this austenite (see p. 494) is surrounded by networks of free carbide or manganiferous cementite in the raw casting, causing great brittleness.

Silicon added to fluid steel helps to eliminate blow holes, but increases the shrinkage and the tendency to formation of pipes. It is almost universal practice to add 0.25 per cent. silicon to all steel for castings. Up to 4 per cent. it increases the magnetic permeability and reduces its retentivity. Over 6 per cent. of silicon renders steel exceedingly brittle like cast iron. **Silicon steel** has high magnetic permeability with high electrical resistance, making the steel valuable for electromagnets, electric generators, and motors. The silicon content varies between 1 and 5 per cent., but usually is 2.75 per cent., with smallest possible amounts of C, Mn and other impurities. Before the steel is ready for use, it is subjected to a double heat-treatment by first heating to between 1652 and 2012 deg. fahr. and cooling quickly, then reheating to between 1292 and 1562 deg. fahr. and allowing to cool very slowly. In some cases the second cooling extends over several days. Hadfield obtained best results by heating first to 1958 deg. fahr., cooling quickly to atmospheric temperature and then heating to 1832 deg. fahr. and cooling slowly, after which he sometimes again reheats to 1472 deg. fahr. and then cools slowly.

Silicon and manganese in moderate amounts give steel great resistance to shock. Such steel is used chiefly for springs and gears. A typical percentage analysis of **silicon-manganese steel** is as follows: C, 0.47; Si, 1.83; Mn, 0.70; P, 0.012; S, 0.004.

Nickel increases hardness, toughness, elastic ratio and tensile strength of steel, and decreases the ductility only slightly. The ratio of elastic limit to tensile strength increases with increasing nickel. It decreases corrosion and checks segregation, but it does not prevent blow holes. Over 1 per cent. gives bad welding results. It is often used in conjunction with chromium. In **nickel steels**—the most important of the alloy steels—the nickel generally ranges from 1.50 to 4.50 per cent. and usually between 2 and 3.75 per cent., while the carbon ranges from 0.20 to 0.50, usually 0.30 per cent. A typical percentage analysis of electric-furnace nickel steel is as follows: C, 0.20–0.25; Si, 0.18; Mn, 0.69; P, 0.007; S, 0.013; Ni, 3.59. The chief **uses** are for structural work in bridges, railroad rails (especially on curves), steel castings, ordnance, engine forgings, shafting (especially marine shafting), frame and engine parts for automobiles, wire cables, axles (especially for automobiles and railroad cars), etc. The crystalline structure of nickel steel is finer than that of ordinary carbon steel and cracks develop in it relatively slowly. Castings are relatively free from blow holes. The metal has a lower melting point than carbon steel, and runs more easily in the molds. Nickel steel is less liable to segregation than carbon steel.

Table 11 gives results obtained by Hadfield on nickel steels with nickel varying from 0.27 to 29.07 per cent., the carbon being kept at a low and practically constant value throughout the series. Table 12, due to Harbord, compares the physical properties of low-carbon nickel steel and best soft (flange) carbon steel.

Nickel steel containing as much as 30 per cent. nickel, according to Harbord, can be drawn into **wire** as easily as ordinary steel, and wire of this class contains sufficient nickel to make the non-corroding properties of the nickel prominent. It is well adapted to hawsers and cable service in salt water. A sample of nickel steel (0.116 in. diam.) containing 0.4 per cent. carbon and 27.8 per cent. nickel, used as torpedo defense netting by the U. S. Navy, gave the following physical test: Breaking stress, 198,700 lb. per sq. in.; elongation in 2 in., 6.25 per cent.; reduction of area, 16.5 per cent. The high tensile strength of this wire with the comparative small reduction in elongation and contraction of area below that of ordinary carbon steel of the same dimensions, indicates extreme toughness; at the same time, the material is not acted upon, or but very slightly, by salt water.

Table 11. Tests of Low-carbon Nickel Steels of Varying Nickel Contents

Analysis			Unannealed test bars			
C	Mn	Ni	Elastic limit, lb. per sq. in.	Tensile strength, lb. per sq. in.	Elongation, per cent. in 2 in.	Reduction of area, per cent.

Table 12. Comparative Physical Properties of Low-carbon Nickel and Carbon Steels

Composition (per cent.)					Tensile strength, lb. per sq. in.	Elastic limit, lb. per sq. in.	Elongation in 8 in., per cent.	Reduction of area, per cent.
C	Ni	Mn	S	P				
0.08	2.69	0.36	0.038	0.045	65,950	47,080	24.50	51.5
0.10	....	0.27	0.039	0.040	54,430	34,910	27.42	55.4

Chromium is used in the production of chrome steel, either alone or in conjunction with vanadium or nickel. Such steels have a high elastic ratio. **Chromium steels** generally contain from 1 to 2 per cent. Cr and from 0.80 to 2 per cent. C, and are used in the hardened state. They are particularly adapted for armor-piercing projectiles on account of their hardness and very high elastic limit. Also used for armor plate, for parts of machinery, and for very hard steel plate for making 3-ply and 5-ply plate for plows and burglar-proof safes, the plates being alternated with plates of wrought iron for this purpose. Steel with 0.50 to 2 per cent. Cr is also used for automobile parts where hardness is required, *e.g.*, gears and other special parts, although a nickel-chrome steel is more generally used. Typical percentage analyses of chrome-vanadium crucible steel and of chrome-nickel electric steel are as follows:

	C	Mn	Si	P	S	Cr	V	Ni
Chrome-vanadium steel......	0.49	0.86	0.15	0.009	0.021	1.18	0.19	....
Chrome-nickel steel.........	0.48	0.44	0.15	0.009	0.009	0.98	....	2.02

Vanadium is not a good commercial deoxidizing agent, as formerly supposed (G. L. Norris). It undoubtedly has considerable deoxidizing power, but is too expensive to be used in this way. It is used as an alloy to improve the physical properties of steel, and should be added to the steel under such conditions that a minimum is lost by oxidation. It increases the elastic ratio and resistance to shock, and is largely used in conjunction with chromium. **Vanadium steels** contain generally between 0.15 and 0.25 per cent. of vanadium, and present knowledge indicates that for structural steels, *i.e.*, forging and machinery steels, there is little gained by adding higher percentages. They must be heated gradually, but are forged without difficulty, although they must be worked carefully at first. Chrome-vanadium or nickel-vanadium steels are used more than plain vanadium steels, though recent developments indicate that there will be in the future a strong trend to simple carbon-vanadium steel.

Table 13. Properties of Carbon-Vanadium Steels (Norris)

Steel	Analysis per cent.					Treatment	Yield point, 1000 lb. per sq. in.	Elastic limit, 1000 lb. per sq. in.	Ultimate strength, 1000 lb. per sq. in.	Elong. in 2 in., per cent.	Contr. of area, per cent.
	C	Mn	P	S	Va

0.80	1.11	0.45	120,960	172,700	10.0	17.6

Table 14 shows the influence of vanadium on ordinary mild steel and on mild nickel steel. The bars were tested as rolled, being ¾-in. rounds. Table 15 shows the influence of vanadium on high-carbon steels supplied by Wiener and tested by Harbord, a bar of pure iron with 0.85 per cent. vanadium being included in the tests for comparison. Test bars were ¾-in. rounds. Table 16 (Harbord) illustrates the effect of vanadium, both alone and when alloyed with chromium, in raising the tensile strength and the yield point without very appreciably reducing the elongation or reduction of area.

Table 16. Effect of Adding Vanadium and Chromium on the Physical Properties of Various Steels

Steels	Yield point, lb., per sq. in.	Ultimate stress, lb. per sq. in.	Elastic ratio	Elongation, per cent. on 2 in.	Reduction of area, per cent.
Crucible steels (carbon, 0.22 to 0.25 per cent.):					
Plain carbon, manganese	35,840	60,480	0.592	35.0	60.0
Plain carbon + 0.5 per cent. Cr.	51,300	76,160	0.673	33.0	60.6
Plain carbon + 1.0 per cent. Cr.	56,000	85,570	0.654	30.0	57.3
Plain carbon + 0.1 per cent. V.	63,840	77,950	0.819	31.0	60.0
Plain carbon + 0.15 per cent. V.	68,100	81,760	0.833	26.0	59.0
Plain carbon + 0.25 per cent. V.	76,380	88,030	0.867	24.0	59.0
Plain carbon + 1.0 per cent. Cr. + 0.15 per cent. V.	81,090	108,860	0.745	24.0	56.6
Plain carbon + 1.0 per cent. Cr. + 0.25 per cent. V.	110,660	135,300	0.818	18.5	46.3
Nickel steel	58,240	94,080	0.619	24.0	50.0
Nickel steel + 0.2 per cent. V	116,700	129,700	0.899	20.5	52.4
Open-hearth steels (carbon, 0.25 to 0.27 per cent.):					
Plain carbon, manganese	39,650	72,130	0.549	34.0	52.6
Plain carbon + 1.0 per cent. Cr. + 0.15 per cent. V.	77,060	117,820	0.654	25.0	55.5

Chrome-vanadium steels combine the good effects of chromium and vanadium in the same steel. Table 17 (Stoughton) gives the composition of five types of such steels, all of which should contain as little sulphur and phosphorus as possible ($S \leq 0.035$ per cent.). With $P = 0.02$ per cent., Si may be 0.15 per cent. in *D* and 0.10 in *A*, *B* and *C*. With P at 0.03 per cent., Si should not exceed 0.05–0.06 per cent. in *A*, *B* and *C*, or 0.10 in *D*.

Table 17. Types of Chrome-vanadium Steel

Percentage composition	Type *A*	Type *B*	Type *C*	Type *D*	Type *E*
Carbon	0.25–0.30	0.20	0.20	0.45–0.55	0.12–0.15
Manganese	0.40–0.50	0.30–0.40	0.40	0.80–1.00	0.20
Chromium	1.00	0.50	0.80	1.25	0.30
Vanadium	0.16–0.18	0.12	0.16	0.18	0.12

Type *A* is designed for use in light axles, connecting rods, side and main rods, driving axles and piston rods, and should be annealed at 1472 deg. fahr. for 1 or 2 hr. and then cooled in air or ashes according to the nature of piece. It may be used for crankshafts, transmission parts and crank pins after quenching from 1652 deg. fahr. in lard or fish oil, annealing at 1022 deg. fahr. for ½ to 2 hr. and then cooling in air. Also for gears in constant mesh when not unduly pressed in service, after quenching from 1742 deg. in lard oil, tempering at 680 deg. for 15 to 30 min. (preferably in a lead bath) and cooling in air.

Type *B* is used in axles, hammer rods, bolts and in places where great resistance to torsion is demanded. Type *C* is an intermediate steel useful for car axles, holding bolts, etc.

Type *D* is used for solid wheels for railway use, gun barrels, crank pins, etc.; it should be annealed for 1 hr. at 1472 deg., and cooled slowly, taking great care not to chill or to pass from 1472 deg. to 1112 deg. too quickly. It may also be used for automobile, carriage and locomotive springs when quenched in oil from 1652 deg., tempered at from 752 to 842 deg. (preferably in a lead bath), and cooled in air.

Type *E* is a steel for all engine and machine parts that are to be case-hardened. Treatment: ordinary case-hardening process.

Table 18 gives some results of mechanical tests of typical chrome-vanadium and other steels for automobile purposes. Steel No. 3, designated as Type *A*, No. 1, is the Type *A* steel given in Table 17. Steel No. 4, designated as Type *A*, No. 2, is the same steel with the heat-treatment recommended for crank shafts. No. 5 steel, designated as Type *A*, No. 3, is the same steel with heat treatment recommended for gears in constant mesh.

Table 18. Results of Mechanical Tests of Typical Chrome-vanadium and Other Steels (Stoughton)

Test	No. 1. Carbon "axle" steel	No. 2. Nickel "axle" steel	No. 3. Vanadium crank-shaft steel. (Type *A*, No. 1)	No. 4. Vanadium crank-shaft steel. (Type *A*, No. 2)	No. 5. Vanadium gear steel, continual mesh. (Type *A*, No 3)
Yield point, lb. per sq. in.	41,330	49,270	63,570	110,100	224,000

Molybdenum increases the hardness of steel by keeping the carbon in solution. It is used especially in conjunction with tungsten in the production of high-speed cutting tools.

Tungsten also increases the hardness of steel by keeping the carbon in solution. It is largely used in the production of high-speed cutting tools. It increases the magnetic retentivity of high-carbon steel. Steel of approximately the following (percentage) analysis is largely used for permanent magnets: C, 0.60 to 0.75; Si, 0.15; Mn, 0.32; P, 0.015; S, 0.015; W, 5.0.

Aluminum in small quantities (about 0.10 per cent.) increases the fluidity of steel, reduces the iron oxide present, and tends to the elimination of blow holes, but greatly increases the tendency to pipe. Over 0.85 per cent. reduces toughness.

Titanium removes nitrogen and oxides from steel and goes chiefly into the slag as TiO_2. About 0.1 per cent. is usually added when used at all.

Copper increases the red-shortness of steel when much sulphur is present, but otherwise small amounts are not deleterious. It is said to increase the resistance of steel to corrosion.

Oxygen in the form of iron oxide dissolved in iron makes the metal both red-short and cold-short; in combination with manganese this effect is not so noticeable. Ledebur states that iron containing combined oxygen up to 0.10 per cent. can be worked, but that above this the metal is bad.

Nitrogen makes steel brittle, but little is known about it in a quantitative way.

Table 19 gives a résumé of the known effects of the chemical composition upon the physical properties of steel. A plus sign indicates that the element increases the value of the physical property, a minus sign that it decreases it, and a zero that there is no effect, so far as known.

Table 19. Influence of Chemical Composition on the Physical Properties of Steel

	Tensile strength	Elastic ratio	Ductility	Hardness	Hardening power	Brittleness	Resistance to shock	Resistance to vibratory stresses	Forgeability, absence of red-shortness	Weldability
Carbon	(1)	+	−	+	(2)	+	(12)	+	−	−
Phosphorus	(13)		(3)	0		(4)	−	−	0	
Manganese	+	−		+					(5)	
Sulphur				0					−	−
Silicon			(6)	0					(7)

Copper				0					(11)	
Oxygen						+			−	
Nitrogen						+				

(1) + up to 1 per cent., then −; (2) + up to 0.85 per cent.; (3) 0 up to 0.1 per cent.; then −; (4) + over 0.1 per cent.; (5) + up to 0.5 per cent.; (6) − above 1.5 per cent.; (7) − over 6 per cent.; (8) − over 0.85 per cent.; (9) − slightly; (10) − over 1 per cent.; (11) − from 2 to 7 per cent.; (12) + up to 0.3 per cent., then − ; (13) + up to 0.1 per cent., then −.

Self-hardening Steel is steel which is hard without being subjected to any quenching treatment or other hardening process. It can be made soft enough for machining only by long and careful annealing. It is often called **air-hardening steel,** because when it cools in the air from a red heat or above it is not soft like ordinary steel but is hard and capable of cutting other metals. All self-hardening steels are austenitic and non-magnetic. A typical analysis of self-hardening **Mushet steel** shows 9 per cent. tungsten, 2.50 per cent. Mn, and 1.85 per cent. C. Steels of this type are used very largely at the present time for very heavy or deep cuts and especially for cutting extra-hard metal, such as roughing cuts on armor plate and other hard alloys. The cutting speed is not much if any greater than that for ordinary carbon tool steel, but the economy of its use is due to the fact that it will take very deep cuts and requires less frequent regrinding. The 2.50 per cent. of manganese in Mushet steel can be replaced by 1 or 2 per cent. of chromium, giving a self-hardening tool steel which has the same advantageous properties. The 9 per cent. of tungsten may be replaced by from 4 to 6 per cent. of molybdenum, this latter increasing the toughness.

High-speed Steels (see also pp. 1430 and 1458) are alloy tool steels of remarkable cutting power. The following table (mainly deduced from Hibbard, Bull. 100, Bureau of Mines) shows the composition of high-speed steels made since 1913. Steel A represents the variation in composition in 16 American steels from nine different makers. Steel B represents the average analysis from one important American maker; C the average of two English samples, and D the average of three German samples.

Analyses of High-speed Steels (Percentage Composition)

Steel	C	Mn	Si	S	P	Cr	W	V	Co
A	0.64–0.77	0.14–0.45	0.07–0.40	0.02–0.04	0.01–0.05	3.30–5.28	13.30–19.10	0.45–1.35	2.70–5.28
B	0.65	0.31	0.27	0.013	0.007	2.99	16.87	0.85–1.0	
C	0.68	0.22	0.26	0.025	0.02	2.95	18.46	1.10	
D	0.66	0.11	0.18	0.023	0.027	4.30	15.73	0.78	4.05

In one sample of steel A, Mn was 2.29 and in another V was 2.50; in a few of the steels Ni from 0.17 to 0.28 occurs (probably added accidentally); in steel A the cobalt was found in only 5 samples. Mo was found in 2 of the German steels, D, 0.67 and 0.72 respectively.

In recent high-speed steels, carbon generally varies between 0.40 and 0.80 per cent., the majority of steels containing about 0.65 per cent. For cutting hot steel of comparatively low carbon content, the cutting tool should have about 0.45 per cent. carbon. Chromium varies between 2 and 6 per cent. in American steels, while sometimes reaching 9 per cent. in Europe. Molybdenum gives a fine cutting edge (its effect is about twice that of tungsten) but its use is being discontinued since tools containing it are liable to crack in quenching and to develop physical imperfections. The vanadium content usually varies from 0.8 to 1.75 per cent.; like chromium, it increases the red hardness of the cutting edge and the life of the tool before regrinding. Cobalt up to about 4 per cent. is said to increase the ability to hold the cutting edge in work and to increase the red hardness.

High-speed steel can be worked satisfactorily under hammer or press at a temperature of about 2150 deg. fahr. (1180 deg. cent.). It may be annealed by machining by heating carefully to 1472 deg. fahr. with extreme slowness and cooling very slowly. The modern heat treatment for high-speed tools is to heat carefully to a temperature near the melting point and quench in oil. Cooling by air blast, and double treatment, formerly recommended, are now uncommon. Milling cutters and similar tools are generally tempered. High-speed steels are austenitic after heat treatment and become harder in use or after moderate tempering.

Gledhill found that a certain high-speed steel after being annealed 12 or 18 hours at 1400 deg. fahr. had the following physical properties: E. L., 98,600 lb. per sq. in.; T. S., 129,200; elong. 18 per cent. in 2 in.; contr. of area, 35 per cent.

In addition to the large use of high-speed steels for cutting tools they have given excellent results in exhaust valves for automobile engines and for the dies used in the manufacture of extruded brass which is near its fusion point when it is forced through the die.

Influence of Mechanical Treatment on the Physical Properties of Steel

Hot Work consists of mechanical treatment such as forging, rolling, pressing, etc., at temperatures above the thermal critical range. It is applied to ingot metal either shortly after solidification or after cooling and reheating to the working temperature of about 2150 deg. fahr. (1180 deg. cent.) It increases tensile strength and ductility, and especially resistance to shocks and vibratory stresses. The finishing temperature is important and should be as near as practicable to the thermal critical range and above it, the exact temperature depending upon the carbon content. If the carbon is low enough, blow holes are closed and probably welded together, thus increasing the soundness. It also corrects fragility due to unequal cooling stresses in the ingot. In large sections the finishing temperature should be so regulated that the central portions will not suffer from the weakening influence of too high a finishing temperature, while at the same time the outside will not suffer unduly from the effect of cold-working. This is especially important for rails or other sections of uneven thickness.

Both wrought iron and steel are rendered exceedingly brittle in the cold state by working at a "blue heat" (430–600 deg. fahr., or the temperature range of the color scale for tempering carbon steel), soft steel being the least affected. Boilersmiths commonly desist from working a plate when it has cooled below a temperature at which the mark made by rubbing it with a piece of wood will glow.

The **effect of rolling** is to stretch steel at the same time it is compressed. **Hammering** is more effective than rolling, but the metal at the interior is not as effectually worked as that on the exterior. This is especially true when the hammer is not large or heavy enough for forging. Drop-forgings are usually heated to high temperatures and the amount of reduction on the forgings is comparatively small. For this reason only well-worked blooms or bars of soft steel should be employed for this purpose. **Pressing** more effectively works the steel than either rolling or hammering, and, as all of the energy of the press is utilized in the compression of the steel and the metal is worked to a greater depth, this method is the best for large sections.

Rolling, hammering, and pressing all reduce the size of the grain of the steel and, if thoroughly done, effectively break up the ingotism or coarse crystallization of a cast ingot as well as the coarseness of grain which may have resulted from heating the forging or bloom to too high a temperature during some previous operation. It is usual to roll blooms from ingots having at least four times the cross-section of the resulting bloom, and blooms are hammered or pressed into forgings with reductions varying in the proportion of from 100 to 75 to 100 to 50. Increasing the amount of mechanical hot work beyond certain moderate limits has little influence on the physical properties. The effects of rolling are shown in the comparison of plates of different gages. Taking ½ in. as a basis, there will be the following changes in the physical properties for every increase of ¼ in. in thickness: (1) A decrease in ultimate strength of 1000 lb. per sq. in.; (2) a decrease in elongation of 1 per cent. when measured in an 8-in. parallel section; (3) a decrease in reduction of area of 2 per cent.

Cold Work is work done on the metal while its temperature is below the thermal critical range. It includes cold-rolling, cold-pressing, twisting and wire-drawing. It increases greatly the elastic limit and tensile strength, especially the former, but greatly increases the brittleness. Tensile strengths after **wire-drawing** are substantially as given in Table 20.

The modulus of elasticity E_1 of wire ropes is less than that of the wires composing them, as follows: Single-strand (1 twist), $E_1 = 0.6E$; strands twisted about around a core—ordinary wire rope (double twist), $E_1 = 0.36\,E$; wire ropes twisted into cable (triple twist), $E_1 = 0.216\,E$. Special qualities of tempered and improved cast-steel wire may attain to 300,000 to 340,000 lb. per sq. in. A test on a piano wire of 0.0284 in. diam. developed a tensile strength of 462,870 lb. per sq. in. Steel used for wire-drawing generally contains from 0.05 to 0.90 per cent. carbon. The effects of **cold-twisting** steel bars are shown in Table 21.

Effect of Repeated Stresses. Little information is available on the effect of repeated stresses on the physical properties of steel. J. B. Kommers, experimenting with the Landgraf-Turner machine, obtained the results given in Table 22, which illustrate the influence of increasing carbon content, of increasing phosphorus content, and the effect of cold work on the resistance to repeated stresses. He suggests a "quality factor," which is the product of the unit stress to which the specimen is subjected, multiplied by the number of cycles required for rupture and divided by 10,000.

E. Nusbaumer (Carnegie Scholarship Memoirs, Vol. 6, 1914, *Jour. Iron and Steel Inst.*) finds for the steels commonly employed in industrial practice, as follows:

1. In the annealed state the resistance to rotary bending stresses, to repeated shocks, or to alternating bending (vibrations) is proportional to the percentage of carbon in steels when lower than 0.25 to 0.30 per cent. Above this percentage the ratio between the percentage of carbon and the resistance becomes inverse as regards repeated shocks, but remains as it was in regard to rotary bending and alternating bending (vibrations).

Steels with a low percentage of nickel generally display a higher resistance to repeated shocks and to alternating bending (vibrations) than carbon steels. High-nickel steels resist repeated shocks of small intensity remarkably well in an untreated condition. Nickel-chromium steels offer a yet higher resistance than nickel steels to repeated shocks and to alternating bending (vibrations), the dead-mild steel displaying the maximum resistance.

2. Quenching, followed by annealing, raises the resistance of plain carbon steels and of steels containing small percentages of nickel to repeated shocks and to alternating bending (vibrations). It tends to diminish the resistance of nickel-chromium steels. Quench-

* O. Q. & A. = Oil-quenched and annealed.

ing not followed by annealing raises the resistance of mild carbon steels, and particularly of steels with small percentages of nickel, to repeated shocks. Nickel-chromium steels, particularly the softer grades, also have their resistance increased to a notable degree. It diminishes the resistance of semi-hard nickel-chromium steels, and still more of hard carbon steels with a high percentage of nickel. Quenching not followed by annealing diminishes considerably the resistance of plain carbon steels and of steels with small percentages of nickel to alternating bending (vibrations). It raises, on the other hand, the resistance of nickel-chromium steels.

3. The resistance of a metal to repeated stresses is proportional to its resistance to the simple impact test for notched bars (Frémont test). Austenite is the particular microscopic constituent in steel which offers the greatest resistance to repeated shocks; ferrite offers a far lower degree of resistance, hence the poor results obtained with very soft steels. Martensite is the one whose resistance is lowest, and, generally speaking, very close to zero.

Table 23 gives results of experiments made by the United States Government at the Watertown Arsenal on the endurance of rotating shafts about 1 in. in diameter. It probably gives the best results that can be obtained for the various grades of steel, and shows that a great increase in endurance follows the use of material having a high elastic limit.

Influence of Heat Treatment on the Physical Properties of Steel

The curves given in Figs. 1 and 2 were obtained by Kollmann and Howard, respectively. They show the tensile strength of wrought iron and steels of various carbon percentages at different temperatures, as follows: *aa*, Bessemer steel (0.23 C); *bb*, steel (0.62 C); *cc*, wrought iron (0.1 C); *dd*, steel (0.97 C, 0.8 Mn); *ee*, steel (0.37 C, 0.7 Mn); *ff*, steel (0.09C, 0.11Mn); *gg*, wrought iron. See also p. 543.

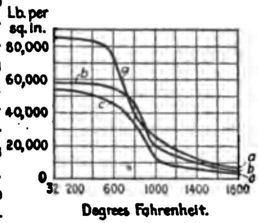

FIG. 1.

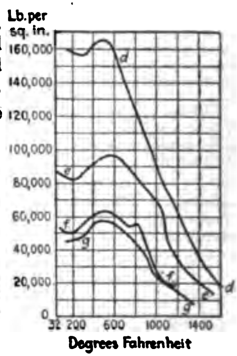

FIG. 2.

Annealing. Steel castings are annealed for the purpose of refining the very coarse microstructure (ingotism) characteristic of all metals cooled slowly through and below the solidification point. The treatment also removes strains due to uneven cooling. Annealing increases the tensile strength and elongation, and particularly resistance to shock. It reduces the hardness. The practice recommended by the American Society for Testing Materials (A. S. T. M. yearbook, 1915, adopted 1914) for the annealing of **carbon-steel castings** is as follows: Castings should be heated slowly and uniformly to temperatures as below.

Carbon content, per cent	up to 0.16	0.16–0.34	0.35–0.54	0.55–0.79
Temperatures, deg. fahr. (cent.)	1697(925)	1607(875)	1562(850)	1526(830)

Temperatures of 122 deg. fahr. (and in special cases 212 deg.) higher than those just given are allowable when necessary. Castings should be kept at maximum temperature sufficiently long to insure the refining of the grain. In general, the heavier the sections the longer must be the time of exposure to maximum temperature. Castings should be cooled slowly and uniformly in the furnace when maximum softness is desired, but may be cooled at an accelerated rate when it is desired that the steel possess rather higher tensile strength and elastic limit than can be procured by very slow cooling. The cooling must be so conducted as to leave the steel reasonably free from cooling stresses.

Objects of **rolled and forged carbon steel** are annealed principally to remove existing coarseness of grain, especially in large sections where the work has not penetrated the metal sufficiently or where the finishing temperature is high. The practice recommended by the A. S. T. M. (yearbook, 1915, adopted 1911) is as follows:

Carbon content, per cent	< 0.12	0.12–0.29	0.30–0.49	0.50–1.00
Annealing temperature, deg. fahr	1607–1697	1544–1598	1499–1544	1454–1499
Annealing temperature, deg. cent	875–925	840–870	815–840	790–815

Heating should be slow so as to allow all parts of metal to reach the annealing temperature without heating the outside needlessly high, which tends to recoarsen the grain. An exposure of 1 hr. at the maximum temperature should be long enough for pieces 12 in. thick. The rate of cooling depends on the carbon content and on the size of the metal. The higher the carbon the slower should be the cooling, and the larger the section the more the bulk will naturally retarded the cooling. The slower the cooling the softer and more ductile the metal will be and the lower will be its tensile strength, elastic limit, and yield point. The greatest softness and ductility are obtained at a certain sacrifice of strength and elasticity, and *vice versa*. For most purposes, neither of these extremes is desired, and the cooling must be so regulated as to give the desired results in any particular case.

Cold-rolled or cold-drawn objects, especially **wire**, are often annealed to remove the great brittleness induced by the mechanical treatment. The A. S. T. M. recommends that the object be heated to about 1427 deg. fahr. (775 deg. cent.) and cooled with a slowness which should increase with the thickness. Thin plates may be heated merely to 1337 deg. fahr. (725 deg. cent.), followed immediately by slow cooling. In the case of thick forgings, the temperature of 1427 deg. fahr. may be maintained for several hours, though always at the cost of superficial decarburization. Steel containing less than 0.15 per cent. carbon should be annealed at 1652 deg. fahr. (900 deg. cent.). Great brittleness may be caused by annealing very-low-carbon steel in the neighborhood of 1290 deg. fahr. (700 deg. cent.) after cold-working.

Ordinary low-carbon steel is unsuitable for manufacture of screws or other inexpensive materials made chiefly by automatic machines. A special grade of steel high in phosphorus and sulphur is therefore indicated for **screw stock**, because the chips are brittle and clear themselves readily from the tool. (See S. A. E. and A. S. T. M. specifications, pp. 460 and 464.) This material is easily machined and cheap, but lacks strength and toughness and is not safe for vital parts. Screws made from hot-rolled bars of this material should be heat-treated and not used in an annealed condition. Screws made from cold-rolled or cold-drawn bars are much stronger, but the best results, in either case, are obtained by the following heat-treatment: After machining, heat to 1500 deg. fahr.; quench; reheat from 600 to 1300 deg. fahr., and cool slowly.

Hardening consists in heating steel above its thermal critical range and cooling suddenly (quenching) in water, oil, or other cooling medium which absorbs heat rapidly. Quenching steel increases its hardness, more especially as the carbon content increases. It also raises the elastic limit and tensile strength and reduces the ductility. It induces cooling strains and the metal is apt to be very brittle, especially with carbon 0.5 per cent. or over. The **effect of carbon on the physical properties of hardened steel** is shown in Table 24.

Table 24. Effect of Carbon on the Physical Properties of Hardened Steels

Carbon, per cent.	Tensile strength in soft state			Tensile strength when hardened		
	Ultimate, lb. per sq. in.	Elastic limit, lb. per sq. in.	Elongation in 2 in., per cent.	Ultimate, lb. per sq. in.	Elastic limit, lb. per sq. in.	Elongation in 2 in., per cent.
0.10	60,300	36,300	29	66,400	40,300	24
0.14	61,500	35,200	27	73,100	39,600	22
0.23	66,500	41,200	26	99,400	54,000	14
0.52	97,800	52,600	20	132,100	81,400	9
0.60	116,400	66,500	14	153,400	102,100	4
0.72	130,700	75,800	9	180,100	105,500	0

The purpose of hardening is to adapt high-carbon steel for cutting-tool purposes, or to increase the elastic limit and tensile strength in low-carbon steel, but it is seldom applied without subsequent tempering or annealing. Hardening refines markedly the microstructure of steel, and for this reason should be done on a rising temperature. In order to obtain maximum results, the temperature of quenching should be above the line *GOS* in the iron-carbon diagram described on p. 493. This line is often called Ac_3.

Tempering consists in reheating hardened or quenched steel to temperatures below the critical range for the purpose of restoring partially its ductility and softness. The rate of cooling is unimportant, although the material is generally quenched in water as a matter of convenience. The elasticity and tensile strength in tempered steels are reduced somewhat below the values for hardened steel, although they are greater than those for the original rolled or forged metal. It is generally necessary to use a pyrometer or other accurate means of measuring temperatures for annealing and hardening, but tempering temperatures are easily controlled by the examination of the surface of the metal, which has previously been made bright. A thin film of oxide forms upon the steel, the color of this film varying with the tempering temperature.

The **tempering temperatures and colors of oxide films for various tools,** arranged approximately in their order on the color scale are as follows: Scrapers for brass, steel-engraving tools, light turning tools, hammer faces, planer tools for steel, planer tools for iron, wood-engraving tools, drills, milling cutters: 437 to 455 deg. fahr. (225 to 235 deg. cent.); light straw to straw. Wire-drawing plates, boring cutters, screw-cutting dies, taps, rock drills, mill chisels and picks, punches and dies, reamers, shear blades, half-round bits, planer knives and molding cutters (to be ground), gouges, plane irons: 456 to 482 deg. fahr. (236 to 250 deg. cent.); dark straw to yellow-brown. Twist drills, flat drills, wood-boring cutters, drifts, cup tools, edging cutters: 483 to 527 deg. fahr. (251 to 275 deg. cent.); yellow-brown to dark purple. Wood bits and augers, cold chisels for steel, axes and adzes, gimlets, cold chisels for cast iron, needles, wood chisels, hack saws, cold chisels for wrought iron, planer knives and molding cutters (to be filed), circular saws for metal, screwdrivers, springs, saws for wood: 528 to 572 deg. fahr. (276 to 300 deg. cent.); dark purple to full blue.

Combined Hardening and Tempering. In tools like chisels where the edge of the tool only is to be hardened, this portion is first heated just above the critical range and then the extreme point only is quenched in water until it is black, after which it is withdrawn and rubbed bright upon a piece of sandpaper or a brick. This is done merely to give a bright surface on which to observe the play of the temper colors. The heat from the shank now begins to creep down into the point, which shows the various temperature colors in order. At the proper time the whole tool is plunged into water to prevent more heat from coming down to the tempered point. It has nothing to do with the tempering operation itself.

Double Quenching. When steel of any carbon content is quenched from above the critical range and then reheated to a point just below the range and quenched again, it is said to have been subjected to "double quenching." The operation is sometimes called "double annealing," but it is in reality a quenching and prolonged tempering operation, since the term annealing refers strictly to comparatively slow cooling from *above* the critical range. It is used principally on steels with 0.5 per cent. carbon or less, but may be applied to steels with higher carbon for the purpose of increasing the resistance to wear while giving a moderate combination of elasticity, tensile strength, and ductility. In the lower-carbon steels, it greatly increases the toughness, elasticity, tensile strength, and resistance to shock, while retaining for the metal considerable ductility. It has been applied successfully to crank shafts as large as 8 in. in diameter, and, although expensive, is coming more and more into use for high-grade mechanical parts. Great care must be observed, however, in carrying out the operations, otherwise incipient quenching cracks will be formed, which later lead to fractures.

The **quenching temperature** should be well above the critical range, and the heating should be slow up to and through the critical range. The quenching may be done in water for very-low-carbon steel, or in oil for higher-carbon, and the piece should be removed from the quenching bath before it reaches 212 deg. fahr. (100 deg. cent.), and preferably above 320 deg. fahr. (160 deg. cent.). This lessens the danger of cracking. The second heating should begin a very few hours after the first quenching, and if possible without ever allowing the piece to cool below 212 deg. fahr. For very high elastic limit and tensile strength, the second heating should be made at from 932 to 1202 deg. fahr. (500 to 650 deg. cent.). In this case the ductility will be low. Some steels, such as watch springs and shafting, are annealed at 662 deg. fahr. (350 deg. cent.). Little commercial annealing is done below 932 deg. fahr. (500 deg. cent.). For tensile strength, elastic limit, and ductility best suited to the majority of cases, the second heating should be at from 1112 to 1202 deg. fahr. (600 to 650 deg. cent.). For the greatest ductility with great strength and elastic limit, the second heating should be at from 1337 to 1382 deg. fahr. (725 to 750 deg. cent.). The object should be held at the second heating temperature long enough not only to allow its interior to reach that temperature, but also to relieve the stress given in the water- or oil-quenching. For pieces of moderate thickness, a 4-hr. exposure should suffice. The above practice is that recommended by the American Society for Testing Materials.

Factors in the Hardening of Tool Steel. Mathews (*Trans. A. S. M. E.*, vol. 36) states that the **carbon content** of tool steels (carbon steels made by the crucible or electric process) ranges from 0.60 to 1.50 per cent. (0.75 to 1.35 per cent. for nine-tenths of the steels used). If the **time of heating** is too short, the temperature of the piece is not uniform and the grain size may be variable. If the piece is held for too long a time above the critical range, the large grain size thus produced is retained on quenching and the result is a weak or cracked piece. The martensitic structure desired in a hardened steel requires **quick cooling** through the thermal critical range. As regards commercial **quenching media,** pure water has a fairly constant quenching rate up to a temperature of 100 deg. fahr., where it begins to fall off. Brine solutions have a quicker rate of cooling and the quenching rate does not begin to fall off seriously below 150 deg. fahr. At 70 deg. fahr. a brine solution quenches about 10 per cent. faster than water. Oils generally have a more constant rate of cooling throughout a larger temperature range than water or brine, but are slower in their quenching powers.

To produce the same hardness a larger section must be heated hotter than a smaller one. Mathews found that a 3/16-in. round bar of a particular steel would harden at 1395 deg. fahr., while a 3/4-in. bar required a temperature of 1450 deg. It is necessary to draw the temper of a tool steel *promptly* after hardening, otherwise the tool may burst and fly apart. The **effect of tempering on hardness** was found by Heyn for a particular steel to be as follows (results in per cent. of original hardness):

Tempering temp., deg fahr..........	212	392	572	752	932	1112
Per cent. decrease in hardness.......	2.5	14	41	70	87.5	97.5

The **effect of time on the tempering process** is shown by Mathews in the following table [Standard 1/2-in. round A. S. T. M. test pieces were quenched in oil from a constant temperature (1550 deg. fahr.) and the temper drawn in the same salt bath at 800 deg. for the number of minutes indicated]:

Time, min.	Elastic limit, lb. per sq. in.	Max. strength, lb. per sq. in.	Elongation, per cent.	Reduction of area, per cent.	Brinell hardness number
8	228,750	260,137	2.5	.....	425
20	201,125	214,562	11.6	45.40	390
40	175,000	183,187	12.0	49.35	340

The following table (Mathews) shows the **influence of mass on the tempering operation.** It also shows that the greater the initial hardness of the piece, the more marked is the effect of drawing the temperature.

Case-hardening. Where steel with a very hard surface is desired, as in gears, bearings, armor plate, etc., a combination of hard exterior with soft and ductile core is obtained by introducing carbon into the skin or shell of the metal. Stock of 0.10 to 0.20 per cent. carbon is generally used, and sometimes nickel steel, chrome steel, or chrome-nickel steel. Ordinarily the steel should not contain over 0.25 per cent. Mn, lest the case be too brittle, although in special cases as much as 1.30 per cent. Mn may be present, with the object of making the case very hard. The elements which exist as double carbides favor the absorption of carbon, *e.g.*, manganese, tungsten, chromium, molybdenum, while those which form solid solutions—nickel, silicon, and aluminum—oppose it.

The **operations** in case-hardening are as follows: 1. Carbonize in case-hardening material. 2. Allow the piece to cool in the box or in air to black in daylight. 3. Reheat to above the critical range of the low-carbon core and quench in oil or water. 4. Reheat to above the critical range of the high-carbon case and quench in oil or water. These four treatments result in a fine, silky core and a hard, close-grained case capable of withstanding heavy shocks and continued wear. Sometimes treatments 3 and 4 are omitted or the steel is quenched directly from the carburizing temperature, but both methods are bad practice.

The **materials used** in case-hardening may be solid, liquid, or gaseous, although solid materials are used most extensively, the most important being charcoal (both wood and bone), charred leather, crushed bone, horn, mixtures of barium carbonate and charcoal, or of salt and charcoal; and for quick or very superficial hardening, powdered potassium cyanide and potassium ferrocyanide, or mixtures of potassium ferrocyanide and potassium bichromate. A molten bath of potassium cyanide heated to 1562 deg. fahr. (850 deg. cent.), in which the steel articles are immersed, produces quickly superficial but hard and even cases. The poisonous character of the escaping gases is a serious objection to the use of cyanide. The carburizing of iron may also be performed at the proper temperature by means of gases, such as illuminating or other coal or oil gases rich in hydrocarbons. At the Krupp works in Germany, gases are used for carburizing the faces of armor plates. The relative merits of wood charcoal, charred leather, and a mixture of barium carbonate and wood charcoal are shown in Fig. 3 (Shaw-Scott). See also Heathcote (*Jour. Iron and Steel Inst.*, 1914) on the relative values of various case-hardening mixtures.

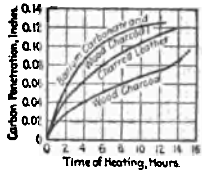

FIG. 3.

Many so-called secret **mixtures** are offered for sale as case-hardening substances, for which extraordinary virtues are claimed, the usual statement being that by their use steel of ordinary or inferior quality may be converted into high-grade metal comparable to the best crucible steel. On investigation they are generally found to be chiefly mixtures of carbonaceous and cyanogen compounds possessing the well-known carburizing properties of those substances.

The **carburizing temperature** will vary somewhat with the results desired, but generally lies between 1652 deg. fahr. (900 deg. cent.) and 1742 deg. fahr. (950 deg. cent.).

The **time required for carburizing** varies with the thickness of the case to be obtained. Fig. 4 (Guillet) shows the influence of temperature and of time on the depth of penetration of carbon. Material used was not stated. The full line represents relative penetrations at 1832 deg. fahr. (1000 deg. cent.) after different lengths of time, while the broken line represents the depths of penetration resulting from heating for 8 hr. at different temperatures.

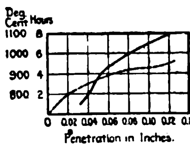

FIG. 4.

The easy way of controlling the case-hardening process is to make microscopic examination of test pieces. The following **case-hardening practice** is recommended by the American Society for Testing Materials (yearbook, 1915, adopted 1914).

1. When hardness of case only is desired and lack of toughness or even brittleness is unimportant, the carburized objects may be quenched from

carburizing temperature, as, for instance, by emptying the contents of the boxes in cold water or oil. Both the core and the case are then coarsely crystalline.

2. In order to reduce the hardening stresses and to decrease the danger of distortion and cracking in the quenching bath, the objects may be removed from the box and allowed to cool before quenching to a temperature slightly exceeding the critical range of the case, namely, 1472 to 1517 deg. fahr. (800 to 825 deg. cent.). Both the core and case remain coarsely crystalline.

3. To refine the case and increase its toughness, the carburized objects should be allowed to cool slowly in the carburizing box within the furnace or outside to 1202 deg. fahr. or below, and should then be reheated to a temperature slightly exceeding the lower critical point of the case (in the majority of instances a temperature varying in accordance with the carbon content and thickness of the case between 1427 and 1517 deg. fahr. will be suitable), and quenched in water, or, for greater toughness but less hardness, in oil. The objects should be removed from the quenching bath before their temperature has fallen below 212 deg. fahr. This treatment is more especially to be recommended when the carburizing temperature has not exceeded 1652 deg. fahr. It refines the case but not the core.

4. To refine the core and the case and to increase their toughness, the objects should be allowed to cool slowly from the carburizing temperature to 1202 deg. fahr. or below and should then be (*a*) reheated to a temperature exceeding the critical point of the core, which will generally be from 1652 to 1742 deg. fahr., followed by quenching in water or in oil; and (*b*) before they have cooled below 212 deg. fahr. they should be reheated to a temperature slightly exceeding the lower critical point of the case (in the majority of instances a temperature varying in accordance with the carbon content and thickness of the case between 1427 and 1517 deg. fahr. will be suitable), and again quenched in water or oil.

The objects should be removed from the quenching bath before they have cooled below 212 deg. fahr. in order to lessen the danger of cracking, and they should be placed in the reheating furnace while still at a temperature of at least 212 deg. fahr. likewise to lessen the danger of cracking, it being inadvisable (*a*) to allow steel to cool completely in the quenching bath and (*b*) to place hardened steel in a hot furnace. Obviously, if the furnace is cold the hardened steel may likewise be cold when placed in it for reheating.

5. In order to reduce the hardening stresses created by quenching, the objects, as a final treatment, may be tempered by reheating them to a temperature not exceeding 392 deg. fahr.

The Special Brittleness of Low-carbon Steel. The special brittleness exhibited by steel with less than 0.15 per cent. of carbon after being subjected to cold work and subsequent annealing, as in thin sheets, wire, etc., is known as "Stead's brittleness." The coarse-grained steel thus produced may be refined by heating to 1652 deg. fahr. or a little higher, that is to say, above the critical range of the steel in question, and cooling slowly.

Burning, Overheating, and Restoring Steel. Overheating is more injurious to high-carbon steels than to those having a low carbon content, but the effects of this treatment can be removed by a proper annealing, provided the steel has not been overheated too much. Overheating may either change the physical properties and the microstructure, the ductility being decreased by an increase in the grain size, or if the temperature is sufficiently high, an actual disintegration of the grains may take place. In the former case it is possible to restore the steel by reworking or by annealing, but no treatment short of remelting will efface the injury to steel heated to temperatures sufficient to cause the separation of the grains, *i.e.*, to temperatures above the curve *AE* of the iron-carbon diagram (see p. 493). For a given steel, the grain size increases progressively with the increase of temperature above the critical range; cooled high-carbon steels are affected more than low-carbon steels by overheating to a given temperature.

because the range through which they must cool before reaching the critical transformation point is greater. The following table (Howe) shows that a 1.20 per cent. carbon steel can be refined when heated to 2400 deg. fahr., but that the steel is burned and the crystals separated by heating above this temperature.

Temperature to which steel was heated, deg. fahr.		2400	2525	2650	2775
Angle through which a 5/16-in. square bar was bent, deg.	steel not refined	14	7	4	3
	steel refined	144	21	10	0

Surface Decarburization of Steel. When high-carbon steel is heated for a long time above the critical range, the surface or skin becomes decarburized, even when packed in sealed iron tubes containing charcoal. This is a common occurrence in the manufacture of tool steel, and the carbon in the skin may be reduced to zero, rendering the outside of the steel useless for cutting purposes. The remedies are either to anneal the steel below the critical point, or to machine off the decarburized skin or "bark."

Special Annealing for Tool Steel. To prevent decarburization and to obtain the free cementite in a globular or spheroidized form (sometimes called granular pearlite), high-carbon steel is often annealed at about 1250 deg. fahr. for several hours, preferably in a neutral packing (cast-iron filings or chips, ashes, or sand). This treatment makes the steel more easily machined and prevents the formation of needlelike crystals or plates of free cementite in the hardened steel.

Formation of Graphite in Steel. When high-carbon steel high in silicon is heated for a long time above the critical range, small rounded particles of graphite (amorphous temper carbon similar to that found in malleable cast iron) are formed, ruining the steel both by the presence of soft spots and the reduction of the combined carbon, sometimes down to 0.4 or 0.5 per cent. The only remedy is remelting. This trouble is especially liable to occur in the manufacture of files.

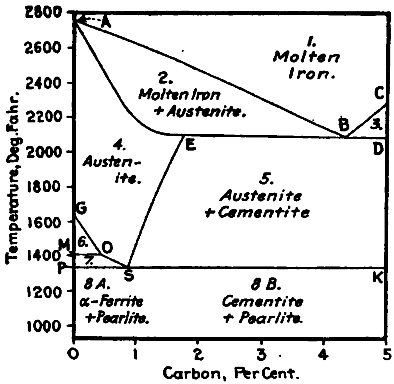

FIG. 5.

Metallography of Iron and Steel

(See Sauveur's "Metallography of Iron and Steel," 1912)

Metallography is the study of the microstructure and the thermal curves of metals. **Critical temperatures** are temperatures at which retardations occur in the heating and cooling curves of iron and steel. The critical temperatures on heating generally occur some 30 to 40 deg. cent. above those on cooling, but indicate reversals of the same phenomena.

Iron-Carbon Equilibrium Diagram. When the critical points (or temperatures) of iron and steel are plotted with temperature and carbon content as co-ordinates, as in Fig. 5, the so-called equilibrium diagram is obtained. This is also called the Roberts-Austen-Roozeboom diagram. The temperatures plotted in the figure are those obtained on heating, since these are of the greater importance in the heat-treatment of steel. They are only approximate. The line *PSK* is often called A_1; *SK*, $A_{3.2.1}$; the line *MO* is called A_2; *GO* is called A_3; the line *OS*, $A_{3.2}$; and the line *SE*, A_{cm}. The diagram represents the pure iron-carbon system. All commercial steels have varying amounts of impurities, and these affect to a considerable extent the positions of the curves and especially the lateral positions of points *S* and *B*; hence it is impracticable to draw a diagram for any actual commercial steel. The **critical range** is the region bounded by *GOS*, *PG*, *PS* and the line *SK*.

The **annealing** of steel is based on the fact that slow cooling through the critical range allows transformation to take place thoroughly and the steel acquires maximum ductility and toughness with fair tensile strength and elasticity. The **hardening** of steel is based on the fact that quick cooling through the critical range serves to retain more or less completely the structures and hence the physical properties normal above that range. Commercial rates of cooling do not prevent the change from austenite to martensite; hence the great hardness of hardened steel.

Microscopic Constituents of Iron and Steel. Specimens of iron and steel, as well as other metals, when polished and suitably etched with weak acids or other reagents, show certain **characteristic crystalline formations** under the microscope corresponding to the various fields on the iron-carbon diagram. In the following list of these constituents are stated their constitution, occurrence, microstructure, and normal position in the iron-carbon diagram.

Alpha (α) **Iron** is the common, strongly magnetic and soft form of iron which is stable for temperatures below *MO*, *OS* and *SK*. It has little or no solvent power for C and Fe_3C. (Known metallurgically as ferrite, alpha ferrite and pearlite ferrite.)

Beta (β) **Iron** is a feebly magnetic, intensely hard and brittle allotropic form of iron, stable (as free beta ferrite) between *GO* and *MO*.

Gamma (γ) **Iron** is the allotropic, non-magnetic iron normal above *G*. When associated with carbon it is stable above *GO*, *OS* and *SK*, and probably to some extent (as austenite) in regions 6 and 7. As regards hardness, it lies between alpha and beta irons.

Austenite is a solid solution of iron carbide in gamma iron. It occurs above *GOSK* (and probably in regions 6 and 7) and is retained when cold in some high-carbon special steels, especially after quick cooling. It appears as polyhedric grains.

Martensite (constitution disputed) is harder than austenite and is the principal constituent of hardened steels. It is normal along *PSK*. Under the microscope it appears as a needlelike structure arranged indistinctly in equilateral triangles.

Troostite is softer than martensite, with which it occurs in hardened steels. It is the principal constituent of steels tempered to 750 deg. fahr. It has no place in the diagram, being a transition form between martensite and sorbite. It etches black or dark brown, the arrangement being either in rosette forms or indistinctly granular at high magnifications.

Sorbite is a transition stage between troostite and pearlite and is softer than troostite. It is the principal constituent of air-cooled (annealed) steels and of hardened steels reheated to 1100 deg. fahr. (double-quenched steel). It has no place in the diagram. It appears as dark grains consisting of extremely fine black and white dots under high magnification.

Pearlite is a mechanical mixture of alpha ferrite and cementite. It is the principal constituent of slowly cooled (annealed) steels. It is always associated with an excess of ferrite or of cementite except when steel contains from 0.70 to 0.90 per cent. carbon. It is normal in regions *8A* and *8B*. It appears as dark grains at low magnification, and as alternate curved white and black laminæ at high magnifications.

Ferrite is nearly pure iron. It may contain a little P and Si. It is the softest constituent of iron and steel and the principal one of wrought iron and low-carbon steels. It also forms 87½ per cent. by weight of pearlite. It is found in regions 6, 7, *8A*, *8B*. It appears under the microscope as polyhedric grains or networks when free, or as the dark laminæ in pearlite.

Cementite is definite iron carbide (Fe_3C) and the hardest constituent. It occurs free in steels containing more than 0.90 per cent. carbon, and also forms 12½ per cent. by weight of pearlite. It is normal in regions 3, 5, *8A* and *8B*. It appears as white, brilliant masses, networks, or needles when free or as the light laminæ in pearlite.

Graphite is the crystallised carbon found in gray and mottled cast iron. It is normal in regions 3, 5, *8A* and *8B* when very slowly cooled and especially when much Si is present. It appears as long, black, wormlike particles in gray cast iron, straight or curved, and as round black dots in malleable cast iron where it occurs in the amorphous form and is known as "temper" graphite.

Steadite is a mechanical mixture of ferrite and iron phosphide (Fe_3P) occurring in cast irons high in P. It appears as fine black dots on a brilliant white background, the latter surrounded by fine black border.

Manganese Sulphide (MnS) occurs in iron and steel containing more than a trace of S, appearing as round or lenticular dove-gray spots.

Effect of Mechanical Treatment on the Microstructure of Steel. Hot work, that is, work performed above the line *GOSK* in the iron-carbon diagram, crushes the coarse crystals in the casting due to slow cooling and prevents recrystallization if the finishing temperature is close to the temperature *GOSK*. If the finishing temperature is much higher than this, the steel is free to recrystallize between the finishing temperature and the critical temperature *GOSK* and coarse-grained steel results, which can be refined only by repeated hot work or annealing. Cold work, or work performed below the critical temperature *GOSK* and more especially below the critical temperature *PSK*, causes distortion of the grains in the direction of the work, with consequent increase of elastic limit and tensile strength and great loss of ductility. This distorted structure can be made symmetrical again by annealing and the ductility restored.

Relation Between Microstructure and Physical Properties. Everything else being equal, a fine granular structure means greater strength, greater ductility, greater resistance to shock, and greater resistance to wear. Martensitic structures are sought when intense hardness is desired; sorbitic structures are strong, have great wearing qualities, and are moderately ductile if fine-grained; pearlitic structures are sought where maximum softness and ductility are desired, but the elastic limit and tensile strength are lower than in sorbitic or martensitic steels. Any of these structures may be fine or coarse, depending on the maximum temperature at which the steel is cooled and the rate of cooling, both above and through the critical range. The higher the maximum temperature from which the steel cools, the coarser the grain; and the slower the rate of cooling above the critical range, as well as through the critical range, the coarser the grain.

Sauveur gives the following **formulæ connecting the microstructure of steel with its physical properties,** which hold good only for slowly cooled or pearlitic steels.

The tensile strength (T. S., lb. per sq. in.) of any hypoeutectoid steel (with less than 0.83 per cent. carbon) can be determined from T. S. $= 500F + 1250P = 50{,}000 + 750P$, where F is the per cent. of ferrite, and P the per cent. of pearlite.

The tensile strength of any hypereutectoid steel (containing more than 0.83 per cent. carbon) may be obtained from T. S. $= 1250P + 50Cm = 5000 + 1200P$, where Cm is the per cent. of cementite.

The ductility of any hypoeutectoid steel in the pearlitic condition is determined by the formula $D = 40 - 0.3P$.

* For other widths the weights are obtainable by addition; for example, 54 × 3/4 in. = [(10 × 5) + 4] × 3/4 in., and weight = (10 × 12.75) + 10.20 = 137.7 lb. Similarly, for greater thicknesses, the weights are obtainable by addition.

Weights of Rolled Sheet Steel

Wire and Sheet Metal Gages

(Diameters and thicknesses in decimal parts of an inch)

Gage No.	American wire gage, or Brown & Sharpe (for copper wire)	Steel wire gage, or Washburn & Moen or Roebling (for steel wire)	Birmingham wire gage (B.W.G.) or Stubs' iron wire (for steel wire or sheets)	Stubs' steel wire gage	British Imperial standard wire gage (S.W.G.)	U. S. standard gage for sheet metal (iron and steel)	Trenton Iron Co.	Standard Birmingham sheet and hoop (B. G.)

IRON AND STEEL CASTINGS

BY

RICHARD MOLDENKE

CLASSIFICATION OF CASTINGS

In selecting the variety of casting best suited for a given purpose, the following classification of the regular iron foundry product will be of assistance.

Gray-iron Castings. Three types of castings are made in the ordinary gray-iron jobbing foundry. (*a*) **Soft gray-iron machinery castings** are made from an iron which can be machined readily, is not specially strong, and is sound and reliable; they should be used for the ordinary run of machine construction work. Three weights are to be considered, namely, light, medium, and heavy. Medium machinery mixtures (see Table 1) are used for ordinary castings satisfactorily, but it is not safe to make heavy castings from light machinery mixtures, as they will be very weak, and very light castings from heavy machinery mixtures will be quite hard.

(*b*) **Strong Gray-iron Machinery Castings** are adapted for medium and heavy work where a greater strength than that of ordinary cast iron is desired, but not the special strength of the steel casting. They are made by adding from 10 to 40 per cent. of steel scrap to the ordinary mixtures in which the required silicon has been provided to carry the steel burden safely. There is much variation in the strength of such castings, however, and where extreme care must be exercised, it is safer to use steel castings.

(*c*) **Chilled-iron Castings.** Such castings as crusher jaws, grinding plates, etc., requiring chilled-iron surfaces and soft bodies, are made in the jobbing foundry from special low-silicon irons. Chilled rolls, car wheels (chilled treads), and work of a similar nature are better obtained from roll or car-wheel foundries, as these work to service guarantees and are specially careful in the selection of their melting stock.

Special Gray-iron Castings. Certain classes of castings can best be made in foundries giving special attention to a given line of work. Thus, (*d*) **cylinder and pump castings,** whether for steam, compressed air, or ammonia, requiring a close-grained, dense iron, free from shrinkage spots, are made in pump works, locomotive, and engine shop foundries. This iron, particularly for cylinders, should be fairly hard, though just machining properly, fine in grain, and in wearing very slowly acquires a high polish. Very intricate and light castings requiring fair strength should be obtained from foundries specializing on automobile cylinders. (*e*) **Dynamo-frame castings** are made from very soft iron in which the combined carbon content (though not necessarily total carbon) is as low as possible, to prevent retention of residual magnetism. Certain foundries specialize in this line of work. (*f*) **Stoves, radiators, and ornamental castings** are made from high-phosphorus (and because of being very thin work) high-silicon iron, which is very fluid when molten, in order to fill the finest lines in the mold. This iron is brittle, and, unless carefully produced, inclined to run to hard corners and edges. (*g*) **Gun iron** is the most reliable and highest-grade cast iron made. It is the product of the air furnace (all the castings previously described being made of cupola iron), is improved by steel scrap additions as in (*b*), and for the same mixtures is regularly better than the corresponding cupola iron. Formerly used for cannon and mortars, it is now employed in the construction of high-grade engines, turbines, rolls for the finest finishing of brass and steel, tin plate, etc., and in all work where its comparatively higher cost is no objection. Many other varieties of castings, such as pipe, agricultural implement parts, pipe fittings, flywheels, etc., fall within the above given classes so far as mixtures for making them are concerned.

Malleable Castings range in strength between gray iron and the steel castings, and hence are used where gray iron is too weak and steel too expensive. They are made ordinarily only in sections less than ¾ in. thick, the pieces not much over 4 ft. in length, and the weight not over 300 lb. The usual weights are a few ounces for light, 15 lb. for medium, and 150 lb. for heavy castings. The metal will bend, twist, resist shock remarkably well—its special characteristic—better even than cast steel, is cheap, easily made and specially adapted to repetition work, and therefore in general use for car castings, pipe fittings, agricultural work, hardware, etc. Care must be taken in designing malleable castings to avoid sharp corners and to have as nearly the same thickness of section throughout as possible; round sections are not as good as rectangular. These castings should not be machined, as the interior is not as strong as the metal at and near the surface. Tensile strength, 35,000 to 48,000 lb. per sq. in. European malleable cast iron, made by a somewhat different process, is not as sensitive to machining; the castings, which are thin only, are practically decarbonized in the annealing process; whereas in the American "black-heart" malleable iron, only the skin is decarbonized, the metal adjacent for about ¼ in. partially so, and the central portions contain the full carbon percentage of the original hard white casting.

Chilled castings in which an all-white fracture is wanted, can be made in the malleable casting foundry, as this class of iron forms the basis of the malleable casting process. This iron is very weak and crystalline, difficult to produce in heavy sections unless specially chilled while being poured, and is only useful for its extreme hardness. This metal can be used for slabs for grinding marble surfaces smooth, and for stars for cleaning softer castings in the rumbling barrel.

Steel Castings are made commercially by four methods at the present time: By the **crucible process**, which makes very fine but expensive and only small castings; by the **open-hearth-process**, which makes castings from a few ounces to any tonnage desired; by the **Bessemer process**, which is used principally for small castings, and by the **electric furnace**, which is just coming into use in this country and makes the highest grade of castings of all the methods.

The steel casting should be selected where **strength and reliability** are essential. It should always be annealed, so that the original casting strains are removed and the grain structure improved. It is a difficult casting to make and great skill in molding is required, as the shrinkage is even greater than in white iron, and hence strains, cracks and shrinkages are easily formed.

A variety of compositions can be made, as, for instance, the several carbon steels (for 0.20 and below, up to tool-steel compositions), vanadium, nickel, chromium, titanium and other alloy steels, so that the range is quite wide, and the designing engineer can give special attention to wearing qualities. For ordinary work, however, attention is confined to seeing that important parts are free from blowholes, and that steel castings are only specified where gray-iron or malleable ones will not do.

Miscellaneous Castings. Under this head would be included castings made from "mitis" metal (melted wrought iron)—which is no longer available—hybrids such as "ductile iron castings," "malleable steel," etc. All of them had better be left alone, as their uniformity cannot be depended upon.

Table 1. Suggested Analyses for Various Kinds of Iron and Steel Castings
(Porter)

	Silicon, per cent.	Sulphur, per cent. (below)	Phosphorus, per cent. (below)	Manganese, per cent. (below)	Total carbon, per cent.

* Limits. † Below 4.00.

Composition of Castings. The analyses given in Table 1 are intended to serve as a general guide, the limits being fairly close. It is possible to make good castings by exceeding the limits given for silicon, manganese, etc., but this must be left to the judgment of the foundry selected to do the work. It is not always possible to obtain pig irons of just the composition required.

The lower limits for silicon should be used for the heaviest classes of castings, and the higher figures for the lightest. The variation in the total carbon is accomplished by adding steel to the mixtures.

No analysis is given for the "annealed" malleable casting, as the only change from the composition of the "hard" is in the total carbon (all combined), which is reduced by the annealing process from the full amount in the center of thick castings to about 0.20 in the skin and converted from the combined form to an amorphous variety of graphite called "temper carbon."

No subdivision of the total carbon into graphite and combined carbon is given in Table 1, as this division is a function of the silicon content, the casting temperature, and the rate of cooling after pouring determined by the thickness of section of the castings in question.

CHEMISTRY OF CAST IRON

Cast iron is a structure of steel with mechanically mixed graphite flakes between the crystals. This steel, with its high silicon and phosphorus, is a very poor material, and the graphite still further weakens the strength. The low combined carbon content and the abundance of graphite scattered throughout the mass, indicate it as a metal that may be easily machined without the use of a tool lubricant. With an increase in the combined carbon and a corresponding decrease in the graphite, the metal would no longer be coarse-flaked and machining would be hard on the tools and the casting. It is the object, in producing the strong cast-iron grades by steel additions, to reduce the planes of weakness due to graphite by lowering the total carbon, and yet to keep down the combined carbon as low as possible to facilitate machining. This is accomplished by silicon additions to the mixture, leaving a casting with proper silicon and a low total carbon; and in the case of heavy steel additions, by the use of ferro-manganese in the ladle as a deoxidizer of the iron.

Carbon. Beginning with the smallest percentages of carbon, there are the three commercial grades of steel castings. Just beyond a 2 per cent. content will be found the hard castings making tough (when good) malleables. From 2.50 per cent. on, good malleables are obtained, and from 2.75 per cent. upward the strong cast-iron varieties. When 3.75 per cent. is reached, the limit for ordinary cast irons ends, and only the low-silicon charcoal irons used for chilled-casting work run higher (up to 4.25 per cent., or almost the theoretical maximum).

The carbon in iron is of two general kinds: (*a*) **Combined carbon**—as carbides of iron, and in forms and distribution interesting only metallographically for ordinary foundry purposes, though important in heat-treatment work for steel castings; (*b*) **graphite**, or uncombined carbon, present as a mechanical admixture. This form of carbon is subdivided into two classes: (1) The crystalline graphite present in gray iron, produced in the "setting" of the molten metal, and varying in size from the big-flaked "kish" thrown off as excess carbon from blast-furnace casts to the very finely crystallized graphite of the soft cast irons made to set very quickly by means of chills; (2) graphite found in malleable castings, and resulting from the heat-treatment of white irons of the proper composition. Instead of separating out in the molten mass while setting this graphite is formed from the solid, the amorphous particles reposing in the interstices of the crystalline iron structure which are opened up by the long-continued high-temperature application. It is amorphous in shape and is called **temper carbon,** from the German "tempern."

In cast-iron founding, where heat-treatment subsequent to casting is rarely used, the total carbon present may be either all in the combined state, as one extreme, making white-fracture, hard, brittle and almost useless castings, or all graphitic, as the other extreme, making a black-fracture, soft, easily machined and highly useful iron. This range is due largely to the percentage of the other elements present, notably silicon; and in smaller measure to the pouring temperature and to the rate of cooling in the mold after pouring, which latter is a function of the thickness of section.

Silicon. Silicon has a **powerful softening effect,** its presence in cast iron reducing the ability of the iron to retain carbon in chemical combination. Thus, with silicon almost entirely absent, the iron will retain all its carbon in combination, making white iron. With about 3 per cent. silicon present almost no carbon can be held in chemical combination, and gray iron results. Beyond 3 per cent., silicon begins to act as a hardener; the Scotch or silvery irons, the high-percentage-silicon pig irons, and finally the ferro-silicons up to metallic silicon, are brittle substances.

In the case of the steel casting, where there is very little carbon present, silicon acts in a different manner, as it has no graphite to form. Here it deoxidizes the iron and promotes sound castings. In larger quantities and with special subsequent heat-treatment the steel made will show peculiar magnetic values.

In gray-iron work the proper selection of the silicon content in the mixture is the most important factor. Within given limits of the other elements every change desired can be brought out in the castings, so far as their strength, machining qualities, etc., are concerned, by variation in the silicon.

In malleable-casting work the silicon is even more important, as the range is quite small for a casting of given section. Thus, in heavy malleable castings the silicon should run between 0.35 and 0.50 per cent.; for medium sections. about 0.65 (which is the range of general car-castings requirements). For light work, such as pipe fittings, the silicon should be 0.75 to 1.00, and for extremely light work may be 1.25. Rarely can a foundry get satisfactory results when making both light and heavy work together.

Sulphur. Sulphur is **an objectionable impurity** in iron castings of practically all kinds. It probably forms a series of weak iron-sulphur compounds which surround the crystals of the iron and iron compounds that are strong and under other conditions strongly coherent, and the already unhomogeneous mass is made still more undependable. Moreover, sulphur and manganese form combinations with iron which make hard spots near the surface of castings and give trouble in the machine shop. Sulphur therefore is to be avoided where possible. Unfortunately, with every remelt more sulphur is taken up from the fuel, and hence the constant raising of the sulphur percentage in the foundry product through its dependence upon scrap for cheapening the mixtures. Well-made pig irons are fairly low in sulphur.

Sulphur **hardens iron** by counteracting silicon in its power to form graphite. Hence, where high sulphur is present, proportionally more silicon must be charged. Sulphur is advantageous **in cylinder work.** Here the peculiar granular iron-sulphur formations make for a fine grain which polishes highly in service. The only other work in which the presence of sulphur is advantageous, is **work** which has **to be threaded.** Here, again, the granular structure allows the cutting of fine, clean threads, a better material giving torn and rough-looking results.

Manganese. Manganese promotes the retention of carbon in the combined form, and hence **counteracts silicon.** This effect, however, is not specially noticeable until the percentage of Mn passes 0.80, which limit is usually set for gray-iron castings. In the case of malleable castings the effect of over 0.40 Mn is noticeable in the annealing process, where it retards the opening up of the structure of the metal to allow the separating out of the "temper carbon" and for that reason is injurious. For heavy sections manganese is not objectionable up to 1 per cent. Where the sulphur is high manganese will combine with it and if, after tapping, with extremely hot iron, the metal is allowed to stand for a while, manganese sulphide rises and can be skimmed off with what slag has come up also, thus often reducing the sulphur of the metal by one-half. If manganese is to be added to a mixture in the cupola, it should be in form of high-manganese pig iron. Ferro-manganese should never be charged anywhere but in the ladle, for the reason that manganese is easily oxidized and expensive. Where much steel scrap is charged in the cupola, and consequently the total carbon is low in the resulting metal, two things occur: first, the low-carbon metal has a higher freezing point, and hence must be melted much hotter than ordinary gray iron and cast at a higher temperature; second, from the nature of the melting process, the metal is bound to be heavily oxidized, and the addition of ferro-manganese in the ladle is necessary to deoxidize it—otherwise the castings will be porous and not sound. At the higher temperatures produced under the conditions necessary to melt the steel, the manganese added also has the power to deoxidize.

Phosphorus. The great value of phosphorus is to make iron very fluid when molten. Hence its use for art work, stoves, radiators, and similar thin and not necessarily strong castings. **Phosphorus is a hardener,** and requires the presence of the proper amount of silicon. The castings made with phosphorus irons being thin, there must be enough silicon present to prevent the retention of combined carbon, as thin sections cool at a rapid rate in the sand after casting.

Oxygen. This is probably the most serious element to contend with in the gray-iron and malleable foundry. In steel-casting establishments, the silicon and manganese added after melting remove any oxygen present from the melting; otherwise the castings would not be serviceable. As the presence of oxygen (probably as dissolved iron oxide) cannot be determined by ordinary chemical means, it is recognized (1) by the loss of "life" in molten iron, the freezing point having gone up; and (2) by the numerous pinholes found in the planed surface of a casting on its cope side. Here prevention is the only proper cure, and the charging and melting practice of a foundry making such defective work should be corrected.

Other Elements. The effects of nickel, chromium, titanium, vanadium, aluminum, copper, etc., need not be touched upon here, as these elements are either seldom found in pig iron in sufficient quantity to be considered, or else are additions which will be discussed under "Ferro-alloys." The iron made from Cuban ores forms an exception, however, as it contains both nickel and chromium, but its expense makes it of interest only to the specializing foundry and the steel trade.

PHYSICS OF CAST IRON

Shrinkage and Contraction. The term shrinkage is usually employed where contraction is really meant. **Contraction in a casting is the** reduction in dimensions due to the cooling from the temperature at the moment of set to the ordinary temperature of the atmosphere. **Shrinkage,** on the other hand, is the separation of the portions of metal from each other, due to an insufficient supply of liquid metal to fill up the spaces left by the reduction in volume as the iron sets. This forms spongy spots and actual cavities, the walls of which may be lined with pine-tree crystals of iron. Shrinkages greatly weaken the interior structure of the metal, and are highly dangerous through their concealed position.

Irons which throw out graphite on setting will not contract nearly as much as those in which this does not occur. The **ordinary "shrinkage"**—or rather contraction—of gray iron is ⅛ in. per ft. That of white iron and steel is about ¼ in. per ft., but varies with differences in the rate of cooling, the composition of the metal, and the shape of the pattern. In the case of malleable castings, where the original hard-iron casting should contract ¼ in. per ft. (one-half of which is restored in the annealing process), some parts do not contract at all, while others show a contraction of 3/16 in. per ft. This indicates that some portions are held tight in the mold and are actually stretched in the setting, while others readily pull away from the walls of the mold.

Segregation. The most frequent difficulties consist of hard spots of manganese and sulphur-iron compounds which interfere with machining where the two elements are too high; and a segregation of iron phosphide, accompanied by increased hardness in the center of a heavy section made with too-high-phosphorus iron. Further, through improper cooling, there may be an artificial chilling of the metal in spots, with consequent hardening effects. Annealing the casting will generally overcome this.

Strength of Cast Iron. A cast iron with a tensile strength of 20,000 lb. per sq. in. is considered a very good metal. By the addition of steel scrap in the melting charges to cut down the total carbon, the tensile strength is raised, so that, in rather small sections, it is not uncommon to get a value of 44,000 lb. per sq. in. Where special strength is wanted, an iron not under 30,000 lb. per sq. in. T. S. should be specified. The tensile test for cast iron is not to be recommended, as the results obtained are of uncertain value, unless the greatest care is taken with the preparation and testing of the specimen. American specifications make the tensile test optional and at the expense of the purchaser.

The **transverse strength** of cast iron is the one most readily obtainable for specification purposes. The so-called **arbitration bar** of the American Society for Testing Materials (which is the universally adopted standard of the country) is 1¼ in. in diam., 15 in. long, and is broken transversely on supports 12 in. apart. For the strength requirements, see p. 506. A breaking strength of from 2500 to 3000 lb. for the above-mentioned bar, with a deflection of 0.1 in. or over, indicates a good iron for ordinary use.

The **elastic limit** of cast iron is close to its ultimate breaking-strength. It is only in the case of very-low-total-carbon irons made by steel additions and carefully deoxidized by titanium or vanadium additions, that an elastic limit somewhat below the ultimate strength is obtainable. Elongation and reduction in area of specimen are not considered in making strength tests of cast iron. The **crushing strength** of cast iron is probably its most important characteristic, and gives it its value for structural use. It runs from 80,000 to 140,000 lb. per sq. in. The **resistance to shock** of cast iron is not high. On the other hand, the malleable casting has this as its prime characteristic. **Hardness** in ordinary cast irons is a condition which may be brought about artificially if desired **by chilling** the molten metal in the molds. Only the lower-silicon irons are amenable. Chilling is the basis of car-wheel manufacture, the casting of hardened-face jaws for rock breakers, stamps, and the like. Ordinarily, hardness in castings is a thing not desired in machine practice, nor is it good to have hard castings for ordinary classes of work, as the danger of brittleness is greater.

SPECIFICATIONS FOR CASTINGS

Standard Specifications for Gray-iron Castings

(American Society for Testing Materials)

1. Unless furnace iron is specified, all gray castings are understood to be made by the cupola process.

2. The sulphur contents to be as follows: Light castings, not over 0.08 per cent.; medium castings, not over 0.10 per cent.; heavy castings not over 0.12 per cent.

3. In dividing castings into classes, the following standards have been adopted: **Light castings**, or those having any section less than ½ in. thick; **heavy castings**, or

those in which no section is less than 2 in. thick; and medium castings, or those not included in the foregoing definitions.

4. **Transverse Test.** The minimum breaking strength of the "Arbitration Bar" under transverse load shall be not under 2500 lb. for light castings; 2900 lb. for medium castings; 3300 lb. for heavy castings. In no case shall the deflection be under 0.10 in. **Tensile Test.** Where specified, this shall not run less than 18,000 lb. per sq. in. for light castings; 21,000 lb. for medium castings; 24,000 lb. for heavy castings.

5. The quality of the iron going into castings under specification shall be determined by means of the "Arbitration Bar," see p. 505.

6. Two sets of two bars shall be cast from each heat, one set from the first and the other set from the last iron going into the castings. Where the heat exceeds 20 tons, an additional set of two bars shall be cast for each 20 tons or fraction thereof above this amount. In case of a change of mixture during the heat, one set of two bars shall also be cast for every mixture other than the regular one. Each set of two bars is to go into a single mold. The bars shall not be rumbled or otherwise treated, being simply brushed off before testing.

7. The transverse test shall be made on all the bars cast, with supports 12 in. apart, load applied at the middle, and the deflection at rupture noted. One bar of every two of each set made must fulfill the requirements to permit acceptance of the castings represented.

8. In making the mold the pattern shall not be rapped before withdrawing. The flask is to be rammed up with green molding sand, a little damper than usual, well mixed and put through a No. 8 sieve, with a 1:12 mixture of bituminous facing. The mold shall be rammed evenly and fairly hard, thoroughly dried and not cast until it is cold. The test bar shall not be removed from the mold until cold enough to be handled.

9. The rate of application of the load shall be 30 sec. for a deflection of 0.10 in.

10. Borings from the broken pieces of the "Arbitration Bar" shall be used for the sulphur determinations. One determination for each mold made shall be required. In case of dispute, the standards of the U. S. Bureau of Standards shall be used for comparison.

11. Castings shall be true to pattern, free from cracks, flaws and excessive shrinkage. In other respects they shall conform to whatever points may be specially agreed upon.

12. The inspector shall have reasonable facilities afforded him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall, as far as possible, be made at the place of manufacture prior to shipment.

Standard Specifications for Malleable Castings

(American Society for Testing Materials)

These specifications are best adapted for the softer varieties of malleable castings, such as for railroad car construction. Special specifications are being proposed for the harder inelastic malleables suitable for conveyor chains, etc.

1. Malleable castings may be made by either air, open-hearth or electric furnace processes.

2. The test specimen for tensile strength and elongation shall be a round bar of the dimensions shown in Fig. 1. The test specimens for transverse strength and deflection shall be 14 in. in length, 1 in. in width and either ½, ⅝ or ¾ in. in thickness. The thickness of the test specimen selected shall be in proportion to the thickness of the casting which it represents. All test specimens shall be cast without chills, and with ends perfectly free in the mold. Four test specimens (two for each tensile and transverse test) shall be cast in each mold with risers of sufficient height at each end to insure sound bars. When the full heat is used for castings which are subject to specification, two molds shall be poured within five minutes after tapping into the first ladle, and two molds from the last iron of the heat. When only a part of the heat is required, there shall be cast two molds from the first ladle of iron used and two molds after the required iron has been tapped.

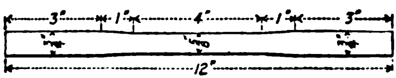

Fig. 1.

The test specimens from one mold each from the first and from the last of the heat shall be annealed in hottest part of the annealing oven and the remaining specimens shall be annealed in the coldest part. From the test specimens from each of the four molds required to represent each heat, there shall be selected for testing one specimen of each type for tensile strength with elongation, and for transverse strength with deflection.

3. The tensile strength of the test specimen shall not be less than 38,000 lb. per sq. in., with an elongation of not less than 5.0 per cent. measured in 2 in.

4. The transverse strength of the standard test specimen tested with cope side up on supports 12 in. apart, pressure being applied at the center, shall not be less than: 900 lb. with 1.25 in. deflection in ½-in. test specimen; 1,400 lb. with 1 in. deflection in ⅝-in. test specimen; 2,000 lb. with 0.75 in. deflection in ¾-in. test specimen.

5. Failure to reach the required limit for the tensile strength with elongation, also transverse strength with deflection on the part of more than one bar from each of the two molds annealed in the two points in the oven specified, rejects the casting from that heat.

6. In addition to the tests above provided for, the inspector shall have the right to satisfy himself of the suitability of the metal used for malleable castings made under these specifications by breaking a reasonable number of castings from the sand to examine for excessive mottling or graphite spots. In the case of castings of special design or importance, he may also require test lugs of such size as will bear proper relation to the thickness of the casting, but not exceeding ⅝ × ¾ in. section. At least one of these lugs shall be left on the casting for final inspection.

7. Castings shall be true to pattern, free from blemishes, scale and shrinkage cracks. A variation of 3/32 in. per ft. shall be permissible.

Standard Specifications for Steel Castings

(American Society for Testing Materials)

1. These specifications cover two classes of castings, namely: *Class A*, ordinary castings for which no physical requirements are specified; and *Class B*, castings for which physical requirements are specified. These are of three grades: hard, medium, and soft.

2. Patterns shall be made so that sufficient finish is allowed to provide for all variations in shrinkage, and be painted three colors to represent metal, cores, and finished surfaces. It is recommended that core prints shall be painted black and finished surfaces red.

3. The steel may be made by the open-hearth, crucible, or by any other approved process.

4. Class A castings need not be annealed unless so specified. Class B castings shall be allowed to become cold; shall then be reheated to the proper temperature to refine the grain, and allowed to cool slowly.

5. The steel shall conform to the following requirements as to chemical composition:

	Class A	Class B
Carbon	not over 0.30 per cent.	
Phosphorus	not over 0.08 per cent.	not over 0.05 per cent.
Sulphur		not over 0.05 per cent.

6. To determine whether the material conforms to the requirements specified in Sec. 5, an analysis shall be made by the manufacturer from a test ingot taken during the pouring of each melt. Drillings for analysis shall be taken not less than ¼ in. beneath the surface of the test ingot. A copy of this analysis shall be given to the purchaser or his representative.

7. A check analysis of Class B castings may be made by the purchaser from a broken tension or bend test specimen, in which case an excess of 20 per cent. above the requirements as to phosphorus and sulphur specified in Sec. 5 shall be allowed. Drillings for analysis shall be taken not less than ¼ in. beneath the surface.

8. The steel for each grade of Class B castings shall conform to the following minimum requirements as to tensile properties:

	Hard	Medium	Soft
Tensile strength, lb. per sq. in.	80,000	70,000	60,000
Yield point, lb. per sq. in.	36,000	31,500	27,000
Elongation in 2 in., per cent	15	18	22
Reduction of area, per cent	20	25	30

The yield point shall be determined by the drop of the beam of the testing machine.

9. The test specimen for soft castings shall bend cold through 120 deg. and for medium castings through 90 deg., around a 1-in. pin, without fracture on the outside of the bent portion.

10. In the case of small or unimportant castings, a test to destruction on three castings from a lot may be substituted for the tension and bend tests. This test shall show the material to be ductile, free from injurious defects, and suitable for the purpose intended. A lot shall consist of all castings from the same melt, annealed in the same furnace charge.

11. Test bars shall be attached to Class B castings weighing 500 lb. or over, provided the design of the castings will permit. If the castings weigh less than 500 lb., or are of such a nature that test bars cannot be attached, two test bars shall be cast to represent each melt; or the quality of the castings shall be determined by tests to destruction as specified in Sec. 10. All test bars shall be annealed with the castings they represent. The manufacturer and purchaser shall agree whether test bars can be attached to castings, and also on the location of the bars on the castings and the method of casting unattached bars. Tension test specimen shall be of the form and dimensions shown in Fig. 2. Bend test specimens shall be 1 × 1½ in. in section.

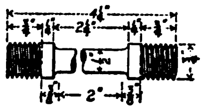

FIG. 2.

12. One tension and one bend test shall be made from each melt. If any test specimen shows defective machining or develops flaws, or if a tension test specimen breaks outside the gage length, it may be discarded; and the manufacturer and the purchaser or his representative shall agree upon the selection of another specimen in its stead.

13. The castings shall substantially conform to the sizes and shapes of the patterns, and shall be made in a workmanlike manner.

14. The castings shall be free from all injurious defects. The castings offered for inspection shall not be painted or covered with any substance that will hide defects, nor rusted to such an extent as to hide defects.

15. Castings which show injurious defects before or after machining will be rejected, and the manufacturer shall be notified.

FOUNDRY MATERIALS

Pig Iron. Pig irons may be generally classified as follows: Charcoal irons, cold blast and hot blast (often called "warm blast"); anthracite irons; coke irons, and electrically made pig irons. This classification is based upon the fuel used in the production. Charcoal gives the best pig iron—also the most expensive. With cold blast the very best results are obtained. Where the ordinary coke pig irons cost $17 a ton, the finest cold-blast charcoal pig iron may cost $45. Hot-blast charcoal iron is a cheaper variety which was formerly used much for malleable castings, car wheels and other work requiring chilling in whole or in part. To-day it is used only for chilled rolls, crusher jaws, and castings which require chilled parts and great strength.

Coke and anthracite irons are all made using a very hot blast. Electrically made pig iron is too new to find much application in the foundry, but is a probable future factor in the foundry business.

Pig iron is now bought almost entirely on its composition. Those who specify by grade number in place of analysis get the iron which could not be shipped to fill chemical specifications.

The requirements of the foundry trade being sharply defined by the classes of castings made, the product of the blast furnace readily divides itself on the phosphorus content. Thus, high-phosphorus pig irons go to the stove trade, while very-low-phosphorus irons, everything else being acceptable, go to the steel foundry. In a lesser degree the sulphur plays a part, the very-high-sulphur irons being unavailable for the better grades of castings. High sulphur means a low selling price. Manganese rarely bothers the foundryman unless a furnace is so situated that high-manganese ores are near by and cheap. The silicon content is the determining factor in the purchase, once the available brands have been gone over and the right ones selected. The foundryman specifies his silicon, and usually also his maximum sulphur.

In order that there may be uniformity in quotations, the following percentages and variations are used. These specifications do not advise that all five elements be specified in all contracts for pig iron, but do recommend that when these elements are specified the following percentages be used:

Silicon (0.25 allowed either way)	Sulphur (maximum)	Total Carbon (minimum)	Manganese (0.20 either way)	Phosphorus (0.15 either way)
1.00	0.04	3.00	0.20	0.20
1.50	0.05	3.20	0.40	0.40
2.00	0.06	3.40	0.60	0.60
2.50	0.07	3.60	0.80	0.80
3.00	0.08	3.80	1.00	1.00
	0.09		1.25	1.25
	0.10		1.50	1.50

Percentages of any element may be specified one-half way between the above. In case of phosphorus and manganese, the percentages may be used as maximum or minimum figures, but unless so specified they are considered to include the variations above given.

In testing pig iron to see whether it will suit for the general work of the foundry, the best method is to use it in regular service for a week to test it out.

Scrap is of two kinds, **domestic**, or that made in the foundry itself, and which remains and is used in the daily heats; and **foreign**, or scrap which is bought in the open market, and consists of several grades of heavy and light scrap machinery, pipe, stove plate, etc. The founder will know how to care for his own scrap, but that which he buys he must watch closely for burnt grate bars, furnace sections, and material which shows evidence of having been subjected to the oxidizing action of continued red heat. Such material is dangerous to add to mixtures and had better go into sash weights only.

Steel when used in foundry practice should be neither too light nor too heavy in section. Clippings from structural steel, rail ends, boiler plate, etc., are best. If too light, the proportion of surface to weight is too great, and oxidation is unavoidable. If too heavy, it will be too low in the bed before being completely melted. Steel should be charged directly on the fuel, pig iron over it, and then scrap cast iron. In this way all portions of the mixture melt at about the same time and good mixing results. In air-furnace practice heavier pieces of steel may be used, though rail, fish plates and the like are preferable.

Softeners, so-called, are the higher-silicon pig irons which are added to the mixture to increase the general silicon content. These irons, also known as **Scotch irons,** run from 4 to 8 per cent. silicon, and should be used with caution, as unless the charges are small and the bull ladle into which the iron is tapped is nearly twice the capacity of the metal in a single charge, there is apt to be hard and soft iron alternately instead of a good mixture. It is far better to charge pig irons of nearly the right silicon than to use extremes.

Ferro-silicon. When the silicon of a pig iron runs above 8 per cent., it begins to be classed as a ferro-silicon. Usually the ferro-silicon pig irons contain about 12 to 14 per cent. of silicon. Above 14 per cent. little is made until the 50 and 75 per cent. ferro-silicons are reached, and the percentage can run still higher than this, though it becomes unavailable for the foundry on account of the expense.

Ferro-manganese, see p. 503, which is used to some extent in the foundry, usually contains about 80 per cent. manganese, and finds its application in car-wheel work, and particularly in cases where much steel scrap is melted. Pig irons with 2 per cent. manganese and over are available and can be charged in the cupola directly. Ferro-manganese should be added to the molten metal in the ladle, and preferably sprinkled on the running stream right at the tap hole.

There are other alloys, such as **silico-spiegel**—a high-silicon ferro-manganese, **ferro-titanium** and **ferro-vanadium,** which also act as deoxidizers. The last-mentioned (see also p. 477), if added in sufficient quantity, leaves some vanadium in the iron. It is expensive, however, and used only for special purposes, as in machinery wearing surfaces. Ferro-titanium is excellent for deoxidation in the case of badly melted iron, but where precautions are taken with the melting practice, its use is not necessary. Both the titanium and vanadium alloys require further investigation, and while they can already be specified for steel, they are of unascertained value for cast iron.

Fluxes. As the pig iron and scrap charged into the cupola carry with them sand and rust, and as the ash of the fuel collects in the melting zone, it is essential for large heats that a flux be added to properly collect this material into a slag that can be drained off through a slag hole just below the bottom of the tuyères. Usually, **slagging off** a cupola is not resorted to for heats smaller than 5 to 10 tons. **Limestone** is the universal flux used, as it is most available. The limestone should contain the maximum possible amount of carbonate of lime, as with much clay or other mineral in it an equivalent amount of lime is used up to flux these substances, and consequently less is available for cupola fluxing. Where available, **oyster shells** form an excellent flux. **Fluor-spar** is another flux which in addition thins the slag very much. It should be used sparingly and in connection with limestone on account of its expense and powerful action on the cupola lining.

Ordinarily, the weight of the flux used is about 2 per cent. of the weight of the metal. In cases of very rusty material, such as stove plate, or all-sand-cast pig iron, which is very dirty, as much as 4 per cent. of limestone may be necessary. On the other hand, with machine-cast pig iron and clean scrap for the mixture, 1 per cent. may be enough. The flux is distributed on the coke charges evenly and away from the lining of the cupola.

Fire Brick for use about a foundry are of two grades. **First-grade fire brick** are intended for the highest temperatures. For the cupola the bricks or blocks used should be rather fine grained to resist abrasion of the charges and chemical action of the slag. For open-hearth and air furnaces, coarse-grained brick are more desirable. In either case they should be made of the highest grade of fire clay to resist the temperatures.

Second-grade fire brick, usually made of the same clay but not finished to size as carefully, are used for annealing-oven work, the upper lining of cupolas, and wherever the temperatures are lower. For gas flues, chimney linings, and where temperatures fall below 1000 deg. fahr., a still lower grade, called **flue brick,** is used.

Fire Sand is a very refractory sand. Sea sand or ordinary building sand, containing a low percentage of fluxing minerals, may be used for furnace bottoms, where a caking-together under heat is wanted; but for mixing with fire clay, as for cupola daubing, or for places where the direct sweep of the flame is to be encountered, the sand must be over 99 per cent. silica, and hence of a highly refractory nature. **Silica brick** (see p. 624) is rarely used in the gray-iron foundry, but is extensively used for the crowns of furnaces in open-hearth malleable casting practice, and entirely so for steel casting work.

Magnesite is used for the bottoms of open-hearth furnaces where basic steel is made, in contradistinction to the sand bottom in the acid open-hearth steel process. Where magnesite is used, and the sides and crowns of the furnaces are of silica brick, it is necessary to interpose a layer of **chrome brick** (see p. 624) and also to patch out the hearth at the slag line with **chromite,** as this is a material neutral to either acid or basic slags. **Dolomite** is also much used as a basic refractory.

Molding Sands, which are refractories so far as being containers for the molten iron for castings is concerned, are treated on p. 1399.

Foundry Facings embrace a variety of substances. The principal one, called **sea coal,** is simply a very finely ground high-grade bituminous gas coal. It is mixed with molding sand usually in proportion of eight sand to one sea coal, and riddled on the patterns in making the molds. These are then backed with ordinary molding sand. The purpose is to present to the running metal a surface which prevents its entrance. The coal generates gases instantly, which, being high in hydrocarbons, decompose with deposition of free carbon. The open structure of the sand allows these gases to escape rapidly, resulting in smooth-surfaced castings. Where the castings are very light and no particularly fine surface is required—as for malleable castings—facings are not used at all. Stove work, however, and other work where fine surfaces are essential, require not only this facing, but often have an application of **graphite** put on in addition.

To prevent **cutting of** the **sand** in larger castings as the consequence of a continued flow of molten metal, the mold surfaces are carefully rubbed with **graphite,** thus giving a very smooth surface. Good grades of this mineral should be used, as the poorer, adulterated ones—particularly if soapstone is present in large quantities—will suffer from the high temperature, and occasionally come off with some sand adhering, leaving bad spots in the surface of the casting. For small, light castings soapstone is not so dangerous, as the metal is in the mold and set before this mineral can melt. Another **blacking,** principally used for a **core wash,** is ground coke. This fills the pores of the core surface sufficiently to make it smooth without spoiling proper venting. Dry and wet **core binders** are dealt with on p. 1400.

MELTING PROCESSES AND MIXTURE MAKING

The melting may be done in crucibles, in the cupola, in the air furnace, the open-hearth furnace (acid or basic) or the electric furnace. Also, in making a special line of steel castings, a small converter is used after preliminary cupola melting of the charge.

The Crucible Process is now obsolete for cast iron, but is still used in making small high-grade steel castings. The absence of contact between metal and fuel makes this an ideal process, but, owing to mechanical difficulties, the output is small and the fuel cost is high. The crucible process, either with coke or oil firing, is the standard one for brass and bronze melting. Where the oil flame is made to play within the crucible—and this is made quite large in that case—the process really becomes that of the hearth furnace. Good brass and bronze castings are made in this way, but for gray iron the process takes too long to make really good work, the oxidation being too marked.

The Cupola is the most generally used melting process for cast iron, the fuel economy being highest, and the ease of manipulation greatest. Iron is melted continuously during the heat and can be poured as melted. The cupola is a shaft furnace, into which a fuel bed is introduced and upon which alternate layers of metal and fuel are charged. Air for combustion is supplied through tuyères near the bottom, placed just high enough to allow the space below to serve as a storage for the required quantity of molten iron. The following conditions must be considered carefully for satisfactory results.

It takes roughly 30,000 cu. ft. of air to melt 1 ton of iron, and the **melting rate** depends upon the rate of air supply. Variation in the melting rate in a given cupola is bad practice, in that it changes the position of the melting zone. Experience has shown that certain definite sizes of cupolas are best adapted for given melting rates per hour. There is some leeway in the following table, but it is not wise to exceed greatly the rates of melting indicated, as the quality of the metal produced will suffer.

Diam. of cupola inside lining, in...	18	24	30	36	42	48	54	60	66	72	78	84	90
Melting rate, tons per hour..........	0.5	1.5	3	4.5	6	8	10	13	16	19	22	26	30

A cupola 30 in. in diam. inside the lining is about as small as should be used in **commercial practice.** On the other hand, while there are cupolas 10 ft. in internal diam. in daily use in the United States, the European practice of using a **series of cupolas,** none of which exceed 48 in. in diam. is to be preferred, as not only is the melting accomplished with smaller variations in temperature, etc., but it is possible to run several mixtures in the shop safely. Ordinarily, American cupolas run between 42 in. and 72 in. diameter inside the lining.

In **charging,** the bed of fuel comes first and is usually made about 20 to 24 in. above the top of the tuyères. If there are upper tuyères, the fuel should go above the top of these. The upper tuyères have a very small area, as they are intended only to give a little extra air to burn the cupola gases and not to start a new melting zone. The cross-section of the lower tuyères, measured at the wind-box entrance, should run from one-fifth the cupola area for small cupolas, to not less than one-tenth for very large ones.

The **height of the fuel bed** is most accurately adjusted by timing the first iron after the blast is put on. It is assumed that the bed has been burned through well, and the charges put on up to the door and allowed to stand for some time to warm through. From the time when the blast is put on to the time at which iron runs from the spout sufficiently to require stopping up, there should elapse from 8 min. for heavy casting work, to 10 min. for very light castings. If less than 8 min., the bed should be raised the next day; if more than 10 min., the bed was too high. Melting within the cupola actually starts in about 5 min., as seen through the peepholes, but the stream should begin to come as above indicated.

The melting zone in the cupola ranges from about 12 in. above the tuyères to some 4 ft. above this, the temperatures rising rapidly from the tuyères to a maximum at about 24 in. above them. The CO_2 then begins to take up carbon from the incandescent fuel, if there is more to be had above this point of maximum temperature, and the formation of CO begins in quantity, with a resultant lowering of the temperature. If the iron is melted at any point other than that of the maximum temperature, the molten iron is "cold" and difficult to handle well. If melted below the zone of maximum temperature, there is also the danger of oxidation, with resulting pinholes, shrinkage spots, etc., in the castings.

As the melting is all done by the upper 4 in. of the fuel bed, the entire charging system should be so regulated that this 4 in. is replaced by the intermediate fuel charges, so that in melting iron the position of the bed may remain unchanged. To determine the size of the charges, place on the charging platform a ring of cupola brick 4 in. high and of the same diameter as the cupola. Fill with fuel, weigh this and make the metal charges 10 times this weight (with variations for carbon content in fuel, temperature of the cupola during melt, etc., as experience indicates and the scoring of the cupola lining demands). The practice of a double first charge is entirely wrong, and the volume of the air blown in should never change during the melting.

The **scoring** in the cupola should be observed from day to day. When from 4 to 6 in. are affected, the cupola is properly charged. If the cutting extends to several feet, there is a fluctuation of the melting position, which should be attended to in the charging.

In **charging** the cupola, care should be taken to charge in very even layers. The coke should be leveled, the pig iron of the charges spread uniformly on this (not all around the edges), and the scrap on the pig iron. Steel, if any is used (and it should not be thinner than ¼ in.), is spread directly on the coke, below the pig iron. The ladle into which the iron is tapped should be sufficient to hold at least 1½ charges to insure a good mixture. The metal charged should not vary widely in composition, as there is apt to be a separation which results in hard and soft castings from the same mixture.

In **the repairs of** the **cupola** only the best fire clay should be used. **Mica-schist** in flakes is often used to patch out the lining at the melting zone. If so, care should be exercised that heating up is slow, so that the moisture is removed without blowing out the patches.

The Air Furnace. Iron made in the air furnace, as well as in the open-hearth furnace, is known as **gun iron,** all the early ordnance having been cast from such metal. The furnace consists of a horizontal chamber with the firing space at one end and the stack at the other. The hearth is sloping, the deep portion being at the fire end. It is necessary to reduce excess air to a minimum so as to get the **maximum temperature** of combustion. Not more than 25 per cent. excess air should be allowed over and above that necessary for combustion. It is essential that the fire should be kept uniform. **Melting** is accomplished not so much by the direct contact of the long flame with the charge of metal as **by radiation** from the incandescent walls and roof of the furnace. The success of an air-furnace heat for a given tonnage in a given furnace, should be measured by the time required between charging and tapping. The longer the metal remains in the furnace the more it is damaged through oxidation from the excess air. The temperature of the bath in the air furnace or open-hearth furnace should be brought up to the desired point, and the bath tapped. Overheating, tapping, and allowing to cool before pouring lead to trouble from spongy iron, etc.

In melting with the air furnace, the bottom is first prepared by spreading sharp sand evenly, placing boards upon this and rolling in the heavy pieces of scrap. The small scrap is next charged so that it comes about in the center of the hearth. The pig iron is then carefully piled at the end, and the big end door closed and luted up. Firing now commences. The flames passing over the hearth first melt the light scrap, the pig and heavy scrap gradually go next, and pigs are then rolled one by one into the molten bath instead letting the mass settle down and melt extremely slowly. As the melting is practically all done by radiation from the crown and sides, the importance of keeping the brickwork of the furnace interior in strict repair is evident.

As soon as the metal is entirely melted, the slag is skimmed off, to afford the metal an opportunity to "refine" or become oxidized to a limited extent.

This reduces the silicon and carbon and at the same time raises the temperature. Recent investigations have shown that this is not desirable. It is better to start with clean iron, so that a minimum of slag is made, to have this thin, so that the heat may penetrate through it, and to obtain the reduction in the total carbon by steel additions. In the open-hearth furnace there is no difficulty in melting with a slag cover, hence the superiority of open-hearth iron over the product of the air furnace, in which this difficulty exists.

The **bath of metal** should be **well rabbled** from time to time to thoroughly mix the metal for composition, as well as to remove the hottest metal from the feather edge of the bath at the far end and promote uniformity in temperature. The old method of rabbling with green hickory poles is still resorted to in some foundries, and is a benefit in so far that it helps to mix the metal well.

The **advantage of** the **air furnace** (and also of the open-hearth) is that it gives a large amount of high-grade metal at one tap. The absence of direct contact of metal and fuel makes possible the very considerable reduction in total carbon by steel additions, without danger of picking up carbon from the fuel afterward; and also the use of heavy pieces of scrap which could not go into a cupola, or even into the open-hearth furnace as usually constructed.

Many attempts have been made to preheat the air used for combustion by recovery from the stack. There are successful furnaces of this nature in use, but it is generally better to resort to the open-hearth furnace as solving the problem in a more scientific and commercially economic way. The cupola does its melting with a ratio of 1 fuel to 8 metal, ordinarily. The air furnace, when run at the highest economy, with several heats a day, can do no better than 1 to 4, while the open-hearth furnace does it with a ratio of 1 to 6.

The Open-hearth Furnace is used for steel principally, for malleable in a limited way, and but very little for cast iron. This furnace, which is really a simple hearth furnace so arranged that the direction of the flame can be reversed at will, and which is provided with means for preheating the air and gas used for combustion, is second only to the electric furnace as regards quality of output.

Gas is used generally, or else oil or tar gasified as it enters the hearth. A gas-producer system is therefore installed for gasifying bituminous coal wherever neither natural gas nor oil is available. The preheated air and gas enter the furnace nearly 1000 deg. fahr. hotter than the room temperature. A 10-ton heat in the air-furnace takes about 4 hr.; the same tonnage in the open-hearth furnace takes only 2½ hr. Hence there is less chance for oxidation, and a better grade of metal results.

As the open-hearth furnace must be kept heated all the time, its use is limited to works which are very steady in running. There is no difficulty in forcing out three heats within the range of daily working hours, though two heats give more assurance of success. The heating of cast iron in an open-hearth furnace differs from the heating of steel in that melting only is to be done, not refining. The hottest temperature of the furnace is required for the shortest possible period. Where, in making a steel heat, the melting only is done in, say, 3 hr., for cast iron it should be cut to less than 2 hr., otherwise the comparatively high temperatures may result in the charge running away, or "Bessemerizing" right in the furnace.

The Bessemer Process is used for malleable to a limited extent in Continental Europe. The **electric furnace** is used only for making small quantities of high-grade steel.

Mixture Making

In making the mixtures for melting, allowance must be made for the burning out of the silicon and manganese, as well as for the absorption of sulphur and carbon from the fuel. Furthermore, the percentage of remelted stock plays an important part, as well as the additions of steel scrap. If the **manganese** does not drop below 0.50 per cent. in the resulting metal, the melting process has been carried out properly. If, however, an initial content of over 0.80 per cent. should be cut down to 0.40 per cent., or even lower, attention must be given to the melting process. In the case of air-furnace or open-hearth malleable practice, these figures do not hold, as it is desirable to finish up with manganese between 0.15 and 0.25.

Silicon is oxidized out by cupola melting to the extent of 0.25 per cent. ordinarily. With high fuel percentages this may drop to 0.20 per cent. The mixtures should always be calculated to contain 0.25 per cent. more silicon than is wanted in the castings. In the case of air-furnace melting the silicon loss is 0.30 and in bad cases even 0.35 per cent.

Sulphur is taken up from the fuel. An initial content of, say, 0.08 per cent. sulphur in the mixture, is often brought up to 0.15 in melting. With proper melting practice it should not exceed 0.10; melting at a high temperature drives off the sulphur from the fuel before much of it goes into the metal.

Steel Additions cut down the total carbon of a mixture only in part, as contact of this low-carbon material with the fuel always results in its absorbing more or less carbon. With special precautions, as high as 50 per cent. of steel can be used. Ordinarily, from 10 to 20 per cent. additions greatly improve the strength of the metal.

The **percentage of scrap gray-iron additions** is important in mixture making. In any case, the gates, sprues, etc., of a foundry plant should be used up as produced. This scrap will amount to from 10 to 50 per cent. of the output, depending upon the grade of castings made. In addition to this, cast-iron scrap bought in the open market is added to cheapen the mixture, and between the two as much as 60 per cent. of scrap may go into it.

Important castings should contain no foreign scrap. In castings which are to have considerable machining, no scrap other than the best selected grade should be used, as oxidized material will ruin the machined surfaces through pin holes and spongy spots. Some castings, as ingot molds, require all pig iron.

Calculations in Mixture Making. In mixture making, it is only necessary to calculate for silicon, if all other elements are known from the pig-iron analyses to be within the requirements. Assume 2000 lb. of iron is required to contain 2.15 per cent. silicon. Assume 20 per cent. of the mixture to be shop sprues, defective castings, gates, etc., containing 2.15 per cent. silicon. Assume also, that 20 per cent. of the mixture consists of purchased scrap containing 2 per cent. of silicon.

The best policy in a foundry is to provide three or more brands of pig iron, each having several silicon analyses, or possibly a dozen or more piles from which to select, and to make the bulk of the mixture from irons of which there are the largest stocks on hand, so that a plentiful variety of compositions may be always remaining. The range of composition should not be very wide, unless a great variety of casting classes are made, since it is not good to mix very-high-silicon with very-low-silicon irons, on account of the danger of uneven melting and mixing and the consequent making of alternate hard and soft castings from the same mixture.

Assume that 500 lb. of an iron with 2.75 silicon be added, and also the same weight of another iron with 2.50 silicon, leaving 200 lb. of the mixture to be disposed of later. The remaining 200 lb. of pig iron should contain 5.2 lb. of silicon or 2.60 per cent.

in order to give 2.40 per cent. silicon for the mixture. If this particular iron is not available, a readjustment of the first two irons is necessary, and by trial calculations this is readily effected. The mixture would then stand:

Sprues, etc.	400 lb. with	8.6 lb. Si
Purchased Scrap	400 lb. with	8.0 lb. Si
No. 1 Pig Iron	500 lb. with	13.7 lb. Si
No. 2 Pig Iron	500 lb. with	12.5 lb. Si
No. 3 Pig Iron	200 lb. with	5.2 lb. Si
	2000 lb. with	48.0 lb. Si

This on melting will yield 2.15 per cent. silicon in the castings made. Mixtures for the air furnace are dealt with in a similar manner.

MALLEABLE CASTINGS

Cupola **melting practice** for malleable cast iron is the same as for gray iron, except that more fuel is used to avoid possibility of oxidation. The allowance for burning out of silicon is 0.30 per cent. for the mixture.

The **composition of** an average-weight **malleable casting** is about as follows: Silicon, 0.65; manganese, 0.18; phosphorus, 0.180; sulphur, 0.07. The total carbon will vary from 0.20 at the skin to the full amount originally in the hard casting at the center, if over ½ in. thick; the original total carbon may have varied from 2.50 to 3.25 for ordinary practice.

The **silicon** should vary with the thickness of the castings. As the casting is white in fracture when coming from the sand, the mixture must be adjusted so that with a given silicon the sand can chill the metal sufficiently. Thus, with 0.65 Si in the iron ready to pour, every casting less than ½ in. in thickness will be good, whereas above that thickness there is danger of mottled or gray iron, which gives poor results when subjected to prolonged heating in the anneal. On the other hand, where all castings are ¼ in. or less in thickness, as in small fittings, the silicon can safely go up to 1.00 and even over. Where castings having parts ¾ in. thick are made, the silicon must be dropped down to 0.45, and it may even be necessary to apply chills to the thick places to get them white in fracture.

Mixtures for Malleable run normally half pig iron, the other half being made up of the sprues, annealed scrap, and some steel (but not over 5 per cent. of steel in any case). This scrap percentage can be varied either way considerably.

In air-furnace and open-hearth practice **the essential point in melting** is to get out the heats rapidly to reduce oxidation to a minimum.

The specifications for **pig irons** used **for making malleable castings** are as follows: Silicon, 0.75 to 1.50, as may be specified, delivery to have an allowance of 0.10 either way from the percentage asked for; manganese, not over 0.60; sulphur, not over 0.50, and phosphorus, not over 0.20. The best way to specify is to call for a given tonnage of the above with 0.75 Si, then for more tonnage with 1.00, more with 1.25, and finally with 1.50. Of these four specified silicon percentages most malleable works use 1.00 and 1.25 per cent. in largest quantity. The small-castings plants use more of the 1.25 and 1.50 per cent., and the heavy-castings plants more of the two lower percentages. All require the other elements as given above.

It is important in the **annealing process**—in which the castings should preferably be packed in an iron oxide of some kind, such as hammer scale, puddle scale, magnetite, hematite, etc.—that the castings be raised fairly rapidly to the full temperature of about 1350 deg. fahr., that this temperature be then maintained steadily for at least 60 hr., and finally, that the castings be allowed to cool very slowly, so that the carbon change effected by annealing may not be disturbed. It is injurious to heat a malleable casting to straighten it; this should always be done cold.

As a general rule, a cupola-iron **malleable casting costs** ½ cent more per lb. than a corresponding gray-iron casting. In the case of air-furnace or open-hearth furnace iron, the advance is about 1 cent per lb.

The **annealing** of the original hard casting converts the combined carbon into "temper carbon." In addition, there is considerable carbon removed from the skin of the casting. It is best not to machine malleable castings, as the toughest portion—the skin—is thus removed. Moreover, normal malleable castings are all subject to an interior shrinkage, due to heavy contraction, poor feeding possibilities of metal with so low a silicon percentage, and irregularities in section. Hence the normal strength of the interior portion is not to be depended upon if the skin is machined away.

In Europe, malleable castings are also made by the converter process, as the first part of the regular converter steel castings process. The best castings, however, are made by the crucible process. This process is too expensive in America, and is only used for high-grade steel castings at the present time.

STEEL CASTINGS

Steel castings may be classified on the basis of quality, from good to best, as follows: (1) Acid Bessemer; (2) basic open-hearth; (3) acid open-hearth; (4) crucible, and (5) electric furnace. In addition, there are the basic Bessemer steel casting, which is not on the market in this country but is used extensively in Europe; and the hybrid steels—in reality malleable castings which have been heated and quenched—which are called steel castings in the trade, and are only used for small edged tools. Their quality cannot stand in comparison with regularly made steel castings.

Basic Bessemer Steel Castings have rather poor physical qualities. The ductility is low, there is a greater chance for occluded gases and slag, and the tendency toward brittleness is specially marked.

Acid Bessemer Steel Castings (usually made in small quantities from steel melted in the "Baby" Bessemer side-blown converter) are much better, as they start with a higher-grade material. The pig iron and steel scrap used are melted in the ordinary foundry cupola, run into the converter—which usually is of 2 tons capacity, blown to low-carbon steel, the proper amounts of silicon and manganese added, and cast.

From the nature of the process there is liable to remain a slight oxidation of the steel, which is not good, as well as a rather high sulphur content. The castings from this process are usually small and unimportant. Their composition will run somewhere between the following limits: Carbon, 0.12 to 0.22; silicon, 0.25 to 0.40; manganese, 0.55 to 0.85; sulphur, 0.03 to 0.08; phosphorus, 0.03 to 0.06. The physical properties are about as follows: Ultimate strength, 70,000 lb. per sq. in.; elastic limit, 40,000 lb.; elongation in 2 in., 30 per cent.; reduction in area, 55 per cent.

Basic Open-hearth Steel Castings are the cheapest to make, and hence lead in tonnage produced. In pouring, the metal is usually somewhat "wild," and a rather high percentage of silicon has to be added to overcome this tendency. The silicon gradually exchanges with the phosphorus of the slag, causing the percentage of the latter to rise, and the former to drop as the steel is poured. The result is spongy parts in the castings. The proper use for this grade of castings is for very heavy and large pieces which require but few portions to be machined. Their composition is usually as follows: Carbon, 0.20 to 0.30; silicon, 0.20 to 0.40; manganese, 0.60 to 0.80; sulphur, not over 0.03; phosphorus, not over 0.04. They have about the same physical properties as those of the acid converter steel castings given above.

Acid Open-hearth Steel Castings are those best adapted for good work which must not be too expensive. They are used for all kinds of work which must be machined extensively, and are quite reliable. The segregation is not serious, except in very bulky pieces, and castings up to 50 tons in weight can be made readily. Like all steel castings, however, they should receive careful attention in the processes of manufacture. For the best classes of work, the castings should always be annealed. The composition of these castings is practically the same as that of the basic variety, except that both the manganese and silicon can be held lower. The physical properties are but little different from those of the castings so far discussed.

A recent development of the acid steel casting process is the introduction of the **"baby" acid open-hearth furnace**, usually of about 2 tons capacity. Here the hearth is swung out of the furnace structure, and the metal poured directly into the molds. The possibilities of the smaller open-hearth units in the acid process for making the higher carbon ranges of cast steel, has brought about a demand for such material; 0.40 carbon-steel castings are now being specified more frequently. Here the ultimate strength may run as high as 90,000 lb., with the elastic limit a little over half as large. The elongation is correspondingly lower, or below 20 per cent., and the reduction in area between 20 and 30 per cent.

Crucible-steel Castings are among the best made. The expense of the process necessarily confines the work to very-high-class and small-weight articles. Chemically, there is little variation from the figures already given, except that the carbon often runs up to 0.50. The elongation may run above 30 per cent., and the reduction in area often exceeds 50 per cent.

Electric-furnace Steel Castings. The melting is non-oxidising and the resulting metal is pure, uniform and quite hot. The castings produced cannot be equaled even by the crucible process. The physical strength runs high, and the reduction in area occasionally exceeds 60 per cent. Chemically, the electric-furnace method of melting makes it possible to keep the sulphur under 0.02 and the phosphorus under 0.015, results which cannot be achieved by any other process.

Alloy-steel Castings are coming into extended use, manganese-, vanadium-, titanium-, nickel- and chrome-steel castings being specified quite frequently. **Vanadium** seems to make for greater wearing quality. **Titanium** purifies by removing oxygen and nitrogen from the steel. **Nickel** will raise the tensile strength up to 100,000 lb. per sq. in., while **chromium** toughens the castings. **Manganese**-steel castings are very hard.

Miscellaneous

Patterns are now made of metal as far as possible. Where wooden patterns must be made, such hard woods as mahogany are selected for the purpose. Allowance for shrinkage is ⅛ in. per ft. for both gray iron and malleable, though in making repetition work the first castings are carefully measured over and the pattern corrected accordingly, as the straining action of the molds and cores upon the setting iron, which in that condition is capable of being stretched, will often nullify the entire so-called shrinkage.

After the metal is cast, care should be taken to see that the molds are not shaken out too soon, as the contact of red-hot castings with the air gives rise to interior strains. Moreover, the surfaces will be chilled somewhat, and this is detrimental to the machining qualities.

Cleaning Castings. Castings are either cleaned by hand with the scratch brush, or else go to the tumbling barrels or into the pickling tanks. Modern practice, in the case of castings allowing it, is rapidly adopting the **sand blast** for cleaning the foundry product. This process gives a very clean surface, removing not only the adhering sand, but also much of the scale due to oxidized iron, slag, and blacking from the mold surface. When well done, sand blasting may even replace the preliminary pickling necessary for subsequent galvanizing and tinning operations.

Foundry Layout. Foundries should be so designed that **transportation** is facilitated as much as possible. For large castings, the flat car should be run directly under the cranes in the foundry proper, or into the cleaning room, if this is thought more desirable. With tracks running directly into the foundry, sand may be brought in direct, saving double handling.

The **carrying of molten metal** is performed preferably in crane ladles, and the ideal foundry of large tonnage has two crane runways, one over the other. These are provided with one to three cranes, with one or two hoists each, depending upon the magnitude of the establishment. The sides are further provided with running jib cranes in any number desired, the radius of the crane action being smaller than half the width of the shop, so that the main cranes can pass while work is suspended from the jib cranes.

The **buildings** should be preferably of brick or structural steel, with steel roof trusses. If these materials are not used, everything about the cupolas should be fireproof. Lean-tos should also be provided with traveling cranes and floor trackage allowing the transfer of ladles from the main hall to the lean-to. Where smaller quantities of molten metal are to be used—not to exceed 1000 lb. at a time, the **overhead track** system is best, as the floor space is left clear of obstructions by trackage. Only as a last resort should metal be transported in ladles on floor track.

In the foundry, **light** is always best obtained through side windows. Skylights either in the slope of the roof or on louvres, are not efficient, as they soon become covered with dust and rusty particles of iron. **Heat** should also be provided in the foundry so that the men may work in comfort in the early winter mornings.

Fire protection is essential. Wooden flasks should not be stored directly against wooden lean-tos or buildings, nor should they be stored where there is a possibility of sparks from the cupola.

Foundry Costs. In the standard system of apportioning foundry costs adopted by the American Foundrymen's Association in 1908, the total expenditures are divided broadly into the actual foundry costs and the commercial costs. Foundry costs are subdivided into cost of metal, surcharges on metal (distributed to classes on a weight basis), cost of applied labor charged to product, and surcharges on applied labor costs (distributed on a percentage basis).

Metal Costs. These comprise the costs of pig iron (freight included), iron and steel scrap purchased, defective castings from foundry, cupola droppings, gates, sprues, etc.

Surcharges on Metal. The main accounts are for cupola expenses (including repairs, labor, materials, supplies, labor for loading and tending, fuel, lime, manganese, etc.); ladle expenses (labor, materials, renewals); foundry castings (charged to foundry at pound rates); molding supplies (sands, gravel, facings, core-room supplies, chaplets, core-oven fuels, lumber for renewing flasks, and labor on these items); general foundry work (*e.g.*, recovering scrap, cleaning up shop, cartage and handling, freight demurrage, power for yard and cupola service, measured or estimated, and charged for at a fixed rate per h.p.-hr.).

Applied Labor Costs include wages paid to molders, helpers, apprentices, core makers and their helpers, cleaners, and chippers. Whenever it is impossible to charge the wages of core makers, cleaners, and chippers to individual jobs, these items must be treated as surcharge labor costs, and distributed on a percentage basis.

Surcharges on Applied Labor. These include the salaries of superintendents, foremen, chemists and foundry clerks; charges for foundry office supplies, for a proportion of the general office expenses, for rent (arbitrary charge per sq. ft. of ground and of floor space), for power, light and heat (measured or estimated, at a fixed rate per h.p.-hr.), for maintenance and renewal of equipment, general miscellaneous work, sundry supplies, and for the wages of pattern makers, carpenters and blacksmiths. (Occasionally it may be possible to treat these wage amounts as applied labor.)

Each of the above accounts and items may be still further subdivided in order to permit distribution of costs to departments or to foremen, so that the progressive cost of iron from its purchase up to its appearance in the form of castings may be shown.

The **commercial costs** embrace all expenditures for administration and for making sales. They are preferably distributed in varying proportions to the different classes of castings, according to judgment rather than on a tonnage, labor or total-cost basis.

From the foundry accounts thus kept the total cost and net weight of good castings produced during the year may be ascertained, and from these the average cost per pound. The output is then divided into a number of classes of work ranging from the heaviest low-grade castings to the lightest and most intricate pieces, and the net price per lb. determined for each. To these are then added their proper shares of the commercial costs. A comparison of the average cost per lb. of all castings with the cost per lb. of each class of work will quickly show the classes in which it will pay the foundry to specialize. Without such a subdivision of costs, and basing estimates on work submitted upon the average cost per lb., a foundry may find itself loaded up with unprofitable work.

NON-FERROUS METALS AND ALLOYS

NON-FERROUS METALS

Copper

Copper is distinguished from all other metals by a peculiar **red color,** which is pinkish or yellowish on the fresh fracture of the pure metal, but inclines to purple in the case of copper containing cuprous oxide. The **fracture** of cast copper is hackly granular; in forged or rolled copper it is fibrous and shows a pale red silky luster. Copper crystallizes in the cubic system. **Specific gravity:** Pure crystalline copper, 8.940; electrodeposited copper, 8.914; cast copper, 8.921; rolled and hammered copper, 8.952. Ordinary commercial copper is more or less porous, and its specific gravity varies between 8.2 and 8.5.

Copper is **malleable** and **ductile.** It becomes hard by rolling and drawing, but is readily annealed. It is completely softened by being held at a temperature of 350 deg. fahr. for 72 hr., or almost instantly when raised to a temperature of 600 deg. fahr.

Mechanical Properties: $E = 15{,}000{,}000$ (about); tensile strength, lb. per sq. in., hammered, 38,400; drawn, 44,800; fire-box (rolled and annealed), 32,700; special stay-bolt (annealed), 38,400. Elongation, 35–38 per cent.; reduction of area, 45–50 per cent. Shrinkage of castings, 0.1875 in. per ft. Compressive strength (cast), 40,000 lb. per sq. in.

There are **three standard grades** of copper on the market, namely, Lake, Electrolytic and Casting.

Lake Copper is obtained from the ores in the region principally bordering on Lake Michigan by wet concentrating methods. The concentrates are then smelted, and, after rabbling and poling, are cast directly into the form of copper ingots or bars. It is usually sold at a slight advance over electrolytic copper.

Electrolytic Copper is produced in great part from the Western United States sulphide ores, which are first matted and then blown in a Bessemer converter to eliminate most of the iron and sulphur; the metal is then cast into slabs, known as "blister" copper, which usually carry about 96 per cent. of copper. The blister copper is melted in large reverberatory furnaces and cast into anodes; these are dissolved in an electrolytic bath and deposited on cathodes, which are melted in reverberatory furnaces; after refining to eliminate impurities taken up in melting, it is cast into wire bars, cakes, slabs, ingots and billets.

Casting Copper is obtained from ores which do not carry sufficient gold and silver to warrant the expense of electrolytic refining, and also from brass foundry by-products known to the trade as "copper-bearing material." It is produced by smelting and oxidizing the ore or by-products in reverberatory furnaces until the impurities have been largely eliminated. Casting copper may range from 99 to 99¾ per cent. pure, depending on the raw material used and the degree of refining. It is considered inferior to electrolytic and lake copper, and sells at a slightly lower figure than electrolytic copper. **Secondary casting copper,** or that recovered from scrap copper, alloys and copper-bearing residues which occur as by-products in brass foundries and manufacturing plants where copper and copper alloys are used, runs from 98½ to 99¾ per cent. pure, depending on the raw material and the degree of refining.

Standard Specifications for Copper Wire Bars, Cakes, Slabs, Billets, Ingots and Ingot Bars were adopted by the American Society for Testing Materials, Aug. 25, 1913, substantially as follows:

METAL CONTENTS: The copper in all shapes to have a purity of at least 99.88 per cent. as determined by electrolytic assay, silver being counted as copper. (In the case of high-resistance Lake copper, silver and arsenic are counted as copper.)

RESISTIVITY. Low-resistance Lake copper wire bars (ingots and ingot bars) to have a resistivity not to exceed 0.1553 (0.15694) international ohm per meter-gram at 20 deg. (0 deg.) cent., annealed. Electrolytic copper in wire bars (ingots and ingot bars) to have a resistivity not to exceed 0.15535 (0.15694) international ohm per meter-gram at 20 deg. cent., annealed. High-resistance Lake copper has a resistivity greater than 0.15694 international ohm per meter-gram at 20 deg. cent.

Wire bars, cakes, slabs and billets to be substantially free from shrink holes, cold sets, pits, sloppy edges, concave tops and similar defects in set or casting. Five per cent. variation in weight or ¼ in. variation in any dimension from refiner's published list or purchaser's specifications may be considered good delivery.

Standard Specifications for Hard-drawn Copper Wire (Abstract of specifications adopted by the A. S. T. M., Aug. 21, 1911). Wire to be free from all surface imperfections not consistent with the best commercial practice. Necessary brazes to show at least 95 per cent. of the tensile strength of unbrazed wire. Specific gravity assumed as 8.89.

Size to be expressed as the diameter of the wire in decimal parts of an inch (to three places). Permissible size variations: For wire 0.100 in. in diam. and larger, ± 1 per cent.; for wire less than 0.100 in. in diam., 1 mil (= 0.001 in.). Coils to be gaged at both ends and near the middle. If, two points being within limits, the third is off more than 2 per cent. (for wire 0.064 and larger) or 3 per cent. (for wire smaller than 0.064), coil may be rejected.

Wire to have a tensile strength and elongation at least equal to the values given in the following table, as determined on fair samples.

Table 2. Specifications for Hard-drawn Copper Wire

Diam., in.	Tensile strength, lb. per sq. in.	Elongation in 10 in., per cent.	Diam., in.	Tensile strength, lb. per sq. in.	Elongation in 60 in., per cent.	Diam., in.	Tensile strength, lb. per sq. in.	Elongation in 60 in., per cent.
0.460	49,000	3.75	0.165	62,000	1.140	0.081	65,700	0.92
0.410	51,000	3.25	0.162	62,100	1.090	0.080	65,700	0.91
0.365	52,800	2.80	0.144	63,000	1.176	0.072	65,900	0.90
0.325	54,500	2.40	0.134	63,400	1.020	0.065	66,200	0.89
0.289	56,100	2.17	0.128	63,700	1.000	0.064	66,200	0.87
0.258	57,600	1.98	0.114	64,300	1.000	0.057	66,400	0.86
0.229	59,000	1.79	0.104	64,800	0.970	0.051	66,600	0.85
....	....	in 60 in.	0.102	64,900	0.970	0.045	66,800	....
0.204	60,100	1.24	0.092	65,400	0.950	0.040	67,000	....
0.182	61,200	1.18	0.091	65,400	0.940	....	....	....

Resistivity to be determined by resistance measurements on fair samples at 68 deg. fahr., and not to exceed 900.77 lb. per mile-ohm for wire from 0.460 to 0.325 in. in diam. or 910.15 lb. per mile-ohm for wire from 0.324 to 0.040 in. in diam.

Copper Castings. Sound copper castings may be made in sand or metal molds by adding about 1 per cent. of boron suboxide flux (containing 0.08 to 0.10 per cent. of boron suboxide) to the molten metal. Tensile strength of such castings, 24,000 lb. per sq. in.; elastic limit, 11,500 lb.; elongation, 48.5 per cent.; reduction of area, 74.5 per cent.; electrical conductivity, as high as 97 per cent.

Weights and Dimensions of Brass and Copper Tubes are given on p. 810. Weights and thicknesses of **brass and copper sheets and bars** are given in Tables 3 to 6. For properties of copper wire, see pp. 1588 and 1589.

(In per cent. of the strength at about + 50 deg. fahr.)

Temperature, deg. fahr.	122	212	392	482	545	693	844	1033
Tensile strength	98	95	91	85	79	75	66	51

Lead

Lead possesses a characteristic bluish-gray color and a dull metallic luster, which is lost on exposure to the air, the surface becoming dull gray. It is soft enough to be indented with the nail and can be cut with a knife, the softness of the metal increasing with its purity. It can be rolled into thin sheets, and, by previous heating, can be "squirted" into rods and tubes; it cannot, however, be drawn into fine wire on account of its want of ductility and its low tensile strength. The **specific gravity**, between 11.254 and 11.395, is only very slightly increased by rolling (according to Knab, 11.352 for cast lead and 11.358 for rolled lead). The specific gravity is lowered by the presence of other metals, so that it furnishes an indication of the softness and purity of the lead.

Lead crystallizes in the cubical system. At a bright red heat, in the presence of air, it volatilizes perceptibly, but only to a very slight extent if air be excluded; at a white heat (2900–3560 deg. fahr.) it boils. Antimony, arsenic, copper and zinc diminish the softness of lead when present to any considerable extent, antimony and arsenic rendering it brittle, hard and easily fusible.

Mechanical Properties: E in lb. per sq. in. = 700,000 for rolled or cast lead (= 1,000,000 for lead wire). Tensile strength in lb. per sq. in. = 1780 for rolled or cast lead (= 3130 for hard and 2420 for soft wire). Shrinkage of castings, 0.3125 in. per ft.

Practically all the lead on the market is obtained from the **sulphide of lead** ore, known as **galena.** Practically all sulphide ores carry gold and silver, and crude lead is therefore subjected to further treatment for the extraction of the precious metals, and finally to an oxidising refining treatment which renders the lead extremely pure.

Specifications for Pig Lead. The Pennsylvania Railroad Specification No. 43–A, adopted Dec. 21, 1908, specifies that No. 1 grade shall contain not less than 99½ per cent. of metallic lead, and No. 2 grade (used only for counterbalancing) not less than 97½ per cent.

Chemical Lead. The lead sold in the United States under this name is obtained in the Flat River District in southeast Missouri, from disseminated ores which are contaminated with copper, cobalt, nickel and other impurities. This lead is alloyed naturally with certain percentages of other ingredients which render it more impervious to acid attacks than other brands of lead. The Hoyt Metal Co., of St. Louis, manufacture a standardized chemical lead known as "**Hoyt process" lead,** which is furnished in the form of sheet and pipe. **Hoyt metal** is a lead carrying from 6 to 10 per cent. of antimony, and in the form of sheets and pipes is extensively used in chemical works and other industries where acids are made or employed. The 10 per cent. Hoyt metal weighs 8 per cent. less than chemical lead, its tensile strength is double that of the latter, and it is much more rigid. It is claimed that it will not buckle, creep, stretch, tear or sag in use, and that it is much superior to chemical lead in acid-resisting qualities.

Lead Wool is lead in a fibrous or shredded form, which is used for calking the joints of water and gas pipes.

Lead Pipe. For tables of sizes and weights of lead pipe and tubing, see pp. 811 and 812.

Table 9. Maximum Sizes in Which Sheet Lead Can Be Furnished

Zinc

Zinc is a bluish-white metal having a **specific gravity** of about 7.1. It boils at about 930 deg., so that it can be readily distilled; there is always a sensible loss when it is used in the manufacture of alloys. The metal in fine shavings or vapor burns readily with an intense bluish-white flame, forming dense clouds of white zinc oxide (philosophers' wool). It is malleable and ductile through a limited range of temperature only, and is largely **used** for rolling into sheets **for roofing** and other purposes. It oxidizes only slightly on exposure to the air, with the formation of a basic carbonate.

Zinc is marketed in the form of **rolled sheets,** and also in cast cakes of about 1 in. thick, known as **spelter.** The cakes are very brittle, and break with a more or less crystalline fracture. If the metal be nearly pure the crystal faces are large, bright and smooth; if there be a small quantity of iron present dull spots appear on the crystal faces; with an increased quantity of iron, as in dross spelter, the **fracture** becomes granular. The amount of iron present can be fairly judged from the appearance of the fracture. Its **tensile strength is low**: 27,000 lb. per sq. in. along the grain; 36,000 across grain, for rolled sheets; spelter, 4000 (coarsely crystalline) to 14,000 (fine-grained). Modulus of rupture, 8000 to 22,000 lb. per sq. in., increasing with fineness of grain. Compressive strength (cast), 20,000 lb. per sq. in. E (average) = 13,700,000; elongation, 12 to 38 per cent.; reduction of area, 23 to 56 per cent.

Zinc casts well, contracts but little on solidifying, and is largely used for the manufacture of statuettes and other ornamental castings which are usually coated with bronze or brass by electrodeposition. Shrinkage of castings, 0.3125 in. per ft. Its **chief uses** are in galvanizing and in the manufacture of brass and other alloys.

Zinc is never pure, the principal **impurities** being iron, lead, tin, copper, arsenic, and cadmium. When zinc is used for galvanizing, a hard zinc which contains several per cent. of iron accumulates in the vats. Good commercial spelter should not contain more than 0.05 per cent. of iron, and this is about the maximum allowable for alloy making.

Lead is invariably present in spelter in larger or smaller quantity. For making brass or other alloys, a spelter containing more than 1.5 per cent. of lead should be rejected. The other impurities are rarely present except in unobjectionable quantities.

Table 10. Typical Analyses of Various Grades of Virgin Spelter

Grade	Iron %	Lead %	Cadmium %	Zinc %
High grade	0.02(0.03)	0.05(0.07)	(0.05)	99.930
Intermediate	0.025(0.03)	0.15(0.20)	(0.50)	99.825
Brass special	0.025(0.04)	0.30–0.60(0.75)	0–0.50(0.75)	balance
Prime Western	0.08(0.08)	1.50(1.50)	0.50	97.920
Sheet zinc*	0.015	0.27	0.29	99.400

* Matthiessen & Hegeler Zinc Co.

High-grade spelter is used mainly for brass for spinning and drawing; for the highest grades of alloys, such as manganese bronze, and for galvanizing telegraph and telephone wires that have to withstand sharp bending; also for artistic castings. The **intermediate** grade is used in brasses and bronzes where the very highest quality is not essential, and also for the better grades of casting-brass. The **brass special** grade is used for the better grades of alloys where high ductility is not required. **Prime Western** spelter is used mainly for the ordinary galvanizing of sheet, wire and miscellaneous articles, also in red-brass alloys and free-cutting yellow brass.

Secondary Spelter is recovered by refining zinc dross—an iron-zinc alloy formed in the process of galvanizing. It carries from 3 to 5 per cent. of iron and from 2 to 3 per cent. of lead. This is refined either by distillation or by a liquating method. If refined by the former method a product of fairly high purity results, and if refined by the latter method a very inferior quality results, carrying a high percentage of iron and lead. This latter product is given a marketable appearance by the addition of a very small percentage of aluminum.

Specifications were adopted by the American Society for Testing Materials, Aug. 21, 1911. Limiting percentages of impurities are specified for the four grades of virgin spelter (see values in parentheses in Table 10), methods of sampling, analyzing, etc. High, intermediate and brass special grades are to be free from aluminum, and their combined contents of iron, lead and cadmium are not to exceed 0.10, 0.5, and 1.20 per cent., respectively.

Spelter for slush castings should be free from cadmium and should not contain more than 0.1 per cent. of lead. Sound castings from less pure metal can be obtained only by making them excessively heavy. (Stone, Trans. A. I. Metals, vol. 8.)

Tin

Tin has an almost silvery whiteness with a slightly bluish tinge and a brilliant luster which depends largely on the pouring temperature; if this is too high the surface will show iridescent colors, while if too low the surface will be dull. The admixture of small quantities of lead, arsenic, antimony, iron, or bismuth also diminishes the luster of tin.

The structure of tin is distinctly crystalline. **Specific gravity:** Cast tin, 7.291; rolled tin, 7.299; electrically deposited tin, from 7.143 to 7.178.

Mechanical Properties. Tin is harder than lead but softer than gold. At ordinary temperatures it can be beaten and rolled into thin leaves (sheet tin and tinfoil). **At higher temperatures** its extensibility diminishes, until at 392 deg. fahr. it **is** so **brittle** that it breaks to pieces when hammered, and can be powdered. If the temperature at which tin is cast be either too high or too low, it will be "short," *i.e.*, brittle. The addition of 1 to 2 per cent. of copper or lead increases its hardness and tenacity. Tin is **ductile** but possesses little tenacity (T.S. = 5000 to 5700 lb. per sq. in.; $E = 5{,}700{,}000$); it is most ductile at about 212 deg. fahr.; a wire 0.08 in. in diam. breaks under a load of 54 lb. For cast tin, tensile strength is 3500 lb. per sq. in. and compressive strength 6000 lb. per sq. in.

Impurities and Their Effects. Iron, if present in considerable quantities, makes the tin hard and brittle; arsenic, antimony and bismuth, if present to the extent of 0.5 per cent., reduce its tenacity; copper and lead (1 to 2 per cent.) make it harder and increase its strength, but make it less malleable; tungsten and molybdenum render it less easily fusible; stannous oxide reduces its tenacity; sulphur is said to render it "short."

Table 12. Typical Percentage Analyses of Various Grades of Pig Tin

Grade	Tin	Antimony	Arsenic	Lead	Bismuth	Copper	Iron	Silver	Sulphur
Banca	99.95	0.007	....	trace	....	0.018	0.045	....	trace
Penang	99.939	trace	0.013	trace	....	0.016	0.028	....	....
Singapore	99.87	0.008	0.045	0.034	0.003	0.052	0.003	0.006	0.005
Range of impurities in other grades.	......	0 to 0.569	0 to 0.065	0 to 4.00 (China)	0 to 0.055	0.018 to 0.445	0 to 0.028	traces	0 to 0.013

Sources. The principal **tin ore** is cassiterite, or tin stone—an oxide of tin. The lowest grades of pig tin come from China and Bolivia, and contain as little as 94 per cent. metallic tin. **Banca tin** has the highest reputation of any on the market, and next to this is Straits tin, from Malacca. Tin is now recovered from tin-plate clippings by an electrolytic or "detinning" process in the form of a fine powder, which is then smelted in a reverberatory furnace and cast into pigs. This **by-product tin** usually runs from 97 to 99 per cent. of tin and carries lead, copper and antimony. For the production of the finest grades of solder, Babbitt metal and high-grade alloys subject to physical tests, Banca, Straits or similar grades of tin should be used. For all other uses the lower grades of tin are suitable, due consideration being given to their actual tin content.

Block Tin Pipe. For table of weights and dimensions, see p. 812.

Antimony

Antimony is characterized by its great brilliancy and by its color—silver white with a slight tinge of blue, the latter being increased by the presence of **impurities,** such as sulphur, arsenic, lead, copper and iron.

When pure molten antimony is allowed to solidify slowly and without disturbance under a layer of slag, a fern-like arrangement of raised lines radiating from the center appears on the surface of the metal (the so-called "antimony star"). This is generally regarded as an indication of the purity of the metal.

Sources. Antimony glance (known also as gray antimony ore, antimonite and stibnite) is the most important ore of antimony. It is a sulphide ore (containing 71.77 per cent. of antimony in the pure state), and is commonly associated with quartz, calc-spar, heavy spar, and spathic iron ore. Zinc blende and galena frequently occur intimately mixed with it.

Production. When the ores exist as pure sulphide of 90 per cent. or over, they are usually roasted direct to form an oxide, which is afterward reduced by carbonaceous matter. If the ores are lean the antimony sulphide is liquated to free it of the gangue, and then roasted and reduced in the same manner. By another method the antimony sulphide is directly reduced by iron, which, having a greater affinity for sulphur than antimony, combines with the sulphur and liberates the antimony. The antimony produced by both methods must afterward be refined.

A typical analysis of commercial antimony shows the following percentage composition: Silver, 0.001; arsenic, 0.120; tin, 0.006; lead, 0.089; copper, 0.076; iron, trace; zinc, none; nickel and cobalt, 0.046; manganese, none; sulphur, 0.008; antimony (by diff.), 99.654.

Uses. Antimony is used in making type metal, Babbitts and other bearing metals, its presence in alloys conferring the properties of hardness and of expanding on solidification.

Nickel

Nickel possesses an almost silvery white luster with a steel-gray tinge and great brilliancy. With **great hardness** and capacity for taking polish it combines great **malleability**; it can be easily hammered, rolled, or drawn into wire. Sheets 0.0008 in. thick and wire 0.0004 in. in diameter may be made from it. Its tensile strength surpasses that of iron: for sheets of pure nickel 0.05 in. thick, rolled hard (annealed), 92,000 lb. (76,000 lb.) per sq. in. and 11 (35) per cent. elongation in 2 in.; for 0.065-in. diam. hard-drawn wire, 150,000 to 160,000 lb. per sq. in.

Nickel is attracted by a magnet, and then becomes **magnetic** itself; it loses this property at 662 deg. fahr. It **can** not only **be welded** to itself at a white heat, but it can also be welded to iron and certain alloys. Fleitmann's method of manufacturing nickel-plated wares consists in welding pure nickel to iron and steel or alloys of copper and nickel, and then hammering or rolling into sheets. In welding, it is necessary to completely exclude the air from the surfaces to be welded.

Commercial nickel is exceedingly impure, containing substances of which even traces affect its valuable properties. The most harmful **impurities** are arsenic, sulphur, oxide of nickel and chlorine. Carbon is dissolved by molten nickel, and seems not to affect its good qualities so long as oxides are not present at the same time. It makes nickel slightly more fusible. According to Ledebur, nickel absorbs its own monoxide, and this injures its tenacity and malleability.

Nickel **does not tarnish** in dry air at ordinary temperatures. When heated in contact with air it is slightly oxidised into nickelo-nickelic oxide. At a red heat it decomposes steam very slightly. It is very little acted upon by hydrochloric or sulphuric acid in the cold, but is readily dissolved by dilute nitric acid and aqua regia.

Production. The chief **ores** of nickel are the silicate ores of New Caledonia, known as garnierite, and magnetic pyrites containing nickel and copper found in Ontario. The silicate ores can be treated by direct reduction, although they are usually treated in connection with sulphide ores. The magnetic pyrite ores are first smelted to form matte. This matte is Bessemerized to oxidize the greater portion of the iron and sulphur, with the production of a nickel-copper matte which is afterward fused with sodium sulphate and coal, forming an easily fusible matte with the copper sulphide which is of less specific gravity than the nickel sulphide, and a fairly complete separation can be made because of the difference in the specific gravity of the two mattes. By repeating the process, practically pure nickel sulphide is produced, which is then roasted to form oxide and finally reduced to metallic nickel. Mond's method consists in roasting the Canadian mattes, eliminating the copper by sulphuric acid, and then exposing the resulting product to the reducing action of producer gas at about 660 deg. fahr. The reduced metal is then exposed to the action of CO at 176 deg. fahr. in a "volatilizer," the nickel carbonyl so formed being received in a chamber heated to about 390 deg. fahr., where it decomposes, the nickel being deposited and the CO returned to the volatilizer.

Nickel as ordinarily reduced by carbon is brittle, but by the addition of a small percentage of magnesium or manganese, it can be made ductile.

A typical percentage composition after the addition of magnesium is as follows: Nickel, 98.24; cobalt, 1.09; iron, 0.36; copper, 0.10; silicon, 0.06; magnesium, 0.11.

Uses. In coinage, plating, crucibles; in the preparation of German silver, nickel steels, resistance alloy wires, etc.

Aluminum*

Aluminum (aluminium)† is a white metal closely resembling tin in color, produced electrolytically in large quantities from alumina prepared from the mineral bauxite—a hydrated oxide of the metal. Its **specific gravity** at 62 deg. fahr. ranges as follows: Pure aluminum, 2.56; pure aluminum sheets and wire unannealed, 2.68; pure aluminum sheets and wire annealed, 2.66; aluminum alloy sheets and wire unannealed or annealed (3 S), 2.75; aluminum casting alloys, 2.82 to 2.99. The alloys contain small percentages of Cu, Ni, W, Mn, Cr, Ti, Zn or Sn to produce hardness, rigidity and strength.

Ordinary commercial aluminum has about the **hardness** of copper. By pressing, rolling, forging, stamping or other similar working it may be made very hard and rigid in the finished shapes, whereas the soft annealed metal would be too weak for the purpose intended. This is especially true of aluminum alloyed with other metals in amounts not to exceed 5 or 6 per cent. Greater percentages render the alloys non-malleable.

Aluminum is very **ductile.** It can be rolled into sheets as thin as 0.0007 in. and then be beaten into leaf; drawn into wire as small as 0.004 in. in diameter; spun, stamped or extruded in various shapes. It is susceptible of a high degree of finish by polishing or burnishing. It becomes **hardened by working,** and sheets for stamping or spinning must be annealed.

At ordinary temperatures aluminum is **highly resistant to** all inorganic **acids** except hydrochloric, is little acted upon by salt water and not at all by sulphur below a red heat, by CO or CO_2. Solutions of caustic alkalies, chlorine, bromine, iodine and fluohydric acid rapidly corrode the metal. A clean surface tarnishes in damp air, an almost invisible coating of oxide being formed, which, however, is very permanent and prevents further attack.

* Much of this information has been obtained from the publications of the Aluminum Co. of America.

† Trade usage in North America sanctions the use of the word aluminum.

As the common metals are electronegative to aluminum in a voltaic couple, care should be taken that aluminum exposed to water or aqueous solutions shall not come in contact with any other metal that will cause **galvanic action** to be set up. For example, tubing can be thoroughly insulated by the use of rubber gaskets, washers or nuts. Aluminum sheets and shapes can be insulated from other metal by the liberal use of good heavy paint between the joints.

Commercial aluminum is sold in three **grades**: No. 1 (pure), No. 2, and extra pure. No. 1 has approximately the following composition: Silicon, 0.30 per cent.; iron, 0.15 per cent.; aluminum, 99.55 per cent. For No. 2 the percentages are respectively 2, 2 and 96. Silicon and iron are the only **impurities** commonly found in aluminum.

The **tensile and compressive strengths** of aluminum (99 per cent. pure) average as follows:

	Tension		
	Elastic limit, lb. per sq. in.	Ultimate strength, lb. per sq. in.	Reduction of area, per cent.
Castings	8,500	12,000–14,000	15
Sheet	12,500–25,000	24,000–40,000	20–30
Wire	16,000–33,000	25,000–55,000	40–60
Bars	14,000–23,000	28,000–40,000	30–40
	Compression		
Short cast columns (height = 2 × diam.)	3,500	12,000	

E for cast aluminum = 9,000,000.

Pure aluminum in castings is a metal somewhat open in texture, and when used for cylinders to stand pressure an increase in thickness over that calculated by ordinary formulæ should be made to allow for its **porosity**. **Shrinkage** of castings, 0.2031 in. per ft.

Under transverse tests the metal will bend nearly double before breaking. The strength of aluminum is greatly improved by forging or pressing the ingots at a temperature of about 600 deg. fahr. Weight for weight, aluminum is only exceeded in tensile strength by the best cast steel.

Aluminum Pipes are made in the dimensions given on p. 813.

Extruded Aluminum can be obtained in shapes possible to manufacture no other way, and in any continuous lengths desired. It is possible to extrude shapes in compositions ranging from pure aluminum to very hard alloys, some of which cannot be rolled. The tools used are much less expensive than are the rolls necessary for rolled shapes, making it commercially possible to furnish smaller quantities of special shapes than rolling-mill costs would justify. The maximum sectional dimension of an extruded shape should not exceed 6 in., and, in general, walls under 1/8 in. in thickness should not be specified.

Aluminum Bronze Powder, or aluminum finely powdered by beating in stamp mills, is largely used as a metallic paint. For this purpose it is mixed with a light coach varnish or with "banana oil," a lacquer made by dissolving gun cotton in amyl acetate.

For S. A. E. specifications for **aluminum alloys,** see pp. 542 and 1197.

BRASSES AND BRONZES

Copper-Tin Alloys (Bronzes)

The term **bronze** should be applied only to those alloys of copper in which tin is the predominating metal affecting or modifying the properties of the copper. A **true bronze** is an **alloy of copper and tin** only, in which copper is in predominating proportion, the most useful alloys being those containing from 4 to 25 per cent. of tin. After 12 per cent. of tin is exceeded, the ductility of the alloys is so diminished that they are subject to breakage by shock. Modifications are often made by the addition of relatively small proportions of lead and zinc, and occasionally of other metals.

Test pieces for compression tests were 2 in. long, 5/8 in. diam.
Test pieces for torsion were 1 in. long, 5/8 in. diam.

Gun Metal is a copper-tin alloy (8 to 11 per cent. of tin) used before the introduction of steel in the manufacture of ordnance. Occasionally it contains small percentages of iron, zinc and lead. The **U. S. Government Specification** for its composition is: Copper, 88 per cent.; tin, 10 per cent.; zinc, 2 per cent. A variation of 1 per cent. is allowed above or below. Iron not to exceed 0.06 per cent.; lead not over 0.2 per cent.

Detail specifications are given in "Specifications for Inspection of Materials, Part II, Bureau of Steam Engineering, Navy Department, Revised July 1, 1910," which call for the following minimum **physical properties:** Tensile strength, 30,000 lb.; yield point, 15,000 lb.; elongation in 2 in., 15 per cent. This alloy is susceptible to quite wide variation in its physical properties, due to the heat treatment which it has had, the manner of attaching test bar, gating and provision for shrinkage. It can also be modified by slight additions of deoxidizing agents.

Effect of Heat Treatment. As these alloys contain different constituents which are stable only at certain elevated temperatures, the effect of quenching alloys at those temperatures at which the various constituents are stable will result in the properties of the alloys being modified by reason of containing such constituents. This accounts for the fact that bronze acts in a manner reverse to steel when quenched above 930 deg. fahr. in water. If quenched at this temperature the alloy is more malleable and stronger, for the reason that the hard and brittle constituent Cu_4Sn has been prevented from forming. This constituent does not form unless the alloy is cooled in the air to below 930 deg. fahr. This important fact is taken advantage of commercially in modifying the properties of copper-tin alloys in a way analogous to the annealing treatments of steel.

Strength of Bronze at Various Temperatures in per cent. of the strength at 68 deg. fahr. averages about as follows:

Temperature, deg. fahr	212	392	572	752	932
Tensile strength (relative)	101	94	57	26	18

Bell Metal alloys are alloys of copper and tin containing from 15 to 25 per cent. of tin. The higher the tin content the more brittle the alloys become, and the higher the note which they will produce. The tones of a bell may also be greatly modified by its general design, the thickness of its walls, etc., by casting at different temperatures, by the method of casting, and by slight additions of other metals, such as lead and zinc. When slowly cooled the alloy is very hard and brittle. If bells are chilled above the temperature of 932 deg. fahr., they are more malleable and rather yellowish in color.

Statuary Bronze as now made is U. S. Government gun metal, to which has been added a small percentage of lead. In the cheaper alloys less tin and more zinc are used. It is a very fluid alloy, easily cast, and capable of being finished and filed. Under the influence of the atmosphere it assumes a pleasing oxidation tint or "patina."

Coinage Bronze. In the United States the alloy used for copper coins contains 95 per cent. copper and 2½ per cent. each of tin and zinc. This alloy is fairly hard (to resist wear), and yet sufficiently malleable and ductile when cold to take the impression of the die.

Speculum Metal, used for **reflectors**, is a hard, flint-like and extremely brittle alloy consisting of two parts copper and one part tin. It takes and retains a high polish. Slight additions of arsenic or nickel increase its whiteness.

Copper-Zinc Alloys (Brasses)

The term **brass** is properly applied to alloys of copper, the properties of which are modified chiefly by the addition of zinc up to approximately 42

Test pieces for compression tests were 2 in. long and ⅝ in. diam.
Test pieces for torsion tests were 1 in. long and ⅝ in. diam.

per cent. Many of the commercial brasses contain small percentages of tin and lead, and certain well-known alloys belonging under the general classification of brass have their properties modified by the addition of iron, manganese and aluminum. Alloys containing approximately 50 per cent. each of copper and zinc are known as **brazing solders.**

Industrial Brass may be divided into two classes, namely, cast brass and wrought brass.

Cast Brass varies in its zinc content from 30 to 40 per cent. The most desirable mixture contains 65 per cent. copper and 35 per cent. zinc. The alloy is given hardness by the addition of a small percentage of tin. The straight alloy is soft and ductile and drags severely under the tool, but the addition of 1 to 2 per cent. of lead allows it to be machined freely, producing short chips.

There are two classes of **yellow brass** ingots made from scrap on the market intended **for casting purposes:**

1. Ingots produced from rod chips, which when melted down make a very satisfactory casting brass; it contains little tin, has the necessary hardness and fluidity in casting, enough lead to insure free machining, and is practically free of iron. A typical analysis is 63 per cent. copper, 2 per cent. lead, no tin, balance zinc.

2. Ingots made from miscellaneous yellow brass scrap and containing from about ½ to 2 per cent. of iron, and often lead and tin in excess of the amounts desirable for good working; used only for cheap classes of work, such as plumbers' ferrules, etc.

Typical specifications for cast yellow brass are as follows:

1. Dept. of Steam Engineering, U. S. Navy Dept.

	Per cent.
Copper	59 to 63
Tin	0.5 to 1.5
Iron (maximum)	0.06
Lead (maximum)	0.60
Zinc	Remainder.

(Known as cast naval brass)

2. National Cash Register Co., Specification No. 39

	Per cent.
Copper, not less than	60
Lead, not to exceed	2
Iron	0.35
Zinc	Remainder.

Other impurities of a detrimental nature (except oxides) not to be present to exceed traces.

Wrought Brass. There is some confusion of nomenclature in relation to wrought brass. The names in the table on p. 538 are the usual commercial names in the U. S. In addition an alloy of 85 copper and 15 zinc is called **rich low brass.** The nomenclature is entirely different from that in use in England.

Hot-working Brass. Alloys containing approximately 56 to 62 per cent. copper and the balance zinc become plastic when heated to redness and are capable of hot working. The most widely used and known alloy within these specifications is **Muntz metal** (60 per cent. copper and 40 per cent. zinc), which was formerly largely used for ship sheathing, it being claimed that this alloy is corroded just sufficiently to prevent the attachment of barnacles. The alloy is also used for many purposes in which a hard sheet brass is desirable. According to Bengough and Hudson, it should not be rolled or extruded at a temperature below 1100 deg. fahr. It is hardened by quenching. Tensile strength, about 55,000 lb. per sq. in.

Modified Hot-working Brass is brass the properties of which have been somewhat altered by the addition of tin and iron. Two alloys of this nature which are largely used are Tobin bronze and Delta metal.

Tobin Bronze is a proprietary alloy of the American Brass Co., containing, according to published analyses, 58 to 60 per cent. of copper and about 40 per cent. of zinc, the remainder being iron, tin and lead. It is made in the form of sheets and plates ($\frac{1}{16}$ to 2 in. thick), rods (up to 7 in. diam.), rectangular bars and seamless tubes. At a cherry-red heat it can be **readily forged.** It is especially **resistant to corrosion,** and is used largely in naval work. **Tensile strength** of rods larger than 1 in. in diam., 60,000 lb. per sq. in. (62,000 for smaller rods); minimum **yield point,** $\frac{1}{2}$ × tensile strength; **elongation** in 2 in., rods larger than 1 in., 28 per cent. (25 per cent. for smaller rods); compressive strength, 170,000 to 180,000 lb. per sq. in. These properties make it adaptable for a wide variety of engineering purposes where a strong, reliable material is required. **Weights of sheets and rods** are $1\frac{1}{4}$ per cent. lower than the weights for brass rods and sheets in Tables 3 and 6.

Delta Metal is similar in composition and properties to Tobin bronze, except that it carries from 1 to 2 per cent. of iron. It is manufactured by the Phosphor Bronze Smelting Co., and is furnished in sheets and rods.

Cold-working Brass. For tubes, cartridge cases, wire drawing, etc., the standard alloy contains 70 per cent. copper and 30 per cent. zinc; this alloy possesses considerable strength and great ductility; higher-copper alloys have still greater ductility. This alloy **can be worked cold,** and when intended for rolling or drawing is cast into a mold of such size and shape that the alloy may be formed into its finished shape with as little working as possible. In wire drawing, ingots of suitable size are first rolled into rods, these being finally drawn into wire. **Spring brass** has the composition copper 72, zinc 28, or copper $66\frac{2}{3}$, zinc $33\frac{1}{3}$. This alloy **hardens under** the effect of **working** and must be frequently annealed in order to correct this condition and allow further reduction. After each **annealing** process the brass must be washed with acid to rid the surface of oxide. The **temperature of annealing** is an **important** matter and must be carefully observed. Annealing below 536 deg. fahr. has practically no effect. There is a particular temperature at which the best results are obtained for each alloy, depending on the amount of hardening the alloy has undergone. At 620–650 deg. fahr. there is a marked softening of 70–30 brass. The maximum effect of annealing is reached at 1400 deg. Above this temperature the brass is burnt. Alloys containing small percentages of tin and lead can be raised to higher temperatures than those not containing these metals without being burnt.

Lead and tin are frequently added to cold-working-brass alloys, in order to confer certain properties. **Lead is added to facilitate machining,** chips of a leaded brass leaving the tool easily, as they are short and brittle. Lead is mechanically mixed in brass and therefore breaks up the continuity of the structure. In brass containing an excess of lead, the lead is present in solid solution, rendering the alloy more brittle. Turnings from brass which does not contain lead come off in long, tenacious curls. Leaded brass must be rolled cold because it is "hot-short." The best alloy is one which contains 60 per cent. copper, 38 per cent. zinc and 2 per cent. lead. This has an average **tensile strength** in the rolled form of about 60,000 lb.; elongation, 15 to 20 per cent.; reduction of area, over 50 per cent. Tin is often added to brass to increase the hardness and to add to the resistance of the metal to the corrosive action of sea water. Antimony and bismuth are detrimental impurities. Arsenic is considered beneficial by some makers.

The following specifications for brass sheets, strips and rods are recommended by the S. A. E. (1912). In all cases the iron must not exceed 0.10 per cent. See also pp. 548 and 1197.

Specification number	Name	Copper, per cent.	Zinc, per cent.	Lead, per cent. not greater than	Tensile strength, lb. per sq. in.	Elongation in 2 in., per cent.

Heat-treatment of Brass

The physical properties of annealed brass vary according to the temperature, and to some extent to the time in which the annealing has been done. When annealed at 650 to 750 deg. fahr. under ordinary annealing conditions, brass strips containing two parts copper and one part zinc may have a tensile strength of about 55,000 lb. per sq. in., with elongation in 2 in. of 40 per cent. When annealed at 1300 to 1400 deg. fahr., under similar conditions, they may have a tensile strength of about 40,000 lb. per sq. in., with elongation in 2 in. of 55 per cent. The process of annealing relieves those internal strains which result from cold-working the material. Annealing of cold-worked brass is accompanied by a re-distribution of the molecules resulting in the formation of a new crystalline structure. The average minimum temperature required to effect re-crystallization of the brasses in one-half hour is 750 deg. fahr. The size of the grain is roughly proportional to the temperature within the safe annealing range (750–1400 deg. fahr.), and for a given time, temperature and alloy the grain size is constant. Under these conditions the grain size has a definite relation to the physical properties; also, grain size has considerable influence on resistance to corrosive action. Impurities such as iron, nickel, etc., retard the growth of the grain size and render necessary the use of a higher temperature to secure a given grain size than with pure brass.

Annealing removes, to a very great extent, the liability of brass to crack or disintegrate on prolonged exposure under unfavorable conditions. For this reason the best practice requires that in structural work all material for tubes, rods, bolts, etc., shall be lightly annealed.

Special Bronzes and Brasses

Casting Manganese Bronze. Manganese bronze is in reality a brass, consisting largely of copper and zinc. The term bronze, however, has been generally applied to it for many years, probably because it has a fine red color similar to that of bronzes. It is very **much stronger than** the **ordinary brasses.** Manganese is simply used as a deoxidizing agent, and the finished alloy very often contains but mere traces of it.

Manganese bronze is now one of the standard alloys on the market and is highly **recommended for propeller wheels** which are used in salt water, both because of the resistance of the metal to the action of salt water, and its remarkable strength and ductility. It is also a favorite alloy for many castings used in automobile construction. In casting, large risers are necessary, due to the high shrinkage of the alloy.

Specifications for manganese bronze have been adopted by the United States Government, by the Society of Automobile Engineers and by the Society for Testing Materials. The Society for Testing Materials' specifications for manganese bronze ingots having notched flat bottoms approx. 3 × 2¾ in. wide by 12 in. long, call for the following percentage chemical composition: Copper, 53 to 62; zinc, 36 to 45; aluminum, 0.05 to 0.5; lead, not over 0.15. Ultimate tensile strength not to be less than 70,000 lb. per sq. in.; elongation in 2 in., not less than 20 per cent. Test specimen to be turned to 0.5 in. diam. and 2 in. gage length, from a piece cut from one corner near bottom of ingot. The compressive strength is about 120,000 lb. per sq. in.

Wrought Manganese Bronze. Manganese bronze is capable of being wrought similar to Muntz metal, Delta metal and Tobin bronze.

Tensilite, a high-strength bronze manufactured by the American Manganese Bronze Co., is stated to have the following physical properties: Tensile strength, rolled or forged, 120,000 lb. (cast, 105,000); elastic limit, 75,000 (60,000); elongation in 2 in., 18 per cent. (15); reduction of area, 22 per cent. (20); elastic limit in compression, 70,000 (60,000); permanent set under a load of 100,000 lb. per sq. in., 0.015 in. (0.020).

Aluminum Bronze is an alloy of copper and aluminum, containing up to 11 per cent. of the latter metal. Some years ago it was a strong competitor of manganese bronze, and in general it may be said that 11 per cent. aluminum bronze (the strongest mixture) has a somewhat higher tensile strength than manganese bronze, but a lower percentage of elongation. It was found that manganese bronze was more easily handled in the foundry and could be better depended upon; and as it could be produced more cheaply than aluminum bronze, it naturally became the more popular alloy for resistance to severe stresses. By the addition of titanium good solid castings of aluminum bronze can be obtained. Aluminum beyond 11 per cent. makes a brittle bronze which is hard to work. Aluminum bronze can be readily soldered.

For S. A. E. specifications for **aluminum alloys** containing 65 per cent. aluminum and over see p. 1197. See also p. 542.

Dagger's tests on copper-aluminum alloys yielded the following results:

Aluminum, per cent.	Specific gravity	Average tensile strength, lb. per sq. in.	Elongation, per cent.
11.00	7.23	95,000	8
10.00	7.69	82,000	14
7.50	8.00	61,000	40
5.00	8.37	37,000	40
2.50	8.69	31,500	50
1.25	....	27,000	55

Aluminum Brass is a copper-zinc alloy containing up to 3 per cent. of aluminum, and a very valuable series of alloys is thus produced with a wide variation of tensile strength and elongation. The alloys are quite analogous to the so-called manganese bronzes, and are often substituted for them. Aluminum brass, as made by the Aluminum Co. of America, has a tensile strength of 40,000 to 50,000 lb. per sq. in. (elastic limit, 30,000), and an elongation of 3 to 10 per cent. in 8 in.

Aluminum, when added in the form of aluminized zinc to brass in quantities up to 1 per cent., makes the brass flow freely, and the resulting castings have smooth surfaces and are free from blowholes. Added in larger quantities (up to 10 per cent.) it imparts increased strength to the castings.

Casting Red Brass. The term red brass is applied to all alloys containing a sufficient amount of copper to be red in color, with the exception of those reddish alloys of copper and zinc carrying approximately 45 per cent. of zinc and 55 per cent. of copper: manganese bronze, aluminum bronze and aluminum brass. Red brasses usually carry upward of 75 per cent. of copper and varying amounts of tin, zinc and lead. These alloys, because of their ease of machining, ease of casting and red color, are used for steam fittings, ornamental castings, miscellaneous brass trimmings, hardware, etc. Different alloys for various purposes have the following percentage compositions:

	Copper	Tin	Lead	Zinc
Valve metal*	85	5	5	5
Steam metal	86	8	3	3
Gas cocks	76	2	6	16
Polishing metal	87	....	1	12
Brazing metal	80	....	....	20

* S. A. E. Specification No. 27 for light castings.

Red Brass Ingots made from scrap, turnings, etc., are sold upon the market, subject to specifications with a variation of 1 per cent. either way on the constituents, at a price below the cost of producing the same composition from new metals. Such ingots are now produced of very satisfactory quality, and show a material saving as compared with making the alloys from virgin metals.

Phosphor Bronze in the **wrought form** (bars and plates) consists of upward of 96 per cent. of copper and up to 4 per cent. of tin which has been deoxidized by sufficient phosphorus. Its tensile strength is approximately 65,000 lb.; elastic limit, 60,000 lb.; elongation, 16–18 per cent. A small percentage of phosphorus can be left in the alloy, and adds to its hardness. Its qualities of toughness and great tensile strength, combined with resistance to corrosion and crystallization, make it superior to German silver for exposed work. It has superior elasticity and can be furnished in wire and sheets to various tempers for use in making **springs.**

Cast Phosphor Bronze (commercially known as "B" grade) contains from 88 to 92 per cent. copper and from 8 to 12 per cent. tin. To get the best results, just enough phosphorus is used to thoroughly cleanse the metal of oxides, none being retained in the finished product. The United States Government Specifications covering phosphor bronze call for a tensile strength of 40,000 lb. and an elongation of 20 per cent. in 2 in. The American Manganese Bronze Co. give for cast phosphor bronze, tensile strength, 25-40,000 lb. per sq. in.; elastic limit, 18-30,000 lb. per sq. in.; elongation in 2 in., 42 per cent.; reduction of area, 32 per cent. To obtain the best results this alloy should contain no lead or zinc. It is a particularly desirable metal for gears, being hard and tough and having a low rate of wear.

SPECIAL ALLOYS

Copper-Nickel Alloys

Cupro Nickel (85 per cent. copper and 15 per cent. nickel) is largely used for bullet jackets for military rifles in which smokeless powder is loaded. The addition of a small percentage of manganese or magnesium greatly facilitates the proper working of the alloy in ingots and under rolls. Outside of this use, which has now become quite extended, the alloy is used for coinage purposes, the American five-cent piece being an alloy of 75 per cent. copper and 25 per cent. nickel. It is also used for the driving bands of projectiles, and then contains from 3 to 5 per cent. nickel. This same alloy has also been tried with success for steam-boiler tubes. **Constantan** (60 per cent. copper, 40 per cent. nickel) has a very low temperature coefficient and is used for electrical resistance purposes.

German Silver is an alloy of copper, nickel and zinc. It is very **ductile** and can be rolled, hammered, stamped and drawn. At the same time it is **hard, tough** and not easily corroded, and above all possesses the valuable property of being **white.** It is softened by annealing.

Hiorns gives the following table showing the **composition** of various qualities of German silver made by the best makers in Birmingham, England. These different alloys are sold under the trade names indicated.

Name	Composition, per cent. Copper	Nickel	Zinc	Name	Composition, per cent. Copper	Nickel	Zinc
Extra white metal..	50	30	20	Seconds................	62	14	24
White metal.......	54	24	22	Thirds..................	56	12	32
Arguzoid..........	48½	20½	31	Special thirds...........	56½	11	32½
Best best.........	50	21	29	Fourths.................	55	10	35
Firsts or best......	56	16	28	Fifths, for plated goods..	57	7	36
Special firsts.......	57	17	27				

Hiorns states that alloys containing less than 16 per cent. of nickel should contain 30 per cent. of zinc in order to give the best results; while with alloys containing more than 16 per cent. of nickel, the quantity of zinc should be less than 30 per cent. The **impurities** found in German silver are iron, lead and tin. Iron increases the strength, hardness and elasticity, and makes the alloy whiter. Tin renders the alloy brittle and unfit for rolling. It also gives the alloy a decidedly yellow color. Lead does not enter the alloy but simply remains mechanically mixed, and therefore should be added if the alloy is intended for casting and subsequent working.

The **weight of German silver wire** made by the American Brass Co. and containing 18 per cent. nickel is 2.5 per cent. lower than that of copper wire of the same size and length; of 30 per cent. nickel it is 1.8 per cent. less.

Monel Metal is a natural alloy consisting of 68 to 70 per cent. nickel, 1½ per cent. iron, and the remainder copper. It is smelted and refined from ore mined in Canada without disturbing the proportions given. It is silver-white in color, takes a high polish and is **highly resistant to corrosion,** not being affected by atmospheric conditions, fresh or salt water, acid fumes or superheated steam. Its **specific gravity** (cast) is 8.87, and its **melting point** 2480 deg. fahr. **Tensile strength**: rods, 36,900 lb. per sq. in. (castings, 78,-240); **elongation** in 2 in.: rods, 40 per cent. (castings, 38.5 per cent.). It is used for ship propellers, in marine construction work, in sheets for roofing metal, and in the form of rods and castings in places where steel and bronze are unsuited because of their corrodibility. The Bureau of Steam Engineering, U. S. Navy Dept., uses the following **specification** for hot-rolled Monel metal rods 1 in. in diam. and smaller: Yield point, 47,000 lb. per sq. in. (45,000); tensile strength, 84,000 lb. per sq. in. (80,000); elongation in 2 in., 25 per cent. (28 per cent.). Figures in parentheses are for rods larger than 1 in.

Aluminum Alloys

Aluminum Alloys are extensively used in automobile construction. The S. A. E. Specification No. 23 for **aluminum-copper** alloy calls for 7 to 8 per cent. of copper. This is a tough alloy having a tensile strength of from 15,000 to 20,000 lb. per sq. in., and is especially adaptable for castings to withstand severe shocks and stresses. Zinc produces the strongest alloys with aluminum, the tensile strength running as high as 30,000 to 35,000 lb. per sq. in. The S. A. E. Specifications Nos. 24 and 25 are for **aluminum-zinc alloys**, the former containing 12.5 per cent. of zinc and 2.5 per cent. of copper, and the latter 35 per cent. of zinc. The copper-carrying alloy is tough, well adapted to forging, and easily machined. See p. 1197.

Magnalium is an alloy of aluminum and magnesium containing from 2 to 23 per cent. of the latter metal. **Specific gravity,** 2.40 to 2.57; **melting point,** 1110 to 1290 deg. fahr. The alloy is lighter than pure aluminum, of much greater strength, and does not tarnish. **Tensile strength**: Cast in chills, 42,000 to 64,000 lb. per sq. in.; sand castings, 17,000 to 30,000 lb.; rolled, 28,000 to 35,000 lb.; stamped, 52,000 to 70,000 lb.

Effect of High Temperatures on the Physical Properties of Metals and Alloys

For a list of investigations on the effects of high temperatures on the strengths of metals and alloys, see M. Rudeloff, 1909, International Ass'n. for Testing Materials. Most of the investigations have been limited in scope and have not dealt sufficiently with the cast and rolled metals at present in commercial use. An extensive series of tests by the Crane Co. on a wide range of metals and alloys is reported by I. M. Bregowsky and L. M. Spring, in *The Valve World*, Jan., 1913. The values given in Tables 17 and 18 are taken from this article, and are averages of from two to ten tests at each temperature.

ANTI-FRICTION ALLOYS (BEARING METALS)

Anti-friction Alloys are divided into **four** distinct **classes**: 1. Copper base, or those carrying over 50 per cent. copper, usually from 65 to 80 per cent. 2. Tin base, or those containing over 50 per cent. tin. 3. Lead base, or those containing over 50 per cent. lead. 4. Zinc base, or those containing over 50 per cent. zinc. Copper-base alloys are harder and stronger than white metals having tin, lead or zinc bases, and are used for bearings which are required to resist heavier pressures. Frequently, however, **compound metal bearings** are used, having a copper-base bearing metal for the backing and lined with an anti-friction metal usually of a tin or lead base.

The **copper-base metals** operate with a lower coefficient of friction because they are harder, but they are more liable to heat under abnormal conditions because they are lacking in the necessary plasticity to conform to irregularities

[1] A strong copper-tin bronze. [2] Containing 5 per cent. of aluminum. [3] Highly resistant to acids; elastic limit not determined. [4] Containing 10 per cent. of aluminum; elastic limit not determined. [5] At 550 deg.: 32,050, 19,300, 23.4 and 31.6. [6] Ferro-steel, used in extra heavy valves over 7 in. [7] Rendered malleable by special process and used for rings, disks and trimmings for iron and steel fittings for high temperatures. [8] For screw pipe fittings (Cu, 77–80; Sn, 4; Pb, 3; Zn, 13–19). [9] (Cu, 88; Sn, 10; Zn, 2.) [10](Cu, 87; Sn, 7; Pb, 1; Zn, 5.) At 550 deg.: 17,200, 14,025, 4.4 and 6.2. [11] (Cu, 62.5; Pb, 2.5; Zn, 35.) [12] Rods, 30 per cent. nickel. [13] Bessemer steel, for valve stems.

of the journals or of foreign particles which may become lodged between the journal and the bearing surface. If bearings could be maintained in perfect adjustment, the harder alloys would give the most efficient service because of their low coefficient of friction and their lower operating temperature. The term anti-friction is generally applied to those alloys which have the highest coefficient of friction, namely, the soft white-metal alloys.

The rate of wear is greater in the hard alloys than in the soft alloys, because the particles of the hard alloys split off in service, whereas the particles of the soft alloys become compressed or flattened out before being torn off. The bearing should be just sufficiently hard and strong to carry its load. If the bearing is too soft it will roll out or be pounded out, and will probably hug the journal, squeeze out the oil film, become heated and be destroyed.

The physical properties of some of the bearing metals, as determined at the Penna. Ry. laboratories, are given in Table 19.

NOTES ON TABLE 18

[1] Bessemer steel, 0.093 per cent. carbon. [2] Cumberland cold-rolled shafting, 0.083 per cent carbon. [3] Open-hearth steel, 0.084 per cent. carbon. [4] (Ni, 3.25; V, 0.45; C, 0.365), oil tempered. [5] 25 per cent. nickel. [6] 30 per cent. nickel; turned from 1 in. to 0.8 in. diam. [7] Turned to 0.75 in. diam. from a ⅞-in. bar. [8] Cumberland shafting, 0.375 per cent carbon. [9] Annealed (Cr, 0.49; V, 0.145; C, 0.722). [10] Rolled rod (Cu, 62.5; Zn, 35; Pb, 2.5). [11] Elephant (phosphor) bronze (Cu, 95.5; Sn, 4; P, 0.31).

Copper-base Bearing Metals

The copper-base alloys (usually known as bronzes) consist of the following classes: 1. Copper and tin. 2. Copper, tin and zinc. 3. Copper, tin and lead. 4. Copper, tin, lead and zinc. Occasionally there are added small proportions of other metals, which modify the general properties of the alloys.

Copper-Tin Bearing Alloys. About 30 years ago these alloys were in popular use, not only for machinery bearings but also for car and locomotive bearings, the alloy of 7 copper and 1 tin being the one most commonly used. This alloy has a high compressive strength, is quite hard and should be used only in cases where heavy pressures are encountered. Their use in other bearings is not justifiable, because the alloys have very little plasticity and therefore become heated upon little provocation, and have a high rate of wear.

Bell metal is a still harder metal than the 7-to-1 bronze, and carries from 16 to 25 per cent. of tin, the balance being copper. Such bearings have been tried because of the false idea that the harder metals will better resist wear. Their use has always met with failure.

Copper-Tin-Zinc Bearing Alloys. The addition of zinc to the copper-tin alloys improves their casting qualities. Such alloys are very rarely used to-day, except for backing a softer lining metal. The housings or backs on marine bearings are usually of this alloy. It is used by the United States Government and to some extent in the automobile trade, the bearings usually being lined with a high-tin-base Babbitt metal. This is a very expensive form of bearing and its use in many cases is not justified, as more satisfactory service could be rendered by cheaper alloys.

Copper-Tin-Lead Bearing Alloys. This class of alloys is the standard bronze alloy in use to-day for bearings. The standard phosphor-bronze bearing metal is an alloy of these three metals containing a small percentage of phosphorus. It was found about 25 years ago that the addition of lead to the then standard copper-tin alloy made the alloy more plastic and therefore better able to conform to irregularities of the service without heating, and diminished the rate of wear.

Dr. C. B. Dudley as a result of many investigations finds that the rate of wear in a bearing metal and its tendency to become heated in service diminish with the increase of lead and with the diminution of tin in the alloy.

The following series of alloys were experimented upon by the Pennsylvania Railroad under the direction of Dr. Dudley:

Metal Tested	Percentage Composition					Relative wear
	Copper	Tin	Lead	Phosphorus	Arsenic	
Phosphor bronze, standard	79.70	10.00	9.60	0.80	....	1.00
Ordinary bronze	87.50	12.50	....	....	....	1.49
Arsenic bronze, "A"	89.20	10.00	....	....	0.80	1.42
Arsenic bronze, "B"	82.20	10.00	7.00	....	0.80	1.15
Arsenic bronze, "C"	79.70	10.00	9.50	....	0.80	1.01
Bronze, "K"	77.00	10.50	12.50	....	....	0.92
	77.00	8.00	15.00	....	....	0.86

An **alloy of 85 per cent. copper, 10 per cent. tin, and 5 per cent. lead** will withstand compression of approximately 24,000 lb. on a 1-in. cube at the yield point; a 1-in. cube will compress 26 per cent. under a load of 100,000 lb. without fracture. The compressive strength is sufficiently high for it to be used in severe service; it is an admirable alloy for connecting-rod brasses.

An **alloy of 80 per cent. copper, 10 per cent. tin, and 10 per cent. lead,** as compared with the alloy carrying but 5 per cent. of lead, shows a diminished resistance to compression, namely, 23,000 lb. on a 1-in. cube at the yield point, and a compression under 100,000 lb. of 29 per cent. This alloy is very largely **used for locomotive, car, and general machinery bearings.** A small percentage of phosphorus is often added and the alloy is then known as standard phosphor-bronze bearing metal. (S. A. E. Specification No. 26—0.05 to 0.25 per cent. P.) The phosphorus adds somewhat to the resistance to compression and to the fluidity of the metal, but it has not been proved that it benefits in any way the quality of the alloy from the standpoint of service as a bearing. In fact, the limited data at hand tend to show that it acts adversely in service, because of the production of the brittle phosphide of copper in the alloy which frequently tends to cause heating. This alloy, nevertheless, is called for in the specifications of many prominent consumers.

The **alloy of 77 per cent. copper, 8 per cent. tin, and 15 per cent. lead** is extensively used, and together with a small percentage of phosphorus (0.2 per cent.) is known on the Pennsylvania Railroad as Ex. B. metal. This is the alloy of highest lead and lowest tin content which Dr. Dudley was able to produce, owing to foundry difficulties. Alloys of lower tin and higher lead segregated, the lead liquating to the bottom of the casting, due probably to the presence of phosphorus which lowers the solidifying point of the alloy and therefore maintains the alloy in a liquid condition for a longer period. This alloy will support a load of 21,000 lb. on a 1-in. cube without distortion. It has a slow rate of wear and is less liable to heat in service than either of the two preceding alloys.

Alloys containing from 4 to 7 per cent. of tin, and 20 to 30 per cent. of lead, are known in the trade as **Ajax plastic bronze** alloys, and are manufactured by the Ajax Metal Co. The patent controlling these alloys is based upon the fact that lead which is only mechanically held in the alloy can be prevented from liquating to the bottom of the casting if the copper and tin matrix which holds it can be made to solidify quickly. Quick solidification of the matrix will result if the copper and tin are in correct proportions, that is, in such proportions that only a solid solution of the two metals is formed. The following table gives the results of tests made in the author's laboratory.

Copper, per cent.	Tin, per cent.	Lead, per cent.	Wear, in grams	Copper, per cent.	Tin, per cent.	Lead, per cent.	Wear, in grams
85.76	14.90	....	0.2800	81.27	5.17	14.14	0.0327
90.67	9.45	....	0.1768	75?	5?	20?	0.0277
95.01	4.95	....	0.0776	68.71	5.24	26.67	0.0204
90.82	4.62	4.82	0.0542	64.34	4.70	31.32	0.0130
85.12	4.64	10.65	0.0380				

It was found that the addition of a small percentage of nickel adds to the compressive strength of the above series of alloys, and also elevates the temperature of solidification of the matrix. Ajax plastic bronzes of various grades, having compositions within the limits above set forth and also with the addition of 1 per cent. nickel, are in use very extensively for locomotive and car bearings, cold-roll neck mill bearings, etc.

Copper-Tin-Lead-Zinc Bearing Alloys are the cheapest form of bronze bearing-metal alloys on the market. Zinc is an adulterant which usually enters the alloy through the use of miscellaneous scrap. The following tests made in the author's laboratory show the effect on the rate of wear of increasing amounts of zinc.

Percentages				
Copper	Tin	Lead	Zinc	Wear in grams
85.12	4.64	10.64	....	0.0380
82.27	5.28	10.25	2.07	0.0415
79.84	4.71	10.30	5.44	0.0466
77.38	5.62	11.42	6.54	0.0672
74.28	4.68	10.61	11.04	0.0848

Zinc adds to the brittleness of the alloys, and this probably accounts for the more rapid rate of wear due to zinc content. The carrying of considerable zinc in the presence of fairly high percentages of lead has the further detrimental effect of causing the alloys to become somewhat weakened under the influence of elevated temperatures. The best bearing bronzes do not contain zinc, and its presence is restricted to below 1 per cent. in the specifications of the most prominent consumers. The Society of Automobile Engineers specification (No. 27) for **red brass** is copper, 85; tin, lead and zinc, each 5 per cent. This is said to machine well and to be an excellent bearing metal where speed and pressure are not excessive.

Tin-base Bearing Metals

Tin-base bearing metals (tin over 50 per cent.) come within the classification commonly known as **Babbitt metals**, and are divided into three classes: 1. Tin, antimony and copper alloys. 2. Tin, antimony, copper and lead alloys. 3. Tin, copper and zinc alloys. They possess in general a higher resistance to compression than the lead-base metals. The resistance to compression, however, is due in a very large measure to the relative percentages of copper and antimony which the alloys contain. Copper and antimony are the hardening constituents in such alloys, and, although they may also contain a certain percentages of lead and infrequently small percentages of other metals, the essential properties are derived from these two metal

The name "Babbitt" is derived from that of the inventor (Isaac Babbitt) of soft-metal-lined bearings. The term "babbitting" has been applied to the process of applying soft anti-friction metals inside of a harder shell for the purpose of producing bearings. The best-known soft-metal alloy at the time of this invention was the high-grade **pewter** alloy then used, the composition of which was copper, 3.70 per cent.; antimony, 7.40 per cent., and tin, 88.90 per cent. This particular alloy became known as "Genuine Babbitt," although the term is now more generally applied and includes all tin-antimony-copper alloys in which tin is the base metal, and which do not contain lead or zinc.

Soft Genuine Babbitt is usually made to the formula above given for Isaac Babbitt's original metal. Sometimes, however, this composition is slightly varied between 91 per cent. tin, 4½ per cent. lead, and 4½ per cent. antimony, and 88 per cent. tin, 4 per cent. copper and 8 per cent. antimony. The latter composition, as quoted by Charpy on a test piece 0.6 in. in height and 0.0155 sq. in. in sectional area, under a load of 1929 lb. showed a compression of 0.008 in., and under a load of 4960 lb. showed a compression corresponding to 0.3 in. This metal is free-flowing, tough, and gives excellent service in bearings where the loads are not heavy.

The specification of the Society of Automobile Engineers for Babbitt Metal No. 1 is: tin, 89 per cent.; antimony, 7 per cent., and copper, 4 per cent. A variation of 2 per cent. either way is permissible in the tin content, and a variation of 1 per cent. either way in the antimony and copper. Only traces of other metals are permissible.

Hard Genuine Babbitt. The composition of this alloy may range from 83 per cent. tin, 8½ per cent. antimony, 8½ per cent. copper, to 80 per cent. tin, 10 per cent. antimony and 10 per cent. copper. For the former Charpy gives the following figures: A test piece 0.6 in. in height and 0.0155 sq. in. in sectional area, under a load of 2646 lb., gave a compression of 0.008 in., and under a load of 5622 lb. a compression of 0.3 in. The metal of the latter formula would sustain a higher load with equal compression.

The method of casting and rate of cooling have a very important influence upon the structure and service which these metals will give. The rate of cooling affects the hardness of the matrix, and the size and number of the tin-antimony crystals. The proper temperature for pouring is approximately 810 deg. fahr., and the metal should preferably be cast against a chill heated to a temperature of approximately 212 deg. fahr., so that the rate of cooling is not too rapid.

The specification of the Society of Automobile Engineers for Babbitt Metal No. 2 is: tin, 84 per cent.; antimony, 9 per cent.; copper, 7 per cent. A variation of 2 per cent. either way is permissible in the tin, and a variation of 1 per cent. either way in the antimony and copper. Only traces of other metals. Specifications Nos. 1 and 2, above given, are also used in making **die-cast bearings.** An alloy of 80 tin, 10 copper and 10 antimony is used on the high-speed bearings of De Laval turbines.

Tin-base Babbitts Containing Lead. Lead has the property of increasing the fusibility of the tin-base alloys by forming a eutectic of low melting point, but the tin present should preferably be over 50 per cent., the antimony not less than 12 per cent., and the copper not less than 3 per cent. for the best results. The alloys may be made within a wide variation of composition, the hardness depending on the increasing percentages of copper and antimony.

Tin-base Babbitts Containing Zinc. The most important alloy of this class is (Parsons') white brass, which consists, approximately, of 62 per cent. tin, 35 per cent. zinc, and 3 per cent. copper. (S. A. E. Specification: Cu, 3 to 6; Sn > 65; Zn, 28 to 30.) It is largely **used for marine** bearings and to some extent for **automobile bearings.** Such bearings should be well lubricated. It is hard, tough, is rather sluggish to pour, and cannot for this reason be cast into thin sections after the manner of using the ordinary Babbitt metals. It must be poured at a fairly high temperature, approaching redness, and is preferably peined after casting to compress the metal and so add to its durability under the influence of wear.

Lead-base Bearing Metals (Babbitts)

Lead-base bearing metals (lead over 50 per cent.) are divided into three classes: (1) Lead-antimony alloys; (2) lead-antimony-tin alloys; (3) lead-antimony-tin-copper alloys. The useful alloys of lead and antimony for bearings contain from 7 to 20 per cent. of antimony. Below 7 per cent. the alloys are too soft, and above 20 per cent. too brittle, for practical uses. Lead and antimony are insoluble in each other in the cold, and the solidified alloys therefore consist of lead and eutectic alloy if antimony is present below 12.8 per cent., and of antimony and eutectic alloy if antimony is present in excess of 12.8 per cent. This is the **cheapest class of anti-friction metal** which can be produced, as lead sells at the lowest price of any of the metals, and antimony usually sells at only two or three times the price of lead. The alloy commercially known as No. 4 Babbitt consists of 88 to 90 per cent. of lead and 10 to 12 per cent. of antimony. **Magnolia metal** is a lead-tin-antimony alloy, together with traces of copper, zinc, iron and possibly bismuth. A recent analysis shows lead 79, tin 5, antimony 16.

Charpy has determined the compressive strength of several of these alloys and his results are given in the following table (test pieces as given under "Soft Genuine Babbitt"):

Composition of alloy, per cent. Lead	Antimony	Load corresponding to a permanent set of 0.008 in., lb.	Load corresponding to a permanent set of 0.3 in., lb.	Remarks
100	0.0	220	1100	
90	10	1433	2866	
82.5	17.5	1433	3197	Broke at
80	20	1676	....	2756 lb.

Lead-Tin-Antimony Alloys are very largely in use as Babbitt metals because of their low price, and because they perform very satisfactorily if used in the proper service and under the proper conditions. Many of the widely advertised brands of Babbitt metal come within this class.

Charpy states that the alloys of lead, tin and antimony are similar to those of lead and antimony; but the addition of tin diminishes the hardness and brittleness of the hard grains and also increases the compressive strength of the eutectic alloy. For this reason the alloys of lead, tin and antimony are superior to those of lead and antimony alone. He states that the tin must be present to the extent of more than 10 per cent., but not necessarily more than 20 per cent., and the antimony may vary between 10 and 18 per cent. The following table compiled by him shows the compressive strength of this series of alloys, test pieces as given under "Soft Genuine Babbitt," p. 549.

Composition		Load corresponding to a compression of		Composition			Load corresponding to a compression of	
Lead	Tin	0.008 in.	0.3 in.	Lead	Tin	Antimony	0.008 in.	0.3 in.
....	100	661	2337	10	80	10	2425	5952
20	80	1323	3858	20	60	20	2976	4850
40	60	1433	3252	40	40	20	2535	4023
60	40	1323	3086	60	20	20	2315	3748
80	20	1047	2535	80	10	10	1764	3913

Lead-Antimony-Tin-Copper Alloys. The addition of copper to the alloy of lead, tin and antimony increases the hardness and causes an increased sluggishness in pouring, depending on the amount of copper present in proportion to the tin.

In the high-tin-carrying alloys the percentage of copper can be increased without increasing the sluggishness. With 10 per cent. of tin, not over ½ per cent. of copper should be added; with 20 per cent. of tin, not over 1 per cent.; with 30 per cent. of tin, not over 1½ per cent.; with 40 per cent. of tin, not over 2 per cent., and with 50 per cent. of tin, not over 3 per cent. copper. A great many Babbitt metals are on the market having these four constituent metals in their composition, which are known in the trade as "copper-hardened Babbitt," and are designated by grades according to the amount of tin which they contain.

Zinc-base Bearing Metals

Lumen Metal consists of 85 per cent. zinc, 10 per cent. copper, and 5 per cent. aluminum. This alloy has a **low coefficient of friction,** a low specific gravity, and is capable of being cast in sand after the manner of brass and bronze castings. It is **easily machined,** and because of its low price and low specific gravity has found considerable favor in certain classes of service such as motor bearings, crane bearings, etc. It should be used, however, in bearings which can be maintained in fairly good adjustment, because, owing to the high zinc content of the alloy, it becomes brittle under the effects of heating, and in the absence of an oil film is quite liable to grip the journal. It is an **excellent** metal **for high-speed bearings carrying little weight. Fenton's alloy** contains 16 per cent. tin, 5 per cent. copper, and 79 per cent. zinc.

Alloys for Die Casting. Castings in which the molten metal is forced under pressure into accurately cut metal dies are now largely used in the place of small sand castings formerly made of brass and machined to size. It is possible in this way to produce parts of more or less intricate shape that are very accurate in size and smoothly finished. Babbitt metals are used in making die-cast bearings, while other machine parts are made from zinc-base alloys, the two most extensively used having the following compositions:

	I	II
Zinc	89.00	82.00
Aluminum	0.25	0.25
Tin	7.00	14.50
Copper	3.25	3.25

These and similar zinc alloys have a tensile strength not exceeding 18,000 lb. per sq. in., and an exceedingly low elongation and reduction of area. They compare favorably in strength with cast iron. They are corroded by aqueous solutions and should not be used for food containers or conveyors. Commercial gasoline when in direct and constant contact will also corrode them; copper plating, however, will aid in resisting its attack.

MISCELLANEOUS WHITE-METAL ALLOYS

Type Metals, or printer's metals, are divided into five classes: 1. Alloys for casting small individual type. 2. Linotype metal. 3. Monotype metal. 4. Stereotype metal. 5. Electrotype metal.

Alloys for Individual Type consist mostly of lead and antimony; sometimes small quantities of other metals are added. The essential requirements of a good type metal are that it shall give good, sharp castings and that it shall be sufficiently strong to withstand the necessary wear and pressure without losing its form.

The first of these requirements is fulfilled by alloys containing not less than 15 per cent. of antimony, which possess the property of expanding on cooling but are not strong enough to stand hard wear. In order to increase the strength of this alloy a certain quantity of tin is added. The composition of type metal varies considerably. An alloy containing lead 50, tin 25, antimony 25, is said to give the best results for high-class work; but the price of such an alloy is too high on account of the tin it contains, and a more usual composition is approximately lead 60, antimony 30, and tin 10. Frequently alloys are made carrying even more lead and less antimony and tin; for example, lead 75, antimony 20, tin 5.

In the **linotype** machine, where molten metal is forced under pressure into matrices to cast an integral line of type, the composition found to give the best results and which has been adopted as a standard, is lead, 79 per cent.; antimony, 16 per cent.; tin, 5 per cent. The **monotype** machine casts but one type at a time, using the same process as that employed in the linotype machine. The best metal for this machine consists of 76 per cent. of lead, 16 per cent. of antimony, and 8 per cent. of tin. **Stereotype metal,** used in the process of reproducing type in the form of an entire page or part of a page, must have the property of casting sharply and being sufficiently hard and durable to maintain a good face for the printing of many copies. The most desirable alloy for this purpose has the following composition: Lead, 83.75 per cent.; tin, 4.00 per cent.; antimony, 11.75 per cent.; and copper, 0.50 per cent. **Electrotype metal** is used as a backing for the thin, electrolytically deposited copper films of electrotypes, to give them the necessary rigidity. The alloy for this purpose does not require to be hard, as the wearing surface of the type or cut is of copper. Composition mostly used: Lead, 92 per cent.; tin, 4 per cent.; antimony, 4 per cent.

Alloys for Metallic Packing. For casting metallic packing rings the following inexpensive alloy has been found to give the best results: Lead, 83⅓ per cent.; tin, 8⅓ per cent.; antimony, 8⅓ per cent. Metallic packing for use with superheated steam should not fuse under the temperature produced by the combined effect of the temperature of the steam and the friction on the rod, should have sufficient plasticity to produce a tight joint, and should show but a slight rate of wear. A composition fulfilling these requirements consists of 80 per cent. lead and 20 per cent. antimony.

Fusible Alloys. By the addition of varying percentages of bismuth or cadmium to lead-tin alloys of different compositions, the melting points may be greatly lowered. Such alloys expand on cooling and are used for soldering lead, pewter and electrotypes, for taking casts from anatomical specimens and impressions from wood and other combustible materials, and for automatic fire sprinklers and alarms. Some of the compositions used (in parts by weight), together with their melting points, are as follows:

Alloy	Tin	Lead	Bismuth	Cadmium	Melting point, deg. fahr.
Lipowitz's	4	8	15	3	140
Wood's	4	8	15	4	158
Darcet's	25	25	50	....	203
Cliché metal	2	2	5	....	221
Rose's	24.6	28.1	50	....	230
Bismuth solder	24.8	22.1	53.1	....	250

Solders and Brazing Metals. Soft solders are used for joining tin plate and other metal sheets. A 90-tin-10-lead solder melts at about 410 deg. fahr., and a 70-tin-30-lead alloy at 384 deg. **Plumber's solder** consists of 2 parts lead and 1 part tin. **Brazing solder,** or brazing spelter, as it is commercially termed, consists of 50 to 55 per cent. of zinc, the remainder being copper. This is cast into ingots and granulated under a drop hammer into grades known as "long grain," "short grain," "fine grain," etc. The alloy mainly used as **brazing metal** consists of 80 per cent. copper and 20 per cent. zinc. Brazing solder and metal are used to unite brass, copper, iron and steel in strong joints. **Silver solder** is used by jewelers and for other fine metal work. The hardest consists of 4 parts silver to 1 of copper; the softest, 2 parts silver to 1 of copper. **Fluxes:** for soft solders, powdered rosin, hydrochloric acid "killed" by the addition of zinc scraps, and tallow (by plumbers); for brazing and with silver solder, powdered borax. Sal ammoniac is sometimes used in brazing copper.

Prices of Non-ferrous Metals, 1910–1915. The accompanying table gives the range of monthly average New York prices (cents per lb.) during 1910–1914 for purchases in large quantities, as well as the abnormal prices current Aug. 1, 1915, and brought about by war conditions in Europe.

	1910	1911	1912	1913	1914	Aug.1, 1915
Copper (Lake)..	12.7–14	12.3–13.8	14.4–17.8	14.8–17.0	11.7–15.0	21.0
Lead...........	4.4– 4.7	4.3– 4.5	4.0– 5.0	4.1– 4.7	3.5– 4.1	5.0
Spelter.........	5.2– 6.3	5.5– 6.6	6.5– 7.6	5.2– 7.2	5.0– 5.7	17.5
Tin.............	32.6–38.2	41.1–46.3	42.8–50.0	37.1–50.3	30.3–48.3	35.5

Aluminum (ingot).......		19.3–21.3	19.1–26.6	18.9–27.1	17.7–20.0	31–33

CORROSION

BY

MORGAN B. SMITH

Engrs.*, vol. 14, p. 375.

General Considerations

The atmospheric corrosion of a metal is a reaction between the metal and water. It may be represented by the equation, metal + water = hydroxide of metal + hydrogen. There are six factors to be considered.

1. THE METAL. Each metal has a tendency to dissolve in water; this tendency is known as the "solution pressure" of the metal and is measured by the potential of the metal when in a solution of one of its salts. The order of **solution pressures** of the more common elements is as follows: Potassium, sodium, barium, strontium, calcium, magnesium, aluminum, chromium, manganese, zinc, iron, cobalt, nickel, lead, cadmium, tin, bismuth, copper, hydrogen, mercury, silver, antimony, gold, iridium, rhodium, platinum. This series indicates the relative tendencies of the metals to corrode, but must be used with the caution mentioned later. Potassium has the maximum and platinum the minimum solution pressure of the metals given.

2. THE WATER. Water is dissociated into its ions hydrogen and hydroxyl. The greater the concentration of hydrogen ions in the water the more rapidly will the metal dissolve; hence, any acid or acid gas such as carbon dioxide or sulphur dioxide dissolved in the water will increase the corrosion of the metal. Increasing the hydroxyl ions by the addition of an alkali or alkaline salt, will retard or prevent corrosion; thus lime water or dense cement concrete will inhibit rusting.

3. THE HYDROXIDE OF THE METAL can influence directly the corrosion of the metal only when in solution in water. Most of the metal hydroxides are insoluble and have little direct bearing on corrosion, but they may have an indirect influence in the tendency to form sponge-like masses on the surface of the metal, thus holding moisture and oxygen in contact with the corroding parts.

4. THE HYDROGEN. When a metal dissolves in water, an equivalent quantity of hydrogen is set free. If the action is violent, the hydrogen appears as an escaping gas; in most cases, however, it separates from the solution and plates out as an insulating gaseous film on the surface of the metal, retarding or even preventing further action (polarization).

5. OXYGEN OF THE AIR. Oxygen and hydrogen unite to form water with extreme slowness under ordinary conditions, but when brought into contact with certain surfaces they unite easily. Upon platinum the reaction is very rapid; on iron much slower, and on zinc or aluminum it is negligible. It is in preventing the formation of this hydrogen film (depolarization) that oxygen dissolved in the water is so necessary to corrosion. The greater the oxygen pressure, or the more active the surface of the metal in accelerating the union of oxygen and hydrogen, the more rapid is the solution of the metal. Thus it happens that while zinc has a larger solution pressure than iron, it is also

more easily polarized by hydrogen than is iron; consequently, iron corrodes in a damp atmosphere, while zinc does not. When, however, zinc and iron are in contact, the hydrogen equivalent of the zinc which dissolves, can and does plate out on the iron; under these circumstances the zinc corrodes rapidly, while the iron does not corrode at all. If air is removed from the water in a boiler or heating system no corrosion will occur.

The depolarizing action takes place with extreme ease on forge or mill scale—the magnetic oxide of iron which covers a piece of iron or steel after it has been highly heated. If this scale forms a close coherent coat it is of value as a protecting surface; but if it is ruptured at any point, corrosion at this point takes place with great rapidity, and a pit is the result. For this reason mill scale should be removed as carefully as possible from ferrous structures exposed to corrosive conditions. An entirely secondary action of oxygen is the oxidation of the ferrous hydroxide formed by the action of the water, producing the red ferric hydroxide which is familiar as rust.

6. STRAY ELECTRIC CURRENTS. The solution of a metal in water and the consequent deposition of hydrogen is always accompanied by a flow of electricity. This action must not be confused with "electrolytic corrosion." The inherent electromotive force driving a metal into solution is, with the metals used in engineering structures, relatively small and the currents flowing very minute. When, however, an electric current due to some external electromotive force flows from a metal through its surroundings, the metal is carried into solution at a rate which may be calculated from Faraday's law.

Factors Stimulating Corrosion. Corrosive action is stimulated by. A very damp atmosphere, thus maintaining a film of water on the metal; atmospheric oxygen dissolved in this water film; acids or acid gases; salts which dissociate in water, producing an acid reaction; contact of dissimilar metals; the presence on the metal of a depolarizing surface, such as mill scale on iron; improperly annealed metals, where one part is under strain; soils containing cinders, coke, coal dust, etc., which carry acid sulphur compounds; an electric current due to an external source leaving a metal surface.

Factors Inhibiting Corrosion are: Reversed polarity-to counteract the effects of stray currents; the use of a self-sacrificing metal electropositive to the metal it is desired to protect, as zinc to prevent the corrosion of iron; protective coatings; the rendering of metals "passive" (or so treating them that they are insoluble in acids and do not precipitate metals from solutions); neutralization of corrosive fumes or liquors; alkaline solutions of sufficiently high alkalinity.

Corrosion Due to Electrolysis is generally caused by the leakage of current from electric circuits, and often takes place at a point far removed from where the leakage occurs. Stray currents of extremely feeble intensity and voltage tend to accelerate corrosion, even when they have not initiated it. Corrosion due to electrolysis may be minimized by providing thorough insulation; grounding all metallic conduits; avoiding combinations of dissimilar metals in a circuit; and by maintaining apparatus in an electronegative state with reference to possible sources of current, either by the so-called "drainage" system, or by "tying up" with some source of current of a higher potential.

Corrosion of Metals

Iron and Steel. Under similar conditions, iron and steel corrode at practically the same rate. Steel, however, corrodes more uniformly than iron.

Tests on steel skelp, wrought-iron skelp, charcoal iron, pipe steel and puddled iron exposed for long periods to the action of river water, sea water, aerated distilled water, aerated brine and the weather, showed on the average that steel lost 97.2 per cent. as much weight by corrosion as did wrought or puddled iron, and 96.1 per cent. as much as charcoal iron. (*Proc. A. S. T. M.*, 1908.)

The results of an investigation by J. H. Woolson of the hot-water systems of a number of bath houses in New York City, showed that there was no perceptible difference in the rate of corrosion of galvanized wrought-iron and galvanized steel pipes.

There is no appreciable difference in the rate of attack on hot-drawn and cold-drawn seamless iron and Bessemer steel tubes, when immersed in air-saturated distilled water. (J. D. Ford, *Jour. Am. Soc. Nav. Engrs.*, May, 1904. See also W. H. Walker, *Jour. Am. Water Works Assn.*, 1912, vol. 26.)

According to G. E. and M. C. Whipple, there is practically no difference in the tendency to form pits in the different types of ferrous metal (8th Int. Cong. Appl. Chem.).

Metals in Brine. M. B. Smith (*Ice and Refrigeration*, vol. xii, p. 159, and *Proc. A. S. R. E.*, 1911–1912–1913), from the results of tests of various commercial metals immersed for 150 days in calcium chloride brine (sp. gr., 1.2) at 73.4 deg. fahr., found that they resist corrosion in the following order: Bronze, brass, iron-copper alloy (3 per cent. Cu), copper, wrought iron, mild steel, cast iron, solder, lead, zinc, galvanized iron—bronze being the least attacked Aluminum showed a gain in weight, due to the accumulation of a coating of oxide. Combinations of these metals showed in each case greater losses, which were at the expense of the electropositive metal.

Couples of different metals similarly tested resisted corrosion in the following order: Brass-iron, copper-iron, wrought iron-galvanized iron, and copper-galvanized iron, the latter being least resistant.

When the brine was air-saturated, it was found the rate of corrosion was about three times as rapid as with normal brine, being especially rapid with metals which are oxidized readily and whose oxides do not adhere to the surface at which they are formed. For combinations of metals in air-saturated brine, the rate of corrosion is only about twice that when normal brine is used.

The **relative corrosiveness of brines** depends upon local conditions except when the brines are of inferior character. If the chlorides used—whether they are calcium chloride, calcium-magnesium chloride, calcium-magnesium-sodium chloride or sodium chloride—are neutral products or even slightly alkaline in reaction, there seems to be no appreciable difference in their attack upon metals, provided that all conditions are similar in each case.

Brines should be maintained in a slightly alkaline condition by the occasional addition of milk of lime, caustic soda or other alkali. When in proper condition they should give the characteristic pink color with the phenolphthalein indicator.

Corrosion of Pipes, Boilers and Structural Work

Pipe Materials. Tests by M. B. Smith of the relative corrodibility in artificial sea water, in fresh water, and when exposed to the weather, at 20–25 deg. cent. for 6 months, gave the following results:

Metals	Weather exposure	Artificial sea water	Fresh water
Soft steel	100	105	100
Nickel steel (3 per cent. Ni)	58	79	72
Nickel steel (18 per cent. Ni)	19	20	19
Wrought iron, best	100	100	100

Mill scale on pipes generally forms centers of corrosion, and should be removed in the process of manufacture.

Boiler Tubes. Ford's investigations of 3-in. lap-welded steel and wrought-iron tubes in air-saturated distilled water at 68–77 deg. fahr. show minimum corrosion for welded Bessemer steel and maximum for welded wrought iron; weldless Bessemer tubes corrode more rapidly than welded Bessemer, but less rapidly than weldless wrought-iron tubes.

Unger investigated the corrosion of boiler tubes in sea water, brine, ordinary well water and in 1 per cent. solution of sulphuric acid and ferrous sulphate. He found that the metals yielded to corrosion in the following order: Ordinary wrought iron, medium quality wrought iron, low-carbon Bessemer steel, best grades of wrought iron, open-hearth steel; the last being the most resistant. Open-hearth steels of high and low manganese contents offered about the same resistance to corrosion.

Steam Boilers. Corrosion in boilers takes place in one or all of three ways, namely, general, pitting, and grooving. **General corrosion** is the least dangerous, but the boiler must be watched closely lest it be gradually weakened to an unsafe degree. **Pitting** is readily detected as a rule and is frequently very difficult to stop without a thorough search after the causes. **Grooving** is often very hard to locate before leaks take place, since such corrosion takes place at points where the metal has been bent or strained, and is hidden from any but the most careful inspection. General corrosion of steam boilers may usually be traced to the water employed, but it is also caused by the action of certain boiler **feed-water compounds** containing tannic acid, sulphate of copper, etc. Copper sulphate reacts with the iron or steel in the well-known reaction wherein copper plates out on the iron, an equivalent amount of iron passing into solution. Great caution should be exercised in the use of such materials in boiler practice.

Where there is a corrosive action because of the **presence of acid** in the water, or of oil containing fatty acids which will decompose and cause pitting wherever the sludge can find a lodging place, it may be overcome by the neutralization of the water by carbonate of soda. This should be carried to a point where the water will just turn red litmus paper blue. As a preventive of such action, only the highest grades of hydrocarbon oils should be used.

Acidity may appear where salt water makes its way into a boiler, as may occur in marine practice from leaky condenser tubes, priming in the evaporators, etc. This acidity is caused by the dissociation of magnesium chloride into hydrochloric acid and magnesium under high pressure. The acid in contact with the metal forms an iron salt, which, as soon as formed, is neutralised by the free magnesia in the water, thereby precipitating iron oxide and re-forming magnesium chloride. Where it is unavoidable that some salt water should make its way into a boiler, the water should be neutralised by milk of lime, which will convert the magnesium chloride into magnesia and chloride of calcium, neither of which is corrosive, but both of which are scale-forming.

Decomposition of Boiler Waters. Constituents which may form **hydrochloric acid** are: Chloride of magnesium plus steam; sulphate of magnesium and the alkaline chlorides; silica and alkaline chlorides; ferric chloride; ferrous chloride; carbonate of magnesium plus chlorides; chloride of ammonium. Constituents which may form **sulphuric acid** are: Normal ferric sulphate; ferrous sulphate; sulphurous acid and ferric chloride; sulphites; hydrogen sulphide; sulphate of calcium plus organic matter; sulphate of ammonia; sulphate of copper. Constituents which may form **nitric acid** are: normal ferric nitrate; alkaline nitrates and acid sulphates or sulphuric acid; nitrate of ammonia.

Air sucked in by the feed pumps is a well-recognised cause of corrosion. Air bubbles form below the water line and the oxygen of the air attack the metal. The rust thus formed is washed away by circulation or dislodged by expansion, leaving a minute pit which serves as a lodging place for other air bubbles, and in this way continues the action. In marine practice it has been found advantageous to pump the water from the hot well to a filter tank above the feed-pump suction valves. The bubbles are liberated from the surface of the tank and a head is assured for the suction end of the pump. The corrosive action of air may also be reduced by introducing the feed water into the steam space above the water line.

Both general corrosion and pitting may be reduced or even eliminated by using an open feed-water heater, thus expelling the air, or better still, a feed-water heater connected to a vacuum pump.

Galvanic action takes place in certain instances. The remedy for it is usually the installation of zinc plates within the boiler, which must have positive metallic contact with the metal of the boiler. The zinc plates are corroded instead of the boiler, and the latter is protected at the expense of the former. The positive contact necessary is difficult to maintain, and the efficiency of such plates is questionable, except for a short period after their installation.

Some of the **other causes of corrosion** in steam boilers are: Polluted feed water containing manufacturing wastes—auto-electrolysis between the boiler metal and carbonaceous matter such as soot or ashes, especially around mud drums and blow-off pipes; rain water which, through contact with acid-containing soot on roofs, etc., becomes acid in nature; decomposition of sulphate scale, especially calcium sulphate, with the formation of sulphuric acid (some feed waters, apparently neutral at ordinary temperatures, become acid when heated strongly); coal-pit water—generally acid; boiler metal containing much impurity, especially if segregated; straining of the boiler metal, frequently caused by lack of proper staying, which leads to buckling of the plates (torsional strain is far worse than tensile and should be guarded against); certain alkaline waters, the addition of barium chloride to which would probably be advisable; water containing organic matter, as that from peat bogs, swamps, etc.

Copper ferrules should not be used on the ends of boiler tubes when expanding them into the tube sheets, as auto-electrolysis is almost certain to be set up when such dissimilar metals come in contact. Soft iron ferrules may be used. For the same reason, copper feed pipes should not be joined directly to the boiler metal.

Corrosion in **boilers out of service** may be prevented in several ways. In the French Navy the boiler is filled with water, after which milk of lime or soda is added. The exterior is then painted with red lead or tar, inaccessible places being coated by burning tar beneath them. Boilers in American naval vessels are first cleaned thoroughly and then coated inside and outside with a heavy mineral oil. (See also p. 937.)

Condenser Tubes. The corrosion of condenser tubes is often caused by the formation of oxides which are electronegative toward the metal of which the apparatus is constructed, resulting in auto-electrolysis. Other causes are: the combination of dissimilar metals; the decomposition of sulphate scale, liberating sulphuric acid; sudden changes in temperature. Air either in solution in the cooling waters or present as a gas, tends greatly to accelerate corrosion.

Corrosion takes place in one or more of three ways, namely, splits or cracks, pits, and dezincification, the latter conducing to brittleness. Resistance to corrosion apparently depends more on the microstructure of the metal than on its composition; hard-drawn tubes, annealed slowly at a temperature not exceeding 750 deg. fahr., last much longer than untreated tubes.

As a result of tests of several alloys used in making tubes, in sea water at 64 to 104 deg. fahr., Bengough and Jones (*Proc. Inst. of Metals*, 1913) recommend the use of either "Admiralty" metal (70 Cu, 29 Zn, 1 Sn) or Muntz special brass (70 Cu, 28 Zn, 2 Pb). Iron, if present in brass, greatly accelerates corrosion. Copper-aluminum alloy (8 per cent. Al) has given excellent service in salt water. Monel metal is not non-corrosive in salt water (J. J. Sparrow, *Power*, Oct. 14, 1913, p. 531).

The most common method of protecting condenser tubes against corrosion is to use a metal electropositive toward brass. Zinc has been superseded for this purpose by iron. Electrical contact is absolutely essential for protection.

Pumps may be corroded by the solvent action of the liquor passing through them, provided they are constructed from unsuitable material. When dissimilar metals are used, *e.g.*, a cast-iron body with brass glands, seats, etc., auto-electrolysis is almost certain to result when brines or other electrolytes are pumped. If it is not possible to confine the construction to one metal, the attacked metal should be used only for easily renewable parts.

Corrosion is often set up by the leakage of current from the driving motor. This may be prevented by using an insulating coupling between the pump and motor shafts.

Air in the pump, either free or in solution in the liquid pumped, accelerates corrosion. Pumps should be vented so that they may be completely filled with the liquid they are handling.

Underground Pipes. Pipes buried in the ground are often corroded by the action of stray electric currents from trolley-car tracks, the corrosion manifesting itself at the points where the current leaves the pipes. They should therefore be maintained in an electronegative relation to the tracks.

Soils containing organic or carbonaceous matter such as coke, coal, cinders, etc., or impregnated with acid wastes from manufacturing plants, are highly corrosive in their action.

Steel, wrought iron, cast iron and lead corrode in certain natural soils containing soluble electrolytic salts or polluted with corrosive wastes, etc., in localities where there are no stray electric currents. Scofield and Stenger (*El. Ry. Jour.*, Nov. 14, 1914) find that black peaty soils and clays as electrolytes in contact with metals give rise to the following voltages: Sheet iron, 0 to 0.5; steel pipe, 0 to 0.5; cast-iron pipe, 0 to 0.3; pitted cast iron, 0 to 0.7; clean cast iron, 0 to 0.15; the current leaving the metal at clean spots, returning to the impurities in the metal through the external circuit. Clean iron is therefore electropositive toward impurities. The auto-electrolysis of iron buried in soils is recurrent, since oxygen is always present in sufficient amount to act as a depolariser. Tests on 120 different soils with steel test strips showed comparative corrosive action as follows, beginning with the least corrosive soil: Clean dry sand; light sandy soils, loam and drier dark soils; heavy clays; wet black peaty soils. The minimum attack on steel in these tests was equal to a loss in weight of 0.04 gram, the maximum being 0.6 gram, on test pieces 1 × 2¼ in. × No. 16 gage thickness in 66 days. The average is 0.25 gram, or 1.39 grams per year, indicating a probable life for ¼-in. thick pipe of 7.6 years.

Pipes buried in mixtures of two dissimilar soils or in two unlike soils in contact (not mixed) generally corrode more rapidly than in either of the two soils separately. Lead in a mixture or simple contact of dissimilar soils will often corrode markedly. Pipes buried in trenches fulfill these conditions of soils in contact or mixed. Metals corrode at the junction line of dissimilar soils. Cast iron in soils takes on a hard coat of rust and soil, pits being filled with carbon and black iron oxide. Lead shows both the gray and brown oxides when corroded in soils. Potentials up to 1 volt may readily be generated by placing unlike metals in a given soil or by using one metal in two dissimilar soils.

The tendency to corrode, especially in the form of pitting, is said to be reduced by a process, known as "**Spellerizing,**" used by the National Tube Co. This process, applicable to welded pipes up to 5 in. in diam., consists in subjecting the bloom to the repeated alternate action of rolls provided with regularly shaped projections and of smooth rolls, resulting in the production of surface metal of a uniformly dense texture. The same company also furnishes pipes up to 18 in. in diam. which are first dipped in a hot bituminous compound and then wrapped helically on the outside with one or more layers of fabric impregnated with the hot compound. This "National coating" is said to effectually prevent moisture from reaching the metal, making corrosion or electrolysis impossible.

Pipes are often destroyed by the action of dissimilar metals to which they are connected, such as brass valves, etc., in which case short connections, readily replaced, should be used on either side of the brass fittings (see also Pipe Materials, p. 556).

Bridges, Roofs, Stacks, Etc. Iron and steel structures are corroded by the presence in the atmosphere of moisture and waste products from manufacturing and metallurgical plants such as carbon monoxide, carbon dioxide, sulphur dioxide, chlorine, ammonia, zinc and acid fumes, soot, etc. As a rule, they are not corroded in a dry atmosphere. To minimize the corrosive effects of gases, protective coatings (see p. 563) are resorted to. Methods of coating metals with other metals are given below. Metal work exposed to the action of sulphur fumes should be covered with brick or with a paint highly resistant to sulphur dioxide.

The presence of from 0.2 to 0.25 per cent. of copper in sheet steel has been shown to greatly increase its durability both in atmospheric corrosion and in the presence of strong acid fumes. Such steels are now available and much used in structural work. (Buck, *Jour. Ind. & Eng. Chem.*, 1913.)

Concrete Structures. The following notes are taken from Bulletin No. 18 of the U. S. Bureau of Standards:

When current passes from an iron anode into concrete, oxides of iron form on the anode, occupying about 2.2 times the volume of the equivalent iron, and giving rise to mechanical pressure (sometimes as high as 4700 lb. per sq. in.) which may result in cracking the concrete. At temperatures below 113 deg. fahr., and with a potential gradient less than 60 volts per foot, this action is very slight, even in wet concrete.

Concrete near the cathode, or metal through which the current leaves the concrete, becomes softened and remains brittle and friable after drying, destroying the bond between the iron and concrete. This effect is noted at all voltages, high or low, and is due to the concentration of sodium or potassium near the cathode. The content of these elements in the cement should therefore be kept low.

Salt (NaCl) or calcium chloride should never be added to concrete used in structures which will be subject to electrolytic action. Concrete in contact with salt water is very susceptible to electrolysis. In structures exposed to the action of salts, pickling solutions, etc., the potential gradient must be kept low.

In the absence of metallic electrodes the action of current is similar to slow seepage, the water-soluble elements in the concrete migrating toward the cathode. Grounding of electric conductors in such a structure is equivalent to installing electrodes.

Waterproofing compounds when mixed with concrete have but little effect in preventing electrolysis. Waterproofing membranes, properly applied, are fairly efficacious in preventing the entry of earth currents. Painting or otherwise coating the reinforcing metal may minimise the danger from electrolysis, but it prevents proper bonding between the metal and the concrete.

All direct-current circuits within a building should be kept free from grounds. All pipe lines entering a building should be installed with insulating joints outside the building. If passing through, they should have insulating joints on both sides of the building. If the potential drop around the isolated section is 8 volts or more, the isolated section should be shunted by a copper cable. Lead-covered cable should be kept out of contact with the building.

All metallic structures within a building should be interconnected, providing all lines entering the building are installed with insulating joints, but they should not be grounded to any ground plate lying outside of the insulating joints. Maintaining the reinforcing metal negative is worse than no protection at all.

Methods for Minimizing Corrosion

Corrosion may be minimized by (*a*) the use of a coating of protective metal such as zinc, tin, lead, nickel or copper; (*b*) by the production of magnetic oxides on iron and steel surfaces; (*c*) by the application of protective paints (p. 563), and (*d*) by rendering the surface of the metal passive.

Coating Metals with Zinc.—Galvanizing. Zinc is applied to metal surfaces either by the Sherardizing process, by dipping in a bath of molten zinc, or by electrodeposition.

In the **Sherardizing process** the articles, after being thoroughly cleaned by pickling and sand-blasting, are placed in a metal drum together with zinc dust, and heated to a temperature of from 500 to 600 deg. fahr., depending on their size and shape. The coating which results is not pure zinc, but an alloy of about 90 per cent. zinc and 10 per cent. iron (melting point, 1260 deg. fahr.), and is even more highly resistant to corrosion than pure zinc. It is covered in the final stages, however, by pure zinc. Articles of very complex shape may be readily coated by this process, since the zinc fumes reach all parts of the articles. The process is adapted for watch screws, wire, roofing sheets, bolts and nuts, chains, pipe fittings, nails, small castings, and such other articles as may conveniently be placed within a drum 30 in. in diam. and 22 ft. long. In coating screws it is only necessary to allow for the thickness of the zinc coating. The metal coated is often improved by the incidental heat treatment of the process, which is akin to annealing. The cost varies with the character of the articles coated. For a maximum drum charge of closely packed articles of similar shape, it is about $1 per 100 lb.; for thin, bulky material not packing to advantage, from $4 to $8 per 100 lb.

In the **hot process** the articles after being thoroughly cleaned are dipped in a bath of molten zinc. The bath must be maintained at a temperature somewhat higher than the melting point of zinc, making a large consumption of fuel essential and also resulting in a considerable loss in zinc through oxidation at the surface of the bath. The process is best suited to large articles such as wire, large sheets, etc., which may be readily drawn through the zinc bath. The cost is about double that of the Sherardizing process when all losses are taken into account. In order to cut down losses due to oxidation, the surface of the zinc in the bath is covered with a layer of ammonium chloride. From 2 to 3 per cent. of tin is frequently added to accelerate crystallization of the zinc on the metallic surfaces. In order to prevent the formation of hard zinc in coating sheet metal, the bath is often filled to within an inch or so of the required depth with lead, on top of which about 1 in. of zinc containing from 2 to 3 per cent. tin is placed. The lead serves as a reservoir for the heat, maintaining the zinc-tin alloy at an even temperature.

The **electrolytic or cold process** consists in setting up the articles to be coated as cathodes in an electrolytic bath of soluble zinc salts, the anode being metallic zinc. In the Cowper-Cowles process the solution is zinc sulphate, which is regenerated by passing it through tanks containing zinc dust. In the S. Wagners process the zinc anode is covered with flannel saturated with a solution of zinc and is moved over the surface of the object. Small articles are placed in metallic baskets in contact with the basket and with each other, the basket in turn being attached to the cathode of the system. The cost varies widely, but falls between that of the Sherardizing and the hot processes.

In the **Schoop spraying process** a stream of finely divided or molten metal is forced through a blow-pipe flame under air or gas pressure and played upon the surface to be treated, yielding a thin and firmly adherent coating. Lead, copper, brass or tin coatings may be applied by this process to any desired surface, whether of metal, wood, fabric, etc. It is being used commercially in France for coating iron sheets with tin and zinc, and has been proposed as a means for coppering the hulls of ships.

Coating with Tin, Nickel or Copper. Coatings of **tin** or of a **tin-lead alloy** are used principally on thin sheets of iron, being applied as a rule in a manner similar to that of the hot process of galvanising. When so-called **terne plate** is made, a mixture of tin (70 per cent.) and lead (30 per cent.) is generally used. Such coatings, if free from pin-holes, are highly resistant to corrosion.

In coating or electroplating with **nickel or copper,** the object to be coated is made the cathode, the anode consisting of a block of the metal to be deposited and the electrolyte a solution of the metal to be deposited. In nickel plating, a copper coating is generally applied before the nickel to render the latter more adherent.

Copper is sometimes applied in very thin coats by the Monnot and Willis processes, in which copper is cast around the object, which is afterward rolled down to the required thickness.

Magnetic Oxide on Iron Surfaces. In the **Bower-Barff process** the iron or steel articles to be coated are heated in a closed retort to a temperature of 871 deg. fahr., after which superheated steam is admitted. This results in the formation of red oxide (Fe_2O_3) and magnetic oxide (Fe_3O_4). Carbon monoxide (CO) is then admitted to the retort to reduce the red oxide to magnetic oxide, which is highly resistant to corrosion. Each operation takes about 20 min. The **Wells process** is similar to the Bower-Barff. The glossy black coating of magnetic oxide on **Russia iron** is produced by laying up sheets of iron with powdered charcoal between, the whole mass being then heated and hammered.

Rendering Iron Surfaces Passive may be accomplished in several ways, the most common being to immerse the metal in nitric acid (sp. gr., 1.4) after highly polishing it. Other methods consist in immersing the metal in fuming sulphuric acid, potassium ferrocyanide or potassium chromate solution or in chromic acid; coating with a manganese dioxide paint; pickling in a weak acid solution, the metal being connected as the cathode in a circuit of low voltage; treatment with arsenic, sodium nitrite, etc. Thus far, passive treatment has been of very doubtful value.

PAINTS AND PROTECTIVE COATINGS

BY

HENRY A. GARDNER

REFERENCES: Gardner, "Paint Technology and Tests," McGraw-Hill. Cushman and Gardner, "Corrosion and Preservation of Iron and Steel," McGraw-Hill. Hurst, "Painters' Colors, Oils and Varnishes," Lippincott. Wood, "Rustless Coatings," Wiley. Maire, "Modern Pigments and Their Vehicles," Wiley. Reports of Committee D-1 of the A. S. T. M. 1903–1915.

Preparation of Surfaces for Painting. If **new wood** is to be painted, it should be sandpapered lightly in rough spots. All knots should be brushed with turpentine or benzol just before applying the paint. This treatment will allow the paint to form a bond with the softened resin in the knots and thus give better results. At least 15 per cent. of turpentine should be used in the priming coat of paint, to secure penetration. Before applying a second coat, all nail holes and crevices should be stopped with putty. If the surface needs repainting, all "alligatoring," scaling or blistering appearing on the old paint should be leveled with sandpaper. When **new metal** is to be painted, it should be cleaned of rust spots with a wire brush, scraper or sand blast. Small articles are generally pickled in a hot 15 per cent. solution of sulphuric acid to remove the oxide scale from the surface, and then thoroughly washed and dried before painting. Three coats of paint should be used on all structural materials if good results are to be obtained.

Spreading Rates. Although the spreading rate of paints varies greatly, the average rate for a paint of normal consistency is as follows:

	Square Feet per Gal.		
	Wooden Surfaces	Metal Surfaces	Cement and Concrete
Priming coat	300 to 400	500 to 700	150 to 250
Second and third coats	400 to 600	700 to 800	300 to 400

Cost of Painting. The cost of labor for painting any structure is generally twice the cost of the paint, allowing on an average $2 per gal. for the paint. Where the preparation of surface requires chiseling and wire-brushing, or other extra preparation, the cost will sometimes exceed three times the price of the paint. The best paints from the standpoint of efficiency are those described below.

Pigments and Prepared Paints for Wooden Surfaces. The opaque white pigments used in paints for the preservation of wood are corroded **white lead** (basic carbonate white lead), sublimed white lead (basic sulphate white lead), **zinc white** (zinc oxide), and **leaded zincs** (lead sulphate combined with zinc oxide). Lead pigments used alone are apt to chalk and "alligator," while zinc pigments often scale and check. By combining the two types of pigments these defects are overcome. Equal parts of lead and zinc form a very good paint. Mixtures of lead and zinc pigments are often combined with a small percentage of the crystalline pigments such as **barytes** (barium sulphate), **china clay** (aluminum silicate), **silex** (silicon oxide), **asbestine** (magnesium silicate), etc., to increase the durability of the product. Such combinations when finely ground by machine with pure linseed oil form the best paints. They are tinted with **colored pigments** such as chrome yellow (lead chromate), Prussian blue (ferro-ferricyanide of iron), sienna, ochre, umber, lampblack, etc., and sold as prepared paints.

Paint Oils. Pure **linseed oil** (see p. 638), raw or boiled, on account of rapid and hard drying, is preferable for general painting work. Refined raw oil is generally used in paints for wooden surfaces. A mixture of raw and boiled oils is sometimes preferred in paints for metal surfaces. Oils are sold on the basis of 7½ lb. per gal., but are paid for by the gallon. The price of linseed oil varies widely but averages about 60 cents per gal. in 5-bbl. lots. **Menhaden oil,** which is extracted from the menhaden fish, is occasionally used in special paints for sea exposure. This oil is very resistant to moisture, but is apt to take dust and become darkened. **Soya bean oil,** extracted from the soya bean, a legume grown in the South for forage, has been used as a partial substitute for linseed oil. In some cases it has given fair results in combination with linseed oil in different types of paint. **China wood oil** (see p. 637) is heat-treated with driers and used in technical and water-proofing paints. Its rapid drying to a clear, glossy film makes it valuable for such purposes. **Corn oil** and **cottonseed oil** are very slow drying and are apt to make a paint "tacky." **Rosin oil** and **petroleum oil** are dangerous to use in paints for the protection of wooden or steel surfaces, on account of their slow drying and tendency to check.

Paste Paints. **White-lead paste** contains approximately 9 lb. of oil per 100 lb. For spreading this amount there should be added from 4 to 5 gal. of oil. **Zinc-oxide paste** contains 16 lb. of oil per 100 lb. of pigment. For spreading, there should be added 6 gal. of oil or an amount sufficient to produce an easy working paint. **Iron-oxide paste** contains approximately 30 per cent. of oil. **Red lead** is generally bought in the dry form and mixed with oil in the proportion of 20 to 30 lb. of lead to 1 gal. of oil. Red lead containing 15 per cent. of free litharge protects metal much better than red lead which contains only 4 per cent. of litharge. The litharge forms a hard, water-resistant film. Combination pigment paints contain on an average 30 per cent. oil and 70 per cent. pigment. Instructions for reduction and application are given on the label.

Paint Thinners. Paints of a very heavy body or thick consistency are difficult to apply and often show brush marks after application. Such paints should be thinned with **turpentine** or other neutral thinner. Because of the high price of turpentine, **petroleum spirits** of the same boiling point and gravity are being used in some paints, with very satisfactory results.

Driers. Salts or oxides of lead and manganese are boiled into oil to form driers. When these driers are added to paint, they act as catalytic agents and accelerate drying by attracting oxygen. **Litharge** (PbO) is most generally used. **Sugar of lead,** incorporated in oil, is used for light tints. **Sulphate of zinc** and **manganese dioxide** are used by the grinder for certain paints having zinc white as a base.

Paints for Structural Steel. The priming coat of paint should be made of linseed oil containing thoroughly inhibitive or inert pigments such as basic chromate of lead, red lead, sublimed white or blue lead, zinc oxide, iron oxide, zinc chromate, etc. A mixture of the lead, zinc and iron pigments is sometimes preferred to the use of any single pigment.

The **surface area of a steel structure** may be calculated by use of the following formulæ in connection with the material bills giving the tonnage of the various shapes.

Let S = sq. ft. of surface per ton of metal, and w = weight of shape per running foot, lb. Then, for

I-beams: $S = (56{,}800h + 54{,}800)/w$, where h = depth of beam, in.

Channels: $S = (434b + 500)/w$, where b = width of channel, in.

Angles (equal-leg): $S = (660b - 21)/w$, where b = width of each leg, in.

Angles (unequal-leg): $S = 3220b/w$, where b = sum of widths of both legs, in.
Z-bars: $S = (528h + 1090)/w$, where h = depth of web (out to out), in.
Plates (both sides): $S = 100/t$, where t = thickness, in.

One gallon of pure red-lead paint (20.3 lb. red lead in 5.62 lb. of linseed oil without turpentine or other thinner) when applied to new steel surfaces will cover from 500 to 700 sq. ft. for the first coat, 650 to 850 sq. ft. for the second coat, and from 800 to 1000 sq. ft. for the third coat; or, for two-coat work, 1 gal. will cover from 300 to 400 sq. ft. and for three-coat work from 215 to 285 sq. ft. (Cloyd M. Chapman, *Eng. Rec.*, Feb. 15, 1913.)

Carbon Paints. Paints containing graphite, carbon black or lampblack are unsafe to use as a priming coat for metal. Because of electrical conductivity which these pigments possess, they are apt to excite corrosion. Their use as second-coaters or top-coaters is to be recommended.

Ship-bottom Paints. Anti-corrosive priming paints made of the rust-inhibitive pigments noted above and topped with quick-drying anti-fouling paints made of shellac dissolved in alcohol and mixed with powdered zinc and the oxides of zinc, iron and mercury, are widely used in the Navy and merchant marine service for the protection of steel vessels.

Paints for Water Carriers. Cast-iron and riveted-steel water carriers are generally heated and dipped in hot preparations of mineral asphalt, coal tar and lime, or special baking enamels. This treatment is occasionally followed by baking at a high temperature to make the coating more resistant to abrasion.

Paints for Tinned and Galvanized Surfaces. After wiping off the greasy surface with benzine, a linseed-oil paint made of red lead, iron oxide and chromate pigments, thinned with a little varnish. gives the best results. Applying a 5 per cent. water solution of copper nitrate and sal ammoniac to galvanised iron previous to painting is resorted to when peeling is feared.

Rubber Paints. Paints made of caoutchouc, gutta percha, etc., dissolved in acetone, carbon bisulphide and benzol, form elastic films which give protection to metal for a short time. Upon weathering, the films soon show pinholing and brittleness.

Metal Lacquers. Amyl and ethyl acetate solutions of nitrated cotton are used as dipping lacquers for small metallic art objects. These lacquers dry rapidly and produce excellent and clear films. When brushed on, they are apt to show white brush marks. A new material called "**Bakelite,**" which is a condensation product of phenol and formaldehyde, is the base of some excellent clear lacquers and plastics that possess great preservative properties.

Varnishes. Gums melted into oils and thinned with turpentine form oleo-resinous varnishes. For exterior purposes a "long "oil varnish (one that contains a high percentage of oil) is superior. For interior use, a "short" oil varnish gives a highly lustrous surface that is easily rubbed or washed. High-grade varnishes should be judged comparatively by their body, working properties, flowing, clearness, gloss, and durability, Practical exposure **tests** are best suited to determine the latter point. Hardness of film, resistance to scraping, elasticity when rolled with a knife blade, and resistance to moisture, are some of the quicker tests used. Setting in from 6 to 8 hr. and hardening in 24 hr. are the limits sometimes specified. Gilsonite, elaterite, and other **asphalts** are melted into oils to form black, lustrous asphalt varnishes that are used for protection of water tanks, piping, etc., with great success. Clearness when flowed on glass, miscibility, rapid drying, and moderate flash point, are characteristics of the best asphalt varnishes. Hard, flexible, clear, and rapid-drying **insulating varnishes** are used extensively for dipping and brushing commutator rings, transformer coils and other electrical equipment. **Baking varnishes** for armature coils must be resistant to heat without blistering. **Shellac** (see p. 643) and other spirit varnishes, as well as Bakelite compounds, are used extensively for such purposes.

Enamel Coatings. Metal fittings that are to be permanently protected are often coated and baked with a mixture of feldspar, borax, tin and lead oxides, and other similar materials. The enamel coating produced by this method is very resistant to corrosive agencies. It is, however, subject to cracking from expansion or contraction of the metal upon which it is placed.

Concrete Coatings. Paints made of treated China wood oil mixed with hard, abrasion-resisting pigments, such as zinc oxide and barium sulphate, are finding a wide application as protective coatings for cement and concrete. They have given excellent results even when applied to relatively fresh surfaces. Better results are obtained however if the surfaces are first treated with zinc sulphate solution.

Macnichol Treatment for Cement Surfaces. This treatment consists of the application of a 25 per cent. solution of zinc sulphate to the surface of cement or concrete that is to be painted. The lime-neutralizing and void-filling properties of the zinc sulphate are sufficient to produce an excellent surface that will receive ordinary linseed-oil paints without showing signs of disintegration.

Paint-destroying Agencies. Atmospheres containing sulphurous, acid, or ammoniacal gases are very severe in their action upon paint coatings. Sea air is also very destructive in its effect upon paint. Saline drippings from underground tunnels, and fatty acids from machinery are also to be avoided. In dry climates and in communities of little industrial activity, paint coatings last for several years without decay.

CEMENT, MORTAR AND CONCRETE

BY

SANFORD E. THOMPSON

CEMENT, LIME, SAND, ETC.

Portland Cement is used for concrete, reinforced concrete, and, either with or without lime, for mortar and stucco. It is made from a mixture of about 80 per cent. of carbonate of lime (limestone, chalk, or marl), with about 20 per cent. of clay (in the form of clay, shale, or slag). After being intimately mixed, the materials are finely ground by a wet or dry process and then calcined in kilns to a clinker. When cool, this clinker is ground to a fine powder. A typical chemical analysis shows the following percentage composition: Silica (SiO_2), 21.31; alumina (Al_2O_3), 6.89; iron oxide (Fe_2O_3), 2.53; calcium oxide (CaO), 62.89; magnesium oxide (MgO), 2.64; sulphuric oxide (SO_3), 1.34; other constituents, 0.75; loss on ignition, 1.39.

White Cement is used for architectural and ornamental work because of its white color. It is of comparatively recent manufacture, is high in alumina, and low in iron. The best brands are true Portlands in composition.

Natural Cement is used, either with or without lime, for common mortar for brick or stone work. It is manufactured from limestone containing clay. The chemical constituents are similar to those for Portland cement, but it is made from the rock just as it comes from the quarry, so that its chemical composition varies with the composition of the rock in the ledge. The natural rock is fed directly to the kilns without being ground, is calcined at a temperature much lower than that required for Portland cement, and then crushed and ground.

Puzzolan or Slag Cement is used under certain conditions for concrete not exposed to the air. It is made by mixing and grinding together slaked lime with granulated blast-furnace slag or other puzzolanic material like natural lava, without burning. The ancient cements were mixtures of lime and volcanic material.

Portland Cement Tests. Cement should be tested for all but very small and unimportant work. Tests should be made in accordance with methods recommended by the Committee on Uniform Tests of Cement of the American Society of Civil Engineers, and the cement should be required to pass the standard specifications of the American Society for Testing Materials. Samples should be taken at random from sound packages, one from every 10 barrels or 40 bags, and mixed. The total samples should weigh about 10 lb. The **Standard requirements** for Portland cement in brief are as follows (the corresponding figures for natural cement are added in parentheses):

Chemical Limits: The following limits shall not be exceeded: Loss on ignition, 4 per cent.; insoluble residue, 0.85 per cent.; sulfuric anhydride (SO_3), 2 per cent.; magnesia (MgO), 5 per cent.

Specific Gravity: Not less than 3.1 (2.8); White Portland, 3.07.

Fineness: Residue by weight on a No. 200 sieve not more than 22 (30) per cent.

Soundness: A pat of neat cement about 3 in. in diameter and ½ in. in thickness, (1) shall remain firm and hard after 24 hr. storage in moist air, and (2) shall show no signs of distortion, cracking, checking or disintegration when exposed for 5 hr. to steam above boiling water in a loosely closed vessel.

Time of Setting: Initial set not less than 45 (10) min. when Vicat needle is used or 60 min. when Gilmore needle is used; final set not more than 10 (3) hr.

Tensile Strength: Minimum requirements for average tensile strength of not less than three briquettes, 1 sq. in. in cross-section, composed of 1 part cement to 3 parts standard sand, by weight:

Age of Test, days	Storage of Test Pieces	Tensile Strength, lb. per sq. in.
7	1 day in moist air, 6 days in water.	200 (25–75)
28	1 day in moist air, 27 days in water.	300 (75–150)

Common Lime, or Quicklime, is used for interior plastering and for lime mortar. Mixed with cement, it is used for lime and cement mortar and for stucco. It is not fit for mortar for thick walls because of slow setting qualities, and must never be used under water. It is made by burning pure limestone in kilns about 40 ft. high by 10 ft. in diam. at temperatures ranging from 1400 to 2000 deg. fahr. A typical percentage chemical composition is calcium oxide (CaO), 97; iron oxide (Fe_2O_3), 1.3; silica (SiO_2), 1.0; magnesium oxide (MgO), 0.7. It slakes with water, forming calcium hydrate (CaH_2O_2). With proper addition of water it becomes plastic, and the volume of putty obtained is 2 or 3 times the loose volume of the lime before slaking, while its weight is about 2¼ times the weight of the lime. Plastic lime sets by drying, by crystallization of calcic hydrate, and by absorbing carbonic acid from the air. The process of hardening is very slow.

Magnesium Lime is used for the same purposes as common lime. It contains magnesium oxide up to 40 per cent. In slaking, it evolves less heat, expands less, and sets more rapidly than pure lime.

Hydrated Lime is a finely divided white powder manufactured by slaking quicklime with the requisite amount of water. It is used because it does not contain unslaked particles of lime.

Sand to be used for mortar and concrete should be preferably of siliceous material, clean, with grains either coarse or else graded from fine to coarse, free from loam and other deleterious matter. The specific gravity of dry sand may be taken ordinarily as 1.65. The physical condition of sand is more important than the chemical composition, except that vegetable or organic impurities are harmful. A quantity of vegetable matter so small that it cannot be detected by the eye, may render a sand absolutely unfit for use with Portland cement.

Test of Sand. Sand should always be tested for use in important concrete structures. The strength of concrete depends to a great degree upon the quality of the sand and the coarseness and relative coarseness of the grains. Sand or other fine aggregate when made into a mortar of 1 part Portland cement to 3 parts fine aggregate by weight should show a tensile strength at least equal to the strength of 1 : 3 mortar of the same consistency made with the same cement and standard sand. If the aggregate is of poor quality, then the proportion of cement in the mortar should be increased to secure the desired strength. If the strength is less than 70 per cent. of that of Ottawa sand mortar, the aggregate should be rejected. The standard Ottawa sand will pass a No. 20 sieve and be retained on a No. 30 sieve. This sand is supplied by the Ottawa Silica Co., Ottawa, Ill.

Broken Stone and Gravel. Coarse aggregate for concrete may consist of broken stone or gravel. The particles should be clean, hard, durable, and free from deleterious matter and range in size from ¼ in. in diam. up to the coarsest size permissible for the structure. For reinforced concrete and small masses of unreinforced concrete, the maximum size is governed by that which will readily pass around the reinforcement and fill all parts of the forms. Either 1-in. or 1½-in. diam. is apt to be the maximum. For heavy mass work the maximum size may run up to 3 in. or larger.

MORTARS

Lime Mortar consists of lime paste and sand, and is made by slaking lime and mixing with sand or else by making up lime putty in advance to be mixed with sand when needed. Either the mortar or the putty should stand for 10 days or 2 weeks to thoroughly slake. Proportions customarily stated are 2.5 to 3 volumes of sand to 1 volume of lime before slaking. In practice, the proportion of sand is apt to be greater than this, as the mortar man determines the proportion by the way the mortar falls from his hoe in mixing. A large proportion of sand is advantageous. According to Taylor and Thompson, the **volume of lime mortar** made with different proportions of sand is as follows:

One 200-lb. cask of lime and 6 cu. ft. of sand will make 10.2 cu. ft. of 1 : 2 mortar.
One 200-lb. cask of lime and 9 cu. ft. of sand will make 12.2 cu. ft. of 1 : 3 mortar.
One 200-lb. cask of lime and 12 cu. ft. of sand will make 14.5 cu. ft. of 1 : 4 mortar.
One 200-lb. cask of lime and 15 cu. ft. of sand will make 17.1 cu. ft. of 1 : 5 mortar.

Lime and Cement Mortar is made by mixing 1 part of cement with 3 parts of lime mortar having a large proportion of sand. The lime mortar should be made up several days before cement is added. Only small quantities of cement should be mixed at a time, so that there will be no danger of the cement attaining a set before the mortar is used.

Cement Mortar is composed of cement and sand or screenings mixed with water. Proportions in practice are ordinarily 1 part cement to 2 parts sand (1:2), or 1 part cement to 3 parts sand (1:3). Table 1 gives the quantities of sand and cement required for 1 cu. yd. of cement mortar. The **strength** of Portland cement mortar (1) increases with the proportion of cement, (2) in general increases with the coarseness of the sand, and (3) increases with the density of the mortar. With the same aggregate, the strongest and most impermeable mortar is that containing the largest percentage of cement in a given volume of mortar. With the same percentage of cement, the strongest mortar (provided the sand is absolutely clean) is that which has the greatest density, that is, which in unit volume of mass has the largest percentage of solid materials. A small addition of lime, not exceeding 10 per cent., is apt to increase the strength of a lean, say a 1 : 3 or 1 : 4 mortar, and to slightly decrease the strength of a richer mortar. Unslaked lime or imperfectly slaked lime must never be used in mortar either alone or with cement. Even in as small an amount as 2 per cent. it may seriously reduce the strength of mortar because it is liable to produce expansion in the masonry by slaking after the mortar is in place. Table 2 shows the effect of different sizes of grains upon the strength of mortar.

Table 1. Volume of Compacted Plastic Portland Cement Mortar and Quantities of Materials per Cubic Yard*

(Taylor and Thompson, p. 229)

Relative proportions by volume		Volume		Materials for 1 cu. yd., based on barrel of 4 bags or 4 cu. ft.		Relative proportions by volume		Volume		Materials for 1 cu. yd., based on barrel of 4 bags or 4 cu. ft.

Mortar for Stone Work. Lime mortar should not be used for thick walls, as it hardens very slowly; for masonry under water, or in wet soil; nor in structures requiring great strength or which are subject to shock. Lime and cement mortar may be used for masonry above water. The amount of mortar required for a cubic yard of masonry is given in Table 3.

Table 3. Amount of Mortar Required for a Cubic Yard of Stone Masonry
(From Baker's "Treatise on Masonry Construction")

Description of masonry	Mortar, cu. yd.	
	Min.	Max.
Ashlar, 18-in. courses and ¼-in. joints	0.03	0.04
Ashlar, 12-in. courses and ¼-in. joints	0.06	0.08
Rubble, small, rough stones	0.33	0.40
Rubble, large stones, rough hammer-dressed	0.20	0.30
Squared stone masonry, 18-in. courses and ¾-in. joints	0.12	0.15
Squared stone masonry, 12-in. courses and ¾-in. joints	0.20	0.25

Mortar for Brickwork may be made with pure Portland cement and sand, natural cement and sand, lime and sand, or mixtures of lime, cement, and sand, according to the character of the work. For ordinary brickwork, mortars of lime and cement are used; for water-tight brickwork, Portland cement mortar without lime. The amount of mortar required in laying brickwork is given in Table 4.

Table 4. Amount of Mortar Required for Brickwork
(From investigations of Taylor and Thompson)

Mortar for common brick (20 brick per cu. ft.,* size 8¼ × 4 × 2¼ in., with ⅜-in. joints)			Mortar for selected face brick† (8.8 brick per sq. ft., size 7¾ × 3½ × 2¼-in., with 5/16-in. joints)			Mortar for pressed face brick‡ (7½ brick per sq. ft., size 8¼ × 4 × 2 5/16 in., with ¼-in. joints)

* Actual brick laid in wall. For figuring quantities use 22½ brick per cu. ft.
† Laid with headers every 6th course. ‡ Laid running bond (all stretchers).

Mortars for Plastering. Mortar for **interior plastering** consists of lime, clean coarse sand, and cattle hair or fiber. To get best results slake the lime thoroughly, run it through a sieve, if not pure, and allow to stand for at least 24 hr., or, better yet, up to 7 days. Then mix the hair thoroughly with the lime, add sand, and throw in a pile. After at least 7 days, add water and apply immediately on the lathing. The mortar should be protected from freezing. Patented mortars also are largely used. One hundred pounds of lime will make about 3½ cu. ft. of lime putty or paste. The volume of a lime barrel is about 3 cu. ft. **Back plaster** is a coat of mortar placed usually on laths fastened to the boarding between the studs. **Scratch coat** consists of mortar of lime, sand and considerable hair—about 2 to 2½ bu. to one 200-lb. cask of dry lime. It is put directly on the laths. **Brown coat** consists of mortar with less hair, about 1 to 1½ bu. per 200-lb. cask of dry lime. When 3-coat work is used, this is troweled directly on to the scratch coat. **Skim coat** is a finish coat composed of lime putty and fine white sand. It is spread on to the scratch coat in 2-coat work or on to the brown coat in 3-coat work. It is placed in two layers and troweled to a hard finish. **Gaged skim coat** is skimming mixed with a certain amount of plaster of Paris, which makes it practically a hard finish. **Hard finish** consists of 1 part of lime putty to 1 or 2 parts of plaster of Paris. Certain patented plasters are also used for hard finish and are preferred because of uniform composition. **Two-coat work** is used for the cheaper class of houses for plastering on wood laths. For the first coat, the mortar, which contains considerable hair, is spread on in one layer usually on the walls and two layers on the ceiling, smoothed with a darby (a board with two handles) and, when nearly dry, floated with a wooden hand float. The finish coat may be of skim or hard finish. **Three-coat work** has a first or scratch coat of mortar spread on and scratched when nearly dry. The second coat or brown coat consists of mortar with less hair, smoothed off, darbied and floated with a wood float. This is then covered for the third coat with skim or hard finish. The first coat on metal or wire lathing for three-coat work requires a fatter mortar than laths and with less hair in it. Three-fourths-inch grounds or rails are generally used. The total thickness for three-coat work is therefore from ¾ in. to ⅞ in. **Stucco** is used for **exterior plastering**, and is applied to brick or stone or plastered on to wood or metal lath. The first coat may consist of 5 parts Portland cement, 3 parts slaked lime putty, a small amount of hair, and 12 parts clean coarse sand. The second or finish coat may consist of Portland cement mortar with a small quantity of lime paste. For covering wooden buildings, the stucco is plastered either on wood lath or on metal lath in two coats, using mortar similar to that for brick or stone. Concrete in northern climates exposed to frost should never be plastered, but should be finished by rubbing down with carborundum brick or similar tool when the surface is comparatively green; it may also be tooled in various ways.

CONCRETE

Concrete is made by mixing cement and an aggregate composed of hard, inert particles of varying size, such as a combination of sand or broken stone screenings, with gravel, broken stone, cinders, broken brick, or other material. Portland cement should always be used for reinforced concrete, for mass concrete subjected to stress and for all concrete laid under water.

Proportioning Concrete. The object in proportioning concrete is to produce a mix of the greatest possible density, since this with a given quantity of cement produces the highest strength. The proportions to be selected vary with the character of the aggregates and with the use to which the concrete is to be put. Proportions are determined for any special condition in various ways: (1) Arbitrary selection, such as 1 part cement, 2 parts sand, 4 parts stone (written 1:2:4). (2) Determining the voids in stone and selecting proper proportions for mortar by test or judgment; then using mortar slightly in excess of voids in stone. (3) Making trial mixtures of concrete with a given percentage of cement and different aggregates and selecting the mixture producing the smallest volume of concrete. (4) Mixing the cement and aggregate by methods of mechanical analysis curves. The method to select depends upon the conditions. For small structures the proportions may be arbitrarily selected, while methods (3) or (4) should be employed to obtain the most economical results on large constructions.

Proportions for Different Structures. The following four mixtures will serve as a rough guide to the selection of proper proportions for various classes of work (Taylor and Thompson).

(*a*) **Rich Mixture,** for columns and other structural parts subjected to high stresses or requiring exceptional water-tightness. Proportions, 1 : 1½ : 3.

(*b*) **Standard Mixture,** for reinforced floors, beams and columns, for arches, for reinforced engine or machine foundations subject to vibrations, for tanks, sewers, conduits, and other water-tight work. Proportions, 1 : 2 : 4.

(*c*) **Medium Mixture,** for ordinary machine foundations, retaining walls, abutments, piers, thin foundation walls, building walls, ordinary floors, sidewalks, and sewers with heavy walls. Proportions, 1 : 2½ : 5.

(*d*) **Lean Mixture,** for unimportant work in masses, for heavy walls, for large foundations supporting a stationary load, and for backing for stone masonry. Proportions, 1:3:6.

The above specifications give fair average practice. If the aggregate is carefully graded and the proportions are scientifically fixed, smaller proportions of cement may be used for each class of work.

Quantities of Materials. The volume of concrete obtained by a mixture of certain volumes of aggregates is much smaller than the total volume of the aggregates taken separately, since the finer materials (including the cement) enter more or less into the voids of the coarse aggregate. Table 5 gives for different proportions the volume of cement and aggregates necessary to produce 1 cu. yd. of concrete. The table is based on volumes of a barrel of cement equivalent to 4 cu. ft. The percentages of voids assumed in the broken stone or gravel are given at the head of the table.

Table 5. Quantities of Material for 1 Cu. Yd. of Rammed Concrete

(Taylor and Thompson. Based on a barrel of 4 cu. ft.)

Proportions by parts			Volume of mortar in terms of percentage of volume of stone	Broken stone screened to uniform size, voids 50 %			Average conditions, broken stone with dust screened out, voids 45 %			Gravel or mixed stone and gravel, voids 40 %			Scientifically graded mixtures, voids 30 %			Scientifically graded mixtures, voids 20 %

1	6	12	46	0.59	0.52	1.05	0.56	0.50	1.00	0.53	0.47	0.94	0.48	0.43	0.85	0.44	0.39	0.78

Mixing. In order to get good concrete, the cement and aggregates must be thoroughly mixed so as to distribute evenly the cement and sand throughout the whole mass of concrete. Mixing may be done either by hand or machine. Concrete is prepared by **hand mixing** for small jobs or where only a small amount of concrete is deposited in one place. The mixing must be done thoroughly on a water-tight mixing platform. A good method of mixing concrete is as follows: The sand is measured and spread on the platform, then a proper amount of cement placed on the top, and the two materials mixed until the color is uniform. In the meantime, screened gravel or stone is placed in measuring box on the platform. After removing the box, the gravel is hollowed out slightly in the center and sand and cement are shoveled on top, covering the gravel with a layer of even thickness. A definite number of pails of water is poured on the top of these layers, and then the whole mass is mixed by shovels, each man lifting a shovelful of material, turning it, and spreading it on the platform about 2 ft. from its original position. The operation is repeated several times. As a rule, three turnings are sufficient. **Machine-mixed concrete** is employed almost universally on important work. A good concrete mixer not only stirs the mass, which undisturbed would tend to separate into light and heavy particles, but cuts it again and again, and repeatedly transfers the material from one part of the machine to another and in that way makes the product homogeneous.

Concrete Mixers are of two classes: (1) Continuous mixers, into which material is dumped continuously; and (2) batch mixers. Batch mixers are apt to give more uniform results because it is easier to supply the materials in the same proportions. Continuous and batch mixers may be classified in three general types: (a) **Rotating mixers**, consisting of a revolving drum or of a square box revolving about its diagonal axis. Some of these are provided with deflectors and blades which make the mixing more thorough; (b) **Paddle mixers**, consisting of a stationary box with movable paddles which perform the mixing; (c) **Gravity mixers**, which consist either of a steel trough of sufficient length with blades and deflectors, where materials are mixed by falling through the trough and striking the obstructions in their descent in the machine, or a number of boxes placed one above the other so that the materials become mixed in the passage from one box to another. The mixers are placed in many cases under the storage bin, so that the materials are directly discharged into them. In choosing between power and gravity mixers, it must be remembered that the only saving effected by using the gravity mixer is the cost of the power, and this saving may be overbalanced by the poorer quality of the concrete obtained. Rotating mixers are more generally used than those of the paddle type.

Consistency of Concrete. The consistency to be used depends upon the character of the structure. **Medium or quaking concrete** is adapted for ordinary mass concrete such as foundations, heavy walls, large arches, piers, and abutments. **Mushy concrete** is suitable for rubble concrete and for reinforced concrete, such as thin building walls, columns, floors, conduits, and tanks. **Dry concrete** may be employed in dry locations for mass foundations which must withstand severe compressive strain within one month after placing, providing it is carefully spread in layers not over 6 in. thick and is thoroughly rammed. The term "medium" or "quaking" mixture applies to a tenacious, jelly-like consistency which shakes on ramming. A "mushy" mixture will settle to a level surface when dumped in a pile and will flow very sluggishly into the forms or around the reinforcing bars; a "dry" mixture has the consistency of damp earth. A very wet mixture is much weaker than a quaking or a mushy mixture, the quality of the cement being frequently injured by an excess of water.

Weight of Concrete. The following are average weights per cubic foot of Portland cement concrete:

Cinder concrete	112 lb.	Limestone concrete	148 lb.
Conglomerate concrete	150 lb.	Sandstone concrete	143 lb.
Gravel concrete	150 lb.	Trap concrete	155 lb.

Loose unrammed concrete is from 5 per cent. to 25 per cent. lighter than concrete in place, varying with the consistency.

Strength of Concrete

The strength of concrete increases (1) with the quantity of cement in a unit volume; (2) with the density of the concrete; (3) with the size of the coarsest aggregate. Angular aggregates, like broken stone, produce slightly stronger concrete than rounded gravel. Specially graded mixtures of aggregates produce concrete of higher strength. Strength is decreased by an excess of sand over that required to fill the voids in the stone.

Compressive Strength of Concrete. Table 6 gives the results of tests with first-class materials and under first-class conditions. Growth in strength with age depends in a large measure upon the consistency. For medium consistency, the strength at 6 months is apt to be one-third greater than at 28 days. With wet consistency the strength is usually 50 per cent. greater at 6 months than at 30 days.

Table 6. Compressive Strengths of Different Mixtures of Concrete, Lb. per Sq. In.

(From Report of Joint Committee on Concrete and Reinforced Concrete)

Aggregate	Proportions by parts				
	1 : 1 : 2	1 : 1½ : 3	1 : 2 : 4	1 : 2½ : 5	1 : 3 : 6
Granite, trap rock	3,300	2,800	2,200	1,800	1,400
Gravel, hard limestone and hard sandstone	3,000	2,500	2,000	1,600	1,300
Soft limestone and sandstone	2,200	1,800	1,500	1,200	1,000
Cinders	800	700	600	500	400

Transverse Strength of Plain Concrete. The tensile strength of concrete is of less importance than the crushing strength, as the tensile strength of concrete is seldom relied upon and beams are built with steel reinforcement placed in the tensile part of the beam. There is no fixed relation between the tensile fiber stress of concrete beams and the crushing strength. The growth of strength is different in the two classes of strength. Experiments by the author comparing 8-in. cubes and 8-in. beams of 1 : 2½ : 5 concrete give a ratio of crushing strength to modulus of rupture at 1 and 2 months of 6 to 1.

Strength of Concrete in Direct Shear is from 60 to 80 per cent. of the compressive strength of concrete. The direct shear must not be confounded with shear in a beam involving diagonal tension where the concrete may break with a shearing stress equal to 5 to 10 per cent. of its crushing strength.

Water-tightness. Concrete can be made practically impervious to water by proper proportioning and mixing and placing. Leakage through concrete walls is usually due to poor workmanship or occurs at the joints between two days' work or through cracks formed by contraction. New concrete may be bonded to old by wetting the old surface, plastering it with neat cement, and then placing the concrete before the neat cement has set. Contraction cracks are almost impossible to prevent entirely, although a sufficient amount of reinforcement may reduce their width so as to permit only seepage of water. To get the best results, either a quaking or wet consistency should be used; the concrete must be placed carefully so as to leave no visible stone pockets; the entire structure should be made without joints and preferably in one continuous operation.

For maximum water-tightness, mortar and concrete may require more fine material than would be used for maximum strength. Gravel produces more water-tight concrete than broken stone under similar conditions. Pure **clay** finely powdered used in proportions up to 5 per cent. of the weight of sand has been found to appreciably increase the water-tightness of concrete. **Lime** or puzzolan cement added to concrete increases its water-tightness, but decreases its strength. **Patented compounds** are on the market for producing water-tight concrete, but under most conditions results as good may be obtained for less cost by increasing the percentage of cement in the mix. **Membrane waterproofing,** consisting of asphalt or tar with layers of felt or tarred paper with asphalt or tar, is advisable in certain cases. **Mortar** troweled on very hard by a plan similar to that followed in the hydrolithic process, may produce water-tight work.

According to Fuller and Thompson (*Trans. Am. Soc. C. E.*, vol. 59, p. 67), **water-tightness increases** (1) as the percentage of cement is increased and in a very much larger ratio; (2) as the maximum size of stone is increased, provided the mixture is homogeneous; (3) materially with age; and (4) with thickness of the concrete, but in a much larger ratio. It **decreases** uniformly with increase in pressure.

Protection of Metal from Rust and Fire. Reinforcement properly imbedded in dense concrete is protected against rust and against damage by fire. According to tests made by Prof. Charles Norton in America and Probst in Germany, dense concrete not only protects clean steel against rust, but also checks the progress of rusting in rusted steel imbedded in concrete. Small invisible cracks which form in the tensile part of a loaded reinforced beam or slab do not lower appreciably the protective qualities of concrete. On the other hand, with a porous concrete or one which contains serious structural cracks, moisture may penetrate and seriously rust the steel reinforcement. (See also p. 560.)

Freezing retards the setting and hardening of Portland cement concrete and lowers its strength at short periods, but the ultimate strength is but little affected. On exposed surfaces, such as walls and sidewalks, placed in freezing weather, a thin scale is apt to crack from the surface. The setting can be hastened and the action of frost retarded by heating the materials and also by adding salt in quantities up to 10 per cent. of the weight of water. Salt lowers the freezing point of water and its addition does not affect the strength of the concrete, although its use in reinforced concrete is somewhat questionable. Calcium chloride, using 2 per cent. of the weight of the cement, also retards freezing. Natural cement is completely ruined by freezing. Concreting in freezing weather should be avoided if possible; if unavoidable, precautions must be taken to prevent freezing of the concrete.

Sand vs. Broken-stone Screenings. Sand may often be replaced by broken-stone screenings, which will give satisfactory results provided the quantity of dust is not excessive. For most purposes not more than 10 per cent. should pass a No. 100 screen. For floors and sidewalks, the dust must be entirely removed.

Effect of Mica and Clay on Sand. Mica in sand, if over 2 per cent., reduces the density of mortar and consequently the strength. In crushed-stone screenings the effect of the same percentage of mica in the natural state is less marked. Black mica, which has a different crystalline form, is not injurious to mortar. Clay in sand may be injurious because of introducing too much fine material or forming balls in the concrete. When not excessive in quantity, it may increase the strength and water-tightness of a mortar of proportions 1 : 3 or leaner.

Effect of Regaging Mortar or Concrete. Although laboratory tests show that the ultimate strength of Portland cement mortars is not lowered by regaging, it is not permissible in practice to use mortar or concrete that has been regaged after beginning to set. The hardening is greatly retarded and in cases where moisture cannot reach it, it may never harden.

Effect of Oils, Acids, Manure and Electrolytic Action on Mortar and Concrete. Certain tests indicate increased water-tightness from the introduction of oil in cement or mortar. Mineral **oils** externally applied do not injure concrete. Animal fats and vegetable oils, however, tend to disintegrate concrete unless it has thoroughly hardened. Concrete after it has thoroughly hardened resists the attack of diluted **acids**, but is disintegrated by strong acids. Green concrete is injured by **manure**, but is not affected after it has thoroughly hardened. **Electrolysis** injures concrete under certain conditions (see p. 560), and electric currents should be prevented from reaching it.

Effect of Sea Water. Sea water attacks cement and disintegrates concrete unless it is made with the very best materials under the best possible conditions. Deleterious action is greatly accelerated by frost. To prevent serious damage, the concrete must be made with a rich mix (not leaner than 1 : 2 : 4), and with exceptionally good aggregates including a coarse sand, and must be allowed to thoroughly harden before it is touched by the sea water. Tests indicate that there is no essential difference in the strength of mortar gaged with fresh and with sea water, although the latter tends to retard the setting to a slight degree.

WOOD

BY

HERMANN VON SCHRENK AND WILLIAM KENDRICK HATT

GENERAL PROPERTIES OF WOOD

BY

HERMANN VON SCHRENK

REFERENCES: Bulletins and Circulars of the U. S. Forest Service. Weiss, "Preservation of Structural Timbers," McGraw-Hill. Record, "Identification of the Economic Woods of the United States," Wiley. Johnson, "Materials of Construction," Wiley.

Definitions and Classification. Timbers are classed commercially as hardwoods and softwoods. Typical **hardwoods** are oak, ash, chestnut, hickory, maple and poplar; typical **softwoods** are pines, hemlock, spruce, larch, fir and cedar. The terms "hard" and "soft" do not necessarily refer to actual hardness (see table below). In all timbers two forms are distinguished, heart and sapwood. **Heartwood** is the inner part of a tree, usually darker in color than **sapwood** (the outer part), frequently heavier, and more decay-resistant. Knots or branch inclusions (loose or solid) are defined as **pin knots** (not over ½-in. in diam)., **standard knots** (not over 1½ in.) **large knots** (more than 1½ in.), **sound knots** (solidly grown together with the surrounding wood), **loose knots** (not held firmly in place by growth or position), **pith knots** (sound knots with pith holes not more than ¼ in. in diam.), **encased knots** (*i.e.*, entirely surrounded by bark or pith), **rotten** (decayed) **knots, spike knots** (knots sawed lengthwise). Recognized **defects** are **wane,** bark or the lack of wood from any cause on the edge; **shakes,** splits or checks in timber, which usually cause a separation of the wood between annual rings; **sap stain,** a discoloration of the sapwood; **pitch pockets,** openings between the grain of the wood, containing more or less pitch; **dote** and **red heart,** various forms of decay.

Timbers are sold under various names. The following list of **standard names of timbers** has been adopted by the Master Car Builders' Association, and in part by the American Railway Engineering Association and the American Society for Testing Materials. The varieties included in each name are given in parentheses.

Ash (white, black, blue, green and red ash); **basswood** (linden, linn, lind or lime-tree); **beech** (red and white beech); **birch** (red, white, yellow and black birch); **buckeye** (wood from the horse-chestnut tree); **butternut** (butternut also known as white walnut); **cherry** (sweet, sour, red, black and wild cherry); **chestnut; cottonwood; cypress** [red, gulf, yellow and East Coast cypress (bald cypress)]; **elm, soft** (white, water, gray, red or slippery and winged elm); **elm, rock** (rock or cork elm); **Douglas fir** (yellow, red, Western, Washington, Oregon, Puget Sound fir or pine, West Coast fir); **gum** (red gum, sweet gum or satin walnut); **hemlock** (Eastern hemlock, *i.e.*, from all states east of and including Minnesota); **Western hemlock** (hemlock from the Pacific Coast); **hickory** (shellbark, kingnut, mockernut, pignut, black, shagbark and bitternut); **Western larch** (larch or tamarack from the Rocky Mountain and Pacific Coast regions); **maple, soft** (soft and white maple); **maple, hard** (hard, red, rock and sugar maple); **white oak** (white, burr or mossy cup, rock, post or iron, overcup, swamp, post, live, chestnut or tan bark, yellow and basket or cow oak); **red oak** (red, pin, black, water, willow, Spanish, scarlet, Turkey, black jack or barn, and shingle or laurel oak); **pecan; Southern yellow pine** (all pines of the Southern States manufactured into lumber, including longleaf, shortleaf, loblolly and Cuban pines. The lumber is divided according to quality into "dense southern yellow pine" and "sound southern yellow pine;" dense southern yellow pine should show on either end an average of at least six annual rings per inch and at least one-third summerwood, or else the greater number of rings should show at least one-third summerwood, all as measured over the third, fourth and fifth inches on a radial line from the pith; wide-ringed material excluded by this rule is acceptable, provided the amount of summerwood, as above measured, is at least one-half; the contrast in the color between summerwood and springwood should be sharp, and the summerwood should be dark in color, except in pieces having considerably above the minimum requirement for summerwood; sound southern yellow pine includes pieces of southern yellow pine without any ring or summerwood requirement); **white pine** (wood from tree of that name grown in Maine, Michigan, Wisconsin, Minnesota and Canada); **Norway pine** (Norway or red pine grown in Michigan, Minnesota, Wisconsin and Canada); **Idaho white pine** (varieties of white pine grown in Western Montana, Northern Idaho and Eastern Washington); **Western pine** (timber known as white pine grown in Arizona, California, New Mexico, Colorado, Oregon and Washington; sometimes known as Western yellow or ponderosa pine, or California white pine or Western white pine); **poplar** (wood from the tulip tree, otherwise known as whitewood, yellow poplar and canary wood); **redwood; spruce** (spruce timber from points east of and including Minnesota and Canada, covering white, red and black spruce); **Western spruce** (spruce timber from the Pacific Coast); **sycamore; tamarack** (tamarack or eastern tamarack, grown in states east of and including Minnesota); **tupelo** (tupelo gum and bay poplar); **walnut** (black walnut).

Physical Properties

Weight and Specific Gravity. The weight of wood will vary with the amount of water contained, and (within a given species) with the age, part of tree from which the wood is cut, geographical location, etc. In general, green wood will contain 50 to 75 per cent., air-dry wood 10 to 20 per cent. water. In general practice, a wood weighing less than 30 lb. per cu. ft. is called light; one between 30 and 40 lb., medium; and one more than 40 lb., heavy. The approximate air-dry weight of any wood is from 10 to 20 per cent. higher than its absolute dry weight. For the **specific gravity** of various woods, see p. 586; for weights per cu. ft., see pp. 454 and 608.

Hardness. According to Schenck ("Forest Utilisation"), dense woods are the harder. Wide rings in oak and narrow rings in pine indicate superior hardness. Heartwood is harder than sapwood, and dry wood generally harder than green wood. Frost increases hardness.

Relative Hardness of Woods

Hard: Hickory, dogwood, sugar maple, sycamore, locust, hornbeam, persimmon.
Medium: Ash, oak, elm, beech, cherry, mulberry, birch, sour gum, longleaf pine.
Soft: Chestnut, tulip tree, sweet gum, Douglas fir, yellow pine, larch, basswood, horse-chestnut, hemlock, cottonwood, spruce.
Very soft: White pine, sugar pine, redwood, willow.

A scale of hardness frequently used is as follows:

Scale of Hardness of Wood

Shellbark hickory	100	White hazel	72	Yellow oak	60	Chestnut	52
Pignut hickory	96	Apple tree	70	Hard maple	56	Yellow poplar	51
White oak	84	Red oak	69	White elm	58	Butternut	43
White ash	77	White beech	65	Red cedar	56	White birch	43
Dogwood	75	Black walnut	65	Wild cherry	55	White pine	30
Scrub oak	73	Black birch	62	Yellow pine	54		

Cleavability is inversely as the resistance to splitting in a lengthwise direction. According to Schenck ("Forest Utilisation"), cleavability is affected by: (*a*) the straightness, length and elasticity of the fiber; (*b*) the heaviness of the medullary rays; (*c*) straightness of growth; (*d*) branchiness; (*e*) moisture (the higher the moisture the easier the wood can be split); (*f*) frost (reduces cleavability); (*g*) hardness.

Relative Cleavability of Woods

Hard to split: Black gum, elm, sycamore, dogwood, beech, holly, maple, birch, hornbeam.
Medium: Oak, ash, larch, cottonwood, linden, yellow poplar, hickory.
Easy to split: Chestnut, pines, spruce, fir, cedar.

Calorific Value. The **specific heat** of practically all kinds of wood when oven-dry is 0.327 (Dunlap, *Forest Service Bulletin* No. 110, 1912). The calorific value of wood depends on its specific gravity (dry), heavier woods giving more heat than light woods. According to Schenck, 1 cord of green wood contains 250 gal. of water, and the heat required to evaporate this into steam is not available for other heating purposes. According to German experiments, wood with 45 per cent. moisture gives only 50 per cent. as much heat as dry wood. Rosin increases the heating power by about 12 per cent. According to Roth, 100 lb. of wood, as sold in wood yards, contains 25 lb. of water, 74 lb. of (dry) wood, and 1 lb. of ashes. Thus, 100 lb. of green wood (50 per cent. moisture) furnish about 270,000 B.t.u., 100 lb. of air-dry wood (10 per cent. moisture) about 580,000 B.t.u., and 100 lb. of kiln-dry wood (2 per cent. moisture) about 630,000 B.t.u.

Relative Values of Woods as Fuels

Best: Hickory, beech, hornbeam, locust, heart pine.
Good: Oak, ash, birch, maple.
Moderate: Spruce, fir, chestnut, hemlock, sap pine.
Poor: White pine, alder, linden, cottonwood.

Strength of Woods. See p. 585.

Analyses of Wood. See p. 609.

Decay and Destruction of Timber

Decay in timber is caused by fungi growing in the wood fiber and is favored by the presence of oxygen, water, heat and food supply. Timber suffering from the forms of decay usually distinguished as dry **rot**, moist rot, wet rot, brown rot, etc., has little practical value. Decayed wood is lighter than sound wood, and loses its strength rapidly as the decay progresses.

Absolutely dry wood will not decay, nor will wood decay when constantly submerged in water, nor when kept more than 4 ft. under ground. Poles and posts decay chiefly at the ground line. Construction timbers in buildings, bridges, etc., decay most rapidly at points where they come in contact either with other timbers, with the ground, or with stone or concrete walls. Any conditions favoring the retention of water in the timbers, particularly where the temperature is from 60 to 85 deg. fahr., will bring about decay. Sapwood of all timbers decays very rapidly, heartwood is usually more resistant. In structural timbers decay frequently appears in the inner sapwood, so as not to be observable from the outside, even by the most careful inspection. This form of decay is usually termed "internal sap rot." Where strength is the principal requirement, the most careful examination of timbers with large amounts of sapwood should be made, particularly if there is evidence that such timbers have been cut from the tree more than 2 or 3 months after felling. This applies particularly to all forms of piling, stringers, posts, caps, etc.

Blue Stain is a grayish-blue discoloration found in the sapwoods of pines and other coniferous woods, due to a minute fungus (*Ceratostomella pilifera*) growing in the wood fiber. It has no effect on the strength of the wood, and may be prevented by dipping the freshly sawed lumber in a 5-per cent. solution of sodium carbonate kept at about 140 deg. fahr.

Decay of Living Trees. Where decay, or dote, is found in the heartwood of timbers, it is usually due to disease of the living trees. Different forms of such decay are distinguished in conifers as red heart, dote, rot, and in hardwoods as piped rot, brown rot, speckled rot, etc. All of these forms of decay cease after trees are felled, and cannot be communicated to other pieces of sound structural timber.

Weathering is the wearing away of the surface of timbers caused by exposure to the elements, and is of importance only with comparatively soft woods. Different forms are distinguished according to the color, as white, gray or brown weathering.

Life of Woods. The natural length of life of wood and its resistance to decay vary with the kind of wood and the conditions under which it is used. In general, woods may be classed as long-lived, medium-lived and short-lived, as indicated below.

Long-lived: Cypress, redwood, red cedar, white cedar, osage orange, catalpa.

Medium-lived: White oak, slippery elm, black walnut, hickory, longleaf pine, tamarack, Douglas fir.

Short-lived: Red oak, red gum, beech, elm, spruce, shortleaf pine, hemlock.

Destruction of Wood by Marine Animals. Piling and other timbers exposed to salt water in warm climates are destroyed by various species of marine wood borers, of which the principal forms are the teredo (known as the ship worm) and the limnoria (sometimes, through resemblance, called a wood louse). The teredo thrives in waters with a saline density above 1.0054, and at temperatures of from 55 deg. fahr. to the highest found along our coasts. It lives in clear and turbid water, but seldom to a depth below 30 ft. It works most rapidly in warm water. Unprotected pine piles will be destroyed in approximately the following times at various points: Norfolk, Va., 1 to 5 years; Pensacola, Fla., 1 to 3 years; Galveston, Tex., 5 months to 1½ years; Colon, Panama, 9 months to 1 year; Puget Sound points, 1 year; Klawak, Alaska, 1½ to 3 years. The limnoria requires pure salt water and cannot live in dirty water. It occurs sparingly in Long Island Sound, is quite abundant along the coast of Massachusetts, and does great damage along the Gulf of Mexico and along the North Pacific Coast. All woods used for piling are subject to the attack of marine borers. (For preventive measures, see Creosoting, p. 581. For description, see United States Forest Service Circular No. 128, "Preservation of Piling against Marine Borers," and Chas. H. Snow, New York University, Lectures on Marine Borers, 1908.)

Timber Preservation

Seasoning of Timber. Timber can be seasoned either by air drying or by artificial means. In **air drying** excessive splitting may be prevented either by painting the exposed ends of logs, timbers or planks with common paint or preferably with coal-tar creosote, or by driving in sharp-edged irons of wedge section, shaped in the form of the letter S, and usually called S-irons. The base of the wedge section should be ⅛ in. thick. **Artificial drying** is usually done in kilns. Coniferous woods can be dried more rapidly than hardwoods and at higher temperatures, without affecting their strength. The latter should be dried very slowly. Small pieces of wood can be dried so as to prevent checking by soaking them from 1 to 7 days in a concentrated salt solution. The soaked pieces should then be piled in the air to dry. Another plan for drying small pieces is to pile them in bone charcoal.

Timber Preservation. The prevention of decay due to fungi and the protection of timber against wood borers are accomplished by the injection of various chemicals. The principal requirements for successful chemical preservation are: As thorough impregnation of the wood as can be obtained; the injection of sufficiently large quantities of the preservative; the injection of efficient chemicals; and the use of thoroughly sound and seasoned wood.

The **penetration** obtained will vary with the preservative. Water solutions, such as mercuric chloride and zinc chloride, will usually penetrate clear through a stick. Coal-tar creosote will penetrate sapwood only in coniferous woods (the heartwood of pines is slightly penetrable in large pieces, wholly so in small pieces like paving blocks), and in many hardwoods such as gum, white oak, hickory and ash. It will penetrate into the heartwood of red oak, elm and sycamore, and into the heartwood of small pieces of pine, spruce, etc., such as paving blocks. Individual pieces of timber absorb different quantities of preservative. In one run of a thousand ties treated with creosote, where all the ties were exactly the same size, the average absorption was 23 lb. of creosote, but some of the pieces absorbed as low as 2 lb. and some as high as 90 lb.

Wherever possible, only thoroughly air-seasoned timber should be treated, because the higher the percentage of moisture in a wood, the poorer the penetration obtained. Wherever possible, all injuries to wood after treatment should be avoided. All framing, boring and adzing should be done before treatment.

The **principal preservatives** used, mentioned in the order of their efficiency, are coal-tar creosote (known also as dead oil of coal tar, or creosote oil), mercuric chloride and zinc chloride.

Processes of Treatment

Zinc-chloride Treatment or Burnettizing Process. In this process a solution of zinc chloride at 140 deg. fahr., is injected into timber under pressure, with preliminary steaming in the case of green timber. According to standard practice ½ lb. of dry zinc chloride is injected per cu. ft. of timber. For pine and other coniferous woods, the strength of the solution will vary from 2½ to 4 per cent.; for hard-wood, such as red oak, it will usually be about 4 per cent.; under no circumstances should it exceed 5 per cent. The strength of the solution should be controlled either by hydrometer readings or, preferably, by chemical titration. Zinc chloride may be purchased either in crystalline form or in the form of a 50 per cent. solution. Care should be observed that the material does not contain free hydrochloric acid or basic chloride of zinc; the former reducing the strength of the timber and the latter reducing the antiseptic properties. The material is soluble in water and consequently tends to be washed and leached out of timber in damp locations or where subjected to rain. Combinations of zinc chloride with creosote have been used to offset this characteristic, using either the Card or the Allardyce process (see below).

Kyanizing or Mercuric-chloride Treatment. In this process the timber is soaked in a vat built entirely of wood and filled with a solution of corrosive sublimate, one part of sublimate to 150 parts of water. The strength of the solution decreases as it is used, and must therefore be renewed by adding more sublimate from time to time. The vat should be kept covered. The wood is left in the vat for from 5 to 10 days, according to the size of the timber, until a thorough absorption of the liquid has taken place. Corrosive sublimate is an excellent preservative, particularly for fence posts, sticks, and for use where creosote, because of its odor and physical nature, cannot be used. Care should be exercised to prevent unnecessary handling of this very poisonous salt. (In case of poisoning, drink large quantities of milk or water into which well-beaten fresh eggs have been stirred.)

The Factory Mutual Insurance Companies of Boston recommend (1915) that longleaf pine used in mill construction be soaked for a week in a 1 per cent. solution of corrosive sublimate, and state that the cost of treatment at the mills is about $3 per thousand. They require that portions of the wood exposed after treatment by cutting should be thoroughly swabbed with the solution.

Creosoting, with its several modifications, is the best preservative for practically all purposes. There are several processes in use, distinguished as the Bethel or plain creosoting process, the Lowry process, the Rüping process, and the boiling process.

Creosote or Dead Oil of Coal Tar is a by-product of coal tar in the manufacture of illuminating gas and by-product coke. Tar is distilled and the condensed vapors are separated into the light oils or naphtha, the dead oil or creosote, and pitch. Creosote is not a simple substance but contains a large number of chemical constituents. At 65 deg. fahr., it weighs about 8.7 lb. per gal.; at 100 deg. fahr. the specific gravity ranges from 1.03 to 1.08. It has high antiseptic properties and is insoluble in water. There are several grades of coal-tar creosote recognized in the trade, which are distinguished chiefly by their specific gravities and percentages of low and high boiling compounds. The heavier oils are considered the more valuable. Coal-tar creosote is usually injected into timber under pressure. In addition to creosote there are a number of trade-mark compounds (Carbolineum, Barol, etc.) which are usually used for brush applications.

Wood tar, when distilled, yields a **wood creosote** possessing weak antiseptic properties. Water-gas creosote is obtained as a by-product of water-gas tar, and is probably inferior to coal-tar creosote. Very little commercial use has been made of wood creosote for wood preservation, and the term "creosote" generally refers to the dead oil of coal tar.

Difference of opinion exists as to the desirable components of creosote. In view of this fact, most creosote specifications confine themselves to the requirement that the material be a straight product of coal tar distillation, free from adulteration, with limited material insoluble in benzol, and that certain definite percentages distill at standard temperatures.

For Standard Specifications for Creosote, see also Manual of the Am. Ry. Eng. Assn., 1912, p. 65; and *Proc. Am. Ry. Eng. Assn.*, 1915, p. 826.

In the **Bethel Process** a preliminary vacuum is maintained, after which creosote is injected under pressure varying from 40 to 200 lb. per sq. in., which is continued until the desired absorption has been obtained. The amount of creosote injected will vary from 10 to 25 lb. per cu. ft. The plain Bethel or full-cell creosoting process is used largely for the treatment of piling, bridge materials, paving blocks, telegraph poles, etc. It is applied chiefly to timber of which long service is expected, and where mechanical or destructive processes, aside from decay, are of minor importance. In general, bridge materials, piling, poles, and similar timbers are treated with 10 to 15 lb. of creosote per cu. ft. for regions north of the Ohio River and with 15 to 20 lb. for regions south of the Ohio River. Exceptions to this rule are made for piling, for which the following standards may be used: For marine exposure on the Atlantic Coast north of Delaware Bay, 12 to 15 lb. per cu. ft.; on the Atlantic Coast south of Delaware Bay and on the Gulf and Pacific Coast, 20 to 25 lb. per cu. ft. (see *Proc. Am. Ry. Eng. Assn.*, vol. 9, p. 352, 1908).

Lowry Process. This process aims to secure a good penetration with comparatively small quantities of creosote. Air-dry timber only is treated. Creosote oil is forced into the timber without a preliminary vacuum until a large quantity of creosote is absorbed, usually stated as "treatment to a refusal." A quick final vacuum is then applied and a considerable amount of the oil first injected is withdrawn. According to standard practice in railway tie treatment, about 2½ gal. of creosote remain in a 6 × 8 × 8 tie.

Rüping Process. This process likewise is intended to secure a good penetration with comparatively small quantities of oil. Compressed air is first forced into the wood up to a pressure of 75 lb. per sq. in., after which creosote oil is forced in at a higher pressure until treatment to a refusal is obtained. A final vacuum aids the compressed air in driving out a considerable quantity of the oil originally injected. According to standard practice, from 1.8 to 2 gal. are left in a railway tie at the end of the treatment.

Boiling Process. This process is used chiefly for the treatment of Douglas fir on the Pacific Coast. The green timber is placed in the creosoting cylinder, which is then filled with creosote and heated to a point slightly above the boiling point of water. This heating is maintained until practically no water comes out of the condenser. Pressure is then applied and the preservative is forced into the timber to the requisite amount.

Allardyce Process. In this process zinc chloride is first injected into the timber followed by a subsequent injection of creosote, usually 3 lb. of creosote per cu. ft.

Card Process. The preserving liquid used in this process is made up of 15 to 20 per cent. of creosote and the remainder of a 3 to 5 per cent. solution of zinc chloride. The creosote and zinc chloride are mixed in a centrifugal pump and the emulsion thus produced is forced into the timber under pressure.

Open-tank Treatment. Under this name a number of methods have been devised for treating timber, without pressure, with either zinc chloride or creosote. The timber to be treated is put into an open tank or vat and heated in a hot liquid for several hours. It is then quickly immersed in a cold liquid, either zinc chloride or creosote. During the heating process a partial vacuum is produced in the interstices of the wood, and when the hot wood is put in the cold bath, the atmospheric pressure is sufficient to bring about considerable absorption. This process is adapted particularly to the treatment of small quantities of timber in localities where larger treating plants are not available. (For details, see Forest Service Circulars Nos. 101, 104, 111 and 117.)

Cost of Treatment. The cost of treatment with zinc chloride varies from 4 to 6 cents per cu. ft. of timber treated, and with corrosive sublimate from 4 to 5 cents per cu. ft. In the full-cell creosote process the cost ranges from about \$15 to \$25 per 1000 ft. B.M., depending upon the amount of creosote used. In the treatment of 6 × 8 × 8 railroad cross-ties, with injections of ½ lb. of zinc chloride per cu. ft., the cost is from 11 to 15 cents per tie; with injections of creosote according to the Lowry process, about 30 cents per tie; with injections of creosote according to the Rüping process, from 20 to 25 cents per tie.

Length of Life Obtained from Treatment. Red oak and pine cross-ties treated with zinc chloride have given an average service of from 6 to 11 years. Pine timbers treated with creosote have lasted 15 to 20 years in the Southern States, with many of them still in service. Piling, when treated with an oil of high specific gravity, will last 15 years or more under ordinary conditions of service. (For a brief account of wood preservation, see Forest Service Bulletin No. 78.)

Standard Sizes and Shipping Weights of Lumber

Lumber is manufactured in various sizes. The standard of measurement is the board foot, equal to a piece of lumber 1 ft. square and 1 in. thick. Thus, a timber 12 in. × 12 in. × 20 ft. contains 240 feet B.M. (Board Measure). A distinction is made between rough lumber and finished lumber. Excepting only a few rarer woods, lumber and timbers are usually cut in even lengths, that is, 2 × 4 in., 2 × 6 in. 2 × 8 in. etc., in lengths of from 12 to 30 ft. Finished lumber is designated as S1S when surfaced on one side, S2S when surfaced on both sides, as D & M when dressed and matched, and as E when edged.

All lumber is classified into standard grades, these being determined by the size, absence or presence of standard defects. These grades have been standardized by associations of lumber manufacturers.

Shingles. Pine shingles are usually 16 in. long, 2¼ to 14 in. wide, $\frac{1}{16}$ in. thick at the small end and $\frac{5}{16}$ in. thick at the butt end. A standard shingle is 4 in. wide. Cypress shingles are 16 in. long and 5 butts measure 2 in. in thickness. A thousand shingles (4 to 5 bundles) will cover from 100 to 150 sq. ft. of roof, according as laid from 4 to 6 in. to the weather. Shingles are usually laid to show 4 in. of their length, forming with 16-in. shingles a quadruple layer on a roof. The higher the grade of the shingles the larger the weather face permissible. Cypress shingles are the most durable, followed by redwood, cedar, pine and spruce (poor). Redwood shingles are the least inflammable. The **weight** of shingles (lb. per 1000 shingles) is approximately as follows: Cypress, 300; western white pine, 250; Washington cedar, 160 to 220; redwood (6 × 16-in., per bundle of 147), 42.5.

Cordwood. Firewood, pulpwood and other small pieces of wood are usually bought and sold by the cord. A cord is equal to 128 cu. ft. of stacked wood. The **standard cord** is a stack of wood cut into 4-ft. lengths, that is, 4 ft. high and 8 ft. long. A cord foot is one-eighth of a cord. The expression "surface feet" means the number of square feet measured on the side of the stack. In countries using the metric system, wood is piled in cubic meters. (1 cu. m. = 0.274 cord.) The actual volume of solid wood in a cord will depend, among other factors, on the form and size of the sticks, the amount of bark, whether split, and on the method of stacking (see Table 3). Ordinary conifers produce a greater amount of wood per cord than hardwoods, because of the smoother, straighter sticks. One cord of first-class split wood obtained from sound pieces 12 in. in diam. contains 102.4 cu. ft. of solid wood. Composed of inferior pieces having a diam. of 6 in., a cord contains 97 cu. ft. of solid wood. While no absolute ratio can be given of the relation between cord measure and board measure, a fair average is 6 board-feet to each cubic foot.

Bark is usually sold and bought by the cord. The tanneries, however, apply the name to a weight of 2,240 lb., instead of to 128 cu. ft. Twelve cords of bark fill one common (old) freight car. A stack of bark contains from 30 to 40 per cent. solid bark. The specific gravity of fresh oak bark is 0.874; dried, it is 0.764. The bark of white oak varies from 55 per cent. of the wood in trees 20 years old to 21 per cent. in trees 140 years old. The average bark yield of chestnut oaks per tree (in cords) is as follows: Trees 6 in. in diam., 0.013; 12-in. trees, 0.073; 18-in. trees, 0.195; 24-in. trees, 0.375.

STRENGTH OF WOOD

By

WILLIAM KENDRICK HATT

(For references, see p. 577)

The strength of wood-substance, as arranged in wood structures peculiar to different species, must be distinguished from strength of large timbers containing defects such as knots and crooked grain Wood-substance exhibits an elastic limit under usual rates of test loading; under continuous loads it is markedly plastic and the modulus of elasticity may be only half as great as listed in the tables. Under impact, the elastic limit is frequently twice as great as listed in the tables. Strength is also affected by temperature, and very greatly affected by moisture. Table 1 represents results of a series of timber tests of the Forest Service on representative trees collected from the forest. Inasmuch as the strength of species is affected very greatly by the age of the tree, site conditions, and the inherent variability of individuals, strength values of wood cannot be quoted with any exactness.

Table 1. Strength of Green and Air-seasoned Timber

(Average physical and mechanical properties, based on tests of small clear specimens 2 × 2 in. in cross-section; bending span, 28 in. Mainly from Circular No. 213, U. S. Forest Service)

Species, common name	Condition, green or air dried	Moisture content, per cent.	Specific gravity based on volume when tested*	Shrinkage in volume from green to oven-dry condition, per cent.	Static bending: Fiber stress at elastic limit, lb. per sq. in.	Static bending: Modulus of rupture, lb. per sq. in.	Static bending: Modulus of elasticity, 1000 lb. per sq. in.	Static bending: Work to max. load, in.-lb. per cu. in., U_R	Compression parallel to grain: Crushing strength, lb. per sq. in.	Compression perpendicular to grain: Stress at elastic limit, lb. per sq. in.	Hardness—load required to imbed a 0.444-in. ball to one-half its diam.: End, lb.	Hardness—load required to imbed a 0.444-in. ball to one-half its diam.: Side, lb.	Shearing strength, parallel to grain, lb. per sq. in.

* Both green and dried wood were oven-dry when their specific gravities were determined. The difference in specific gravity in the two cases is due mainly to shrinkage.

Table 2. Strength of Green Wood in Small Perfect Specimens*
(Summary of Table 1. Authority, U. S. Forest Service)

Group	Modulus of rupture, lb. per sq. in.	Compressive strength (parallel to grain), lb. per sq. in.	Woods included in group
I	10,000 to 13,000	4,200 to 6,000	Eucalyptus corynocalyx, osage orange, honey locust, mockernut hickory, pignut hickory, eucalyptus globulus and tereticornia, shagbark hickory, shellbark hickory, eucalyptus viminalis.
II	8,000 to 10,000	3,600 to 4,200	White, green and blue ash, slippery elm, eucalyptus rostrata, rock elm, sugar maple, longleaf pine, beech, yellow oak, yellow and sweet birch, red maple, Douglas fir, red oak, white oak, red wood in compression.
III	7,000 to 8,000	3,400 to 3,600	Slippery elm, loblolly pine, hackberry, poorer qualities of white and red oaks, shortleaf pine, tupelo gum, western hemlock, western larch, black cherry, white elm, cypress, tamarack.
IV	5,000 to 7,000	2,400 to 3,400	Redwood in bending, red gum, sycamore, black ash, white fir, red spruce, eastern hemlock, balsam fir, common catalpa, black spruce, sugar pine, white pine, white spruce, western yellow pine, Norway pine, lodgepole pine, chestnut, cedar, aspen, silver maple.
V	below 5,000	below 2,400	Basswood, hardy catalpa.

* Woods are listed in this table in each group according to strength, which, however, varies with locality and conditions of growth. Strength of wood from young, thrifty trees of hardwood is generally greater than that from old, overmature trees. For hardwoods rapid growth yields greatest strength and toughness. For conifers greatest strength is associated with slower growth. The rates of growth (annual rings per in.) shown in the following list are associated with maximum strength. A ring comprises the spring wood and summer wood of one year's growth: Loblolly pine, 6; shortleaf pine, 12; western hemlock, 14; western larch and Norway pine, 18; tamarack, 20; Douglas fir, 24; redwood, 30.

Relation of Physical Properties to Specific Gravity. As a rule, strength varies directly with the dry specific gravity. An approximate value, S, of various strength functions is given by the equation, $S = mg^n$, where g is the specific gravity of the dry wood and m and n have values which vary with the condition of the wood and the kind of stress to which it is subjected. Thus for small clear specimens, the modulus of rupture is obtained by putting $m = 25{,}530$, and $n = 1.20$; when the wood is green, $m = 19{,}140$ and $n = 1.27$; for green longleaf pine, $m = 20.800$ and $n = 1.5$. (Betts, International Engineering Congress, 1915.) See also Fig. 1. The value of n varies with the strength function under consideration and ranges from unity for compression parallel to the grain to 3 for ultimate rupture work. For shearing stress n is approximately unity.

The density and strength of *summer wood* of the pines are about twice as great as in the *spring wood*. The proportion of summer wood forms an excellent measure of strength.

Moisture Content, Shrinkage, Specific Gravity. The **percentage of moisture** in wood is based upon the oven-dry weight of the wood. Thus wood which weighs 35 lb. per cu. ft. when oven-dry and contains 50 per cent. moisture when green, will then weigh 35 plus 17½ or 52½ lb. per cu. ft. In large beams the cubic foot reckoned is not the shrunk cubic foot when oven-dry, but the cubic foot of volume occupied by the wood at the time of the test.

The **specific gravity** as based on oven-dry volume may be obtained from the specific gravity as based on green volume by allowing for shrinkage.

The **volumetric shrinkage** of wood from the green to the oven-dry state, expressed in percentage of volume, is 26.5 times the specific gravity as based on green volume. Thus, for white oak, shrinkage $= 0.46 \times 26.5 = 12.2$ per cent., and consists almost entirely of lateral contraction.

The specific gravity of **cellulose** is very nearly 1.5. A solid cubic foot of wood-substance would weigh nearly 93.6 lb.

Toughness and Strength. The order of **technological values** of various woods does not coincide with that indicated by the strength values. Toughness and strength combined indicate this value, which is shown by the work U_R required to break a beam. Values of U_R (in.-lb. per cu. in.) are given in Table 1; for hickories and rock elm U_R varies from 24 to 40; ashes and elms, 14 to 24; oaks, black spruce, and maple, 8 to 14; white spruce, firs, and other pines, below 8. This factor U_R does not vary directly with specific gravity. For instance, eucalyptus, a strong and heavy wood is comparatively brittle and ranks low in rupture work.

Tensile Strength. The tensile strength of wood parallel to the fibers (or grain) exceeds all other strength values. At 15 per cent. moisture, values of T.S. (lb. per sq. in.) according to Johnson, are: elm, 29,000; hickory, 32,000; larch, 19,000; longleaf pine, 17,300. Bovey gives 11,612 for Douglas fir, and Isaacs, 15,900. Tensile strength parallel to fiber is not important, for other stresses, as shear, or tension perpendicular to fiber, bending, or bearing govern design. Tensile strength **perpendicular to the fibers** may be taken at 900 lb. per sq. in. for hardwoods and 250 lb. per sq. in. for conifers.

Shearing Strength. The shearing strength **parallel to the fibers** of small, clear, green specimens may be taken as approximately 1100 lb. per sq. in. for hard woods and 600 lb. per sq. in. for conifers except the following: Cypress, Douglas fir, red pine, tamarack (800), and longleaf pine (1000). The values are increased from 50 to 100 per cent. by careful seasoning. For **shear in flexure,** see Tables 3 and 4.

The Strength of Large-sized Pieces of structural timber **containing knots** and other defects is usually not more than two-thirds of the values in Table 1. Tables 3 and 4 (abstracted from publications of Forest Service) give results of tests. The strength of small specimens cut from the beams after test is also included. The strength of timbers of the same apparent grade varies greatly. The average of the lowest 10-per cent. group of a series of values will be from 60 to 70 per cent. of the general average value for the group. The range of individual values low to high may be from 50 to 150 per cent. of the average. Bulletin 108, Forest Service, U. S. Dept. of Agriculture (Cline and Heim), is an authoritative discussion of tests of large sizes of timber and the effects of defects upon strength.

Table 3. Strength of Green Timber, Structural Sizes
(U. S. Forest Service)

Species	Weight of oven-dry wood, lb. per cu. ft.	Number of rings per in.	Bending				Compression				Shear

* Only those pieces which failed first by horizontal shear are included in this column.

Influence of Knots and Other Defects on Strength. Forest Service tests indicate the following relations: Knots which interrupt the grain in the tension face of a beam seriously influence its strength. Knots greater than 1½ in. in diam. diminish compression strength from 15 to 20 per cent. They do not influence stiffness or the elastic limit of beams. For beams the range of stress between the elastic limit and modulus of rupture is seriously influenced by knots, crooked grain and other defects. Checks and shakes both in green and seasoned timber bring about failure of beams by splitting at the ends under horizontal shear. When failure by shear occurs, however, the modulus of rupture is approximately equal to that of beams failing otherwise.

Tests of **large sizes in compression** show the following general ranges of ultimate strength (Lanza): White pine and spruce, 2000 to 3000; yellow pine, 3500 to 5500; white oak, 3000 to 5000.

Strength as Affected by Moisture Content. A comparison of the results of tests on air-seasoned material with those on green material shows that, in general, all of the **mechanical properties** are **improved by seasoning.** Increase in strength is especially marked on small pieces free from defects. Increase in strength of wood fiber due to drying is, in the case of large timbers, largely offset by a weakening of the timber due to the formation of checks. If the moisture content of a seasoned timber is increased it loses strength rapidly, and if thoroughly soaked with water will become slightly weaker than when green. On this account it is not safe in practice to depend upon an increase in strength in timbers due to seasoning. When, however, large beams are seasoned with ordinary care, it is safe to assume that they will not at any time be weaker than they were when green.

Seasoned wood in small pieces is much stronger than green wood. The relation of strength to moisture content depends upon species, whether softwood or hardwood, and upon the kind of loading.

Table 5 shows the **reduction in compressive strength** of several woods **due to increasing the moisture content** from 2 per cent. to the amount indicated. Thus, red spruce with 16 per cent. of moisture has but half (0.505) the strength it has with 2 per cent. of moisture. The table also serves to permit calculations of change in strength for other changes in moisture content.

Table 5. Relation of Moisture Content to Compressive Strength

(a) Green. (b) Air-dry.
(c) Kiln-dry (approx.).

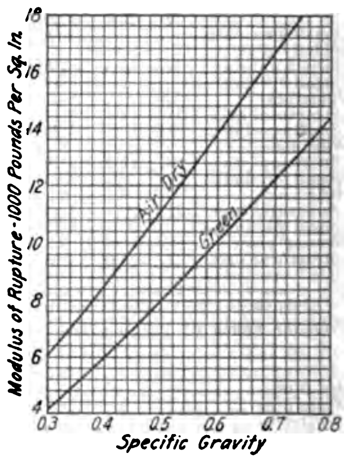

Fig. 1.—Modulus of Rupture of Wood.

The relation between the specific gravity (dry) and the modulus of rupture of both air-dry and green wood as determined by the U. S. Forest Service is shown in Fig. 1. (Newlin, *American Lumberman*, Jan. 16, 1915.)

Working Stresses for Timber for railway trestles and bridges are given in Table 6, and are to be used without increasing the live-load stress for impact. For highway bridges, unit stresses may be increased by 25 per cent. For buildings protected against weather and free from impact, the unit stresses may be increased 50 per cent. The stresses given are for green timbers, but no increase may be allowed for seasoned timber except as stated. **Factors of safety** used in designing timber structures must recognize the uncertainty of the material. Table 6 yields a factor of safety of approximately 5 in bending and 3 in compression.

Table 6. Unit Stresses for Structural Timber in Lb. per Sq. In.
Recommended by the Committee on Wooden Bridges and Trestles of the Am. Ry. Eng. Assn., 1909)

SOLID FUELS

Coal

General. Coal consists of the more resistant parts of ancient vegetation. Different vegetable material has entered into the composition of the different coals, and the geologic experiences of the several beds have been sufficiently different to produce wide variations in composition, constitution and physical characteristics. Any division into groups must be arbitrary, with more or less overlapping of characteristics at the boundaries of each division.

The most evident constituents of any coal can be roughly observed when the coal burns. First moisture is driven off, then volatile matter, leaving coals of fixed carbon, and finally a residue of ash. An analysis which so divides the coal is called a "**proximate analysis.**" These several constituents cannot be sharply separated. The moisture is both free and combined with the coal substance and the amount driven off will depend upon the temperature. The volatile matter is so complex that the amount produced depends upon the temperature and the rate of heating. The ash is also both free and inherent. A proximate analysis depends upon more or less arbitrary standardized methods which, if not rigidly followed, give discordant results for the same coal sample. This analysis is, however, an acceptable indicator of the type of coal.

In the "**ultimate analysis**" of fuels the chemical elements are determined without regard to their combinations. Greater accuracy of determination is possible than with the proximate analysis. This analysis is expressed in terms of carbon, hydrogen, nitrogen, oxygen, sulphur and ash. Either of these analyses may be for fuel "as received," in which case the **moisture** is included in the weight, or may be computed to a "moisture-free" condition or a "moisture-and-ash-free" condition. The moisture in mine samples of fuel is about 2 to 4 per cent. for anthracite coals, 2 to 4 per cent. for bituminous coals of the Appalachian field, 4 to 10 per cent. for Ohio coals and 8 to 17 per cent. for Indiana, Illinois, Iowa and Missouri coals. Lignite fuels increase the amount to 35 per cent. The amount of moisture in commercial coal may be greater or less than that of the coal in the mine. It is usually reduced during shipment and handling, but may be increased by exposure to rain or snow. The free moisture in coal is largely a function of the surface exposed, each surface being capable of holding a film of moisture. Fine sizes of coal will therefore hold much more moisture than lump. Coal which in the mine does not contain more than 4 per cent. of moisture, may, in slack sizes, hold 15 to 18 per cent. moisture. Slack from stock piles in the open may contain as high as 20 per cent. moisture in winter and spring. Lump coal from subaqueous storage or from coal washers contains but little more moisture than the normal coal. The volatile matter in dry fuel covers an equally wide range, from anthracite having as little as 3 per cent. through all gradations to lignite with over 40 per cent.

The character of the **volatile matter** varies quite as much as its quantity, being composed of combustible gases as hydrogen, CO, methane and other hydrocarbons, as well as incombustible gases such as CO_2, water vapor, etc. From 2 per cent. to as high as 42 per cent. of the volatile matter may be incombustible. The ratio of the volatile matter to fixed carbon gives a general indication of the type of coal and its probable behavior in burning. Volatile matter escaping combustion furnishes carbon, tar, acids and ammonia, which, with some ash, form smoke.

The **ash** is an incombustible mineral residue consisting partly of mineral matter originally incorporated in the plant substance, but to a greater extent of clay, silt or sand, laid down with the vegetable matter, either intimately or in well-recognized layers. Parts of the roof or floor of the seam may also furnish some of the ash in commercial coal. To this is added water-borne mineral deposits in fissures or lenses, such as pyrites, gypsum, calcite, etc. Ash and moisture both reduce the net amount of combustible coal substance, but ash also greatly interferes with the combustion process by the formation of **clinkers**. Ash has no true melting point, but it has various degrees of plasticity depending on temperature and whether within an oxidizing or a reducing atmosphere. An arbitrary degree of plasticity is taken as a so-called melting point, ashes showing a low fusibility being most likely to give trouble from clinker, although this is by no means always true. The amount and mode of occurrence of the ash, together with the method of handling the fire, are equally important factors. Iron lowers the fusing temperature and is to be avoided in coals pulverized for burning.

Classification of Coals. Coals are classified according to the relative proportions of volatile matter to fixed carbon, together with their physical peculiarities (U. S. Geol. Survey, Bulletin 531). The content of fixed carbon divided by that of volatile matter is called the **"fuel ratio."** **Anthracite** is a hard coal, mostly obtained in Pennsylvania, having a fuel ratio not less than 10. **Semi-anthracite** has a fuel ratio of 6 to 10. **Semi-bituminous** coal has a fuel ratio of 3 to 6, and is of great commercial importance, embracing the Pocahontas, New River, Georges Creek and Clearfield fields in the Virginias, Maryland and Pennsylvania, which yield the highest-grade steam coals in the country. A small amount is found in the West. **Bituminous coal** is the most important class in the country, and includes most of the coals found east of the Rocky Mountains. Bituminous coals are either **caking** or **non-caking**, the former fusing and swelling in size when heated, the latter burning freely without fusing. **Cannel coals** are bituminous coals rich in hydrogen and hydrocarbons, burning with a bright flame without fusing, and are exceedingly valuable as gas coals. **Sub-bituminous coal** is a class lying between bituminous coal and lignite, the latter being brown and generally woody, with high moisture content.

Trade Names and Sizes of Coal. Bituminous coal as broken in the mine without any screening is called "run of mine." When run over screens to remove fine coal "Pittsburgh" coal is referred to as "lump," 1¼ or ¾, depending on the size of openings in the screens. **Sizing** is the separation of coal into groups of particles which will pass one size of screen and fail to pass another size. (For table of sizes of coal, see pp. 881 and 882.) The results are somewhat dependent on the way the coal breaks and the kind of screen used, whether bar, woven wire or perforated metal with round or square holes. There is no universal standard of sizes or kinds of screens nor of sizes of coal corresponding to certain names. Each coal district has certain sizes and names peculiar to itself and to the trade it supplies. Sizes and trade names of Illinois washed coals are given in University of Illinois Bulletin No. 9. All anthracite coal passing through the 3/32-in. openings when being screened is sometimes designated as buckwheat No. 4. In the Delaware, Lackawanna and Western region the term "birdseye" is used in place of buckwheat No. 3. In the Lehigh region the four sizes below 1/2 in. are designated as buckwheat, rice, barley and birdseye, respectively. In some localities, everything under stove size is sold as screenings. Coal which has been properly sized and graded may be greatly affected by breakage due to frequent handling and to weathering, so that inspection of size to be just should be at the place of sizing. No figures are available showing the degradation of size in bituminous coal due to handling.

Weight and Specific Gravity of Coals. According to Walter R. Johnson, in a report on American coals to the U. S. Navy Department, the specific gravity of anthracite (average of 7 samples) is 1.5, and its average weight (from 312 weighings made in a box holding 2 cu. ft.) is 53.4 lb. per cu. ft. The specific gravity of bituminous coal (average of 12 samples from Md. and Pa.) is 1.359, and its average weight (based on 328 weighings) is 52.8 lb. per cu. ft. The weight of coal as received (in box holding 8 cu. ft.) has been determined by the U. S. Bureau of Mines to be as follows:

Location of mine	Lb. per cu. ft.	Location of mine	Lb. per cu. ft.
Alabama (1 sample)	51.1	Northern China (avg. of 3 samples)	50.5
Illinois (1 sample)	49.3	Japan (avg. of 4 samples)	51.4
West Virginia (1 sample)	52.4	Australia (1 sample)	48.4

Solid coal weighs 85 to 94 lb. per cu. ft. Wilkesbarre anthracite lump weighs 69.4 lb. per cu. ft.; pea coal of same mine, 61 lb.

Heating Value of Coals. The calorific value of a fuel may be approximated by computing the various calorific values of its constituents as shown by the ultimate analysis. **Dulong's formula,** which follows, is used for this purpose, and gives results within 1 1/2 per cent. for most coals not high in moisture, such as anthracite, semi-bituminous and bituminous.

$$\text{B.t.u. per lb.} = 14{,}544C + 62{,}028\,[H - (O/8)] + 4050S$$

This formula assumes that the oxygen in the coal is combined with part of the hydrogen to form water, the remaining hydrogen being available for combustion together with the carbon and sulphur. The more direct determination of the calorific value is that made by using a **calorimeter.** See p. 503. With careful calorimetric work the errors can be kept within 0.3 per cent., or about 50 B.t.u. in high-grade coal. The greatest errors are due to the difficulty of obtaining a truly representative sample. With ordinary careful commercial sampling it is believed the errors are of the order of about 100 B.t.u. on high-grade coal. Where the sampling and calorimetric methods are not known to be of the highest order, the last 200 B.t.u. should be considered as in a region of more or less doubt. For the combustion of coal, see pp. 369 and 881 to 892.

Weathering. Coal suffers a **deterioration in calorific value** by exposure to air, but the amount is small. There is a slight oxidation at the surface of coal at ordinary temperatures, so that fine coal deteriorates more than lump. **West Virginia "smokeless" fine slack exposed to the weather in a temperate climate lost less than 1 per cent. in heating value in 1 year;** run of mine less than half as much; Pittsburgh run of mine less than half of 1 per cent.; Illinois run of mine about 2.5 per cent.; and Wyoming sub-bituminous about 3.5 per cent. The loss of gases or volatile matter from coal during storage at ordinary temperatures is so slight as to be inconsiderable in its effect on heating value (H. C. Porter, Bureau of Mines).

Spontaneous Combustion (H. C. Porter, Bureau of Mines) of coal results from accumulation of the heat of slow oxidation beginning at ordinary temperatures. If conditions are such that the oxygen of the air can be supplied so as to produce heat by oxidation faster than the heat can be dissipated, the temperature rises continuously until ignition results. Two main factors determine the liability of any coal to spontaneous ignition, (1), its friability or tendency to break up into fine coal and dust, and (2) the chemical character of its substance as manifested particularly in its rapidity of oxidation. The compactness of piling or the facility of penetration of air through the coal is one of the largest factors in promoting the progress of spontaneous heating. The oxidation rate of the sulphur compounds occurring in coal is not as great as that of the coal itself, and sulphur therefore is a lesser factor in spontaneous combustion. The relative amount of volatile matter is not in itself an important factor, although coals of high volatile matter frequently show a high rate of oxidation. The influence of moisture is uncertain, varied experience having led to contradictory opinions on the subject.

Spontaneous combustion in stored coal may be avoided by observance of the following precautions, and, of the first three, any one alone will in most cases serve to insure safety:

(1) Store in small piles, no interior part of which is more than 8 ft. from an air-cooled surface.

(2) Store only screened coal, larger than 1 in., eliminating fines and dust.

(3) Follow closely, by driving down iron rods for example, any rise of temperature, and rehandle those portions reaching 120 deg. fahr.

(4) In bunkers, bins or piles avoid draft of air *through* the coal, from open doors or chutes at the bottom or from the collection of lumps near the source of air supply. *Through* ventilation by pipes is dangerous.

(5) Avoid freshly crushed or freshly mined coal.

(6) Remove storage a reasonable distance from external sources of heat, such as boilers, furnaces, flues, steam pipes or hot cinder piles.

(7) Use the older portions of the storage first, avoiding accumulations of old coal in out-of-the-way corners and underneath new lots.

(8) For large stocks procure coal of the least possible friability and reduce to a minimum the breakage caused by drops and mechanical handling. Pile evenly, not in cones.

Coal Sampling. (G. S. Pope, Bureau of Mines Bulletin 63.) Portions are selected from all parts of a delivery of coal, combined into a gross sample, thoroughly mixed and reduced to quantities required by the chemist for his determination. A large gross sample and fine crushing reduce errors. Coal relatively easy to sample showed variations of 200 B.t.u. and 1.2 per cent. ash when 200-lb. gross samples were taken. When 1000-lb. gross samples were taken the variations were 37 B.t.u. and 0.22 per cent. ash. Further increase in the size of the gross sample gains but little in accuracy. It is practically impossible to get a representative sample of coal except while it is being handled. For approved method of obtaining laboratory sample (3 to 5 lb.), see "Specifications for the Purchase of Coal for Steam Power Plants," p. 604.

Methods Used in Proximate Analysis and Calorimetry. The following methods are those described by J. D. Davis in Bulletin 41, U. S. Bureau of Mines.

Preparation of Sample. The sample received at laboratory (2 to 4 lb.) is first reduced in a roll crusher so that it will pass a 20-mesh screen, and 3 oz. are immediately placed in a rubber-stoppered bottle for a later total moisture observation. The remainder is then thoroughly mixed and reduced by riffling to a quantity not more than 3 oz. For most anthracite samples and for any samples that are very wet or contain much foreign matter, the whole sample is thoroughly air-dried by placing it on a pan and in an oven through which air at 90 deg. fahr. is caused to circulate, until it loses no further moisture, as determined by successive weighings. It is then ground to pass a 20-mesh screen, riffled down to 8 oz. and then ground to a powder in a revolving porcelain jar about 2/3 full of flint pebbles. Three ounces of this powder are then placed in a rubber-stoppered bottle for the laboratory.

Determination of Moisture. One gram from the bottle sample (about 1/30 oz.) is weighed into a porcelain capsule (No. 2 size) of known weight, and placed in a drying oven and left there for about 1½ hr. This oven is of sheet copper and has four compartments each holding 12 samples, each compartment being surrounded by a bath of boiling glycerine (2 glycerine : 1 water), by which a uniform temperature of about 221 deg. fahr. is maintained. The capsule is then removed, covered with an aluminum lid and placed in a glass desiccator to cool without absorbing moisture. When cool it is again weighed, and the loss represents moisture.

Determination of Ash. The capsule containing the residue from the moisture determination is placed in an ordinary assayer's furnace or muffle and heated for 1½ hr. at about 1650 deg. fahr., with a slow draft of air circulating over it. This burns out all the combustible and drives off some volatile matter that is not combustible. The capsule is then allowed to cool and is weighed. To make sure that the combustible has been burned, the process is repeated.

Determination of Volatile Combustible Matter. One gram of the coal is weighed into a 30-c.c. platinum crucible of known weight, and the crucible is then covered, placed on supports and subjected for 7 min. to the heat of the 20-cm. carbon-free flame of a Fletcher burner, the bottom of the crucible being 7 cm. from the top of burner. It is then taken off, allowed to cool, and then weighed, the loss in weight representing volatile combustible matter.

Determination of Sulphur. See Bulletin 41, U. S. Bureau of Mines.

Determination of Calorific Value. The standard calorimetric outfit consists of a platinum-lined steel cup or bomb closed with a screw cap, and fitted with an oxygen valve, electrodes for electrical firing of the charge, a metal can for holding distilled water and the bomb, a mechanical device for stirring the water, a thermometer which can be read accurately to 0.001 deg. cent. by means of a cathetometer, and a double-walled felt-lagged metal jacket containing water, in which the can containing the bomb fits. (For calibration of calorimeters, see Circular No. 11, Bureau of Standards, 1911.) In determining the calorific value of a coal sample, 1 gram is weighed into a platinum tray and placed on a support inside of the bomb, a piece of platinum fuse wire being then connected to the electrodes and allowed to dip into the coal. The bomb cap is screwed into place and oxygen is forced in at a pressure of about 350 lb. per sq. in. The bomb is then placed in the weighed water. The temperature of the calorimeter is observed at minute intervals for 5 consecutive minutes, and at the end of the fifth minute the electric circuit is closed, firing the coal. The thermometer is now observed. The first two readings after firing are taken at half-minute intervals. Three more readings are taken at minute intervals. The maximum temperature will now have been reached and the thermometer is observed for five more consecutive minutes.

All the data for calculating the heating value of the coal have now been determined. Corrections must be made for the nitrogen content burned to nitric acid, and for the sulphur content which is burned to sulphuric acid. The **net heating value** is obtained by multiplying the rise of temperature caused by the combustion of the coal by the water value of the calorimeter. Calculations and corrections involved in this determination are given in detail in Technical Paper 8[a] of the Bureau of Mines.

Lignite contains so large an amount of water that the process of drying, either in storage or in the furnace fire, disintegrates the lumps into relatively fine stuff with attendant difficulties of handling and burning. It must be used shortly after being mined, requires a large grate with narrow air passages (see p. 888) and a large combustion space, and burns out quickly. The moisture in lignite as mined varies from 25 to 35 per cent. North Dakota dry lignite will average 50 per cent. fixed carbon, 42 per cent. volatile, and 8 per cent. ash. In a stove for house-heating twice as much lump lignite as mined was required as of Youghiogheny coal. With air-dry egg-size lignite 1½ times the amount was required. Some lignites are particularly liable to spontaneous combustion. Excellent producer gas can be made from lignite, see pp. 1057 to 1059.

Briquetting of Fuel. The advantages claimed for briquetted fuel are uniform size, smokelessness, uniform condition of fire bed, absence of clinkers, reduced attention to fires, increased heating value and efficiency, higher rates of combustion, reduced loss from breakage and weathering. Briquets should possess coherence to stand handling, be hard but not brittle, have a density equal to the lump coal from which they are made, should not absorb more than 3 per cent. of water, and should withstand exposure and retain their shape in the fire. The binder most commonly used is coal-tar pitch, but a great variety of substances singly or in combination has been proposed. The cost of briquets in eight plants in the United States ranges from $1.00 to $2.25 per ton plus the cost of the raw fuel. In Europe the cost is 25 to 50 cents, plus 50 to 80 cents for binder, plus the cost of the raw coal. The low price of good coal in the United States and the small difference in price between slack and lump confine the industry to relatively small fields at this time. Briquetting of North Dakota lignite residue after driving off moisture and a part of the volatile matter produces a product of value nearly equal to anthracite coal. The most favorable field for briquets is for locomotive and household use. Some fuels contain sufficient binding material to make good briquets under pressure and slight heat. Usually from 3 to 8 per cent. of binder is required. Too much pressure shatters the coal particles and weakens the briquets. The lack of waterproofing qualities is a serious defect in many binders. Mixing refuse coal dust as a mortar with clay, making it into balls by hand and air-drying them, is a household industry in some countries. The largest briquetting plant in the United States, at Superior, Wis., utilizes fine refuse coal from stock piles of Virginia coal and produces a product competing with anthracite for household use.

Pulverized Coal Fuel. Coal dust and low-grade coal may be successfully burned in the furnaces of specially designed vertical water-tube boilers (*Iron Age*, Oct. 2, 1913). The coal is fed into a hopper leading to a pulverizer, from which it is blown by air preheated by the waste gases through a vertical nozzle at the bottom of the furnace and then ignited. The flame is mushroom-shaped, returning upon itself on reaching the top of the furnace. The ash is converted by the intense heat into a liquid spray which strikes the fire-brick lining of the furnace and trickles down to its lower edge where it falls in the form of chilled globules into the ash pit. This spray protects the lining, rendering the use of fire clay unnecessary in laying the bricks. Preheating the air used by the blower makes it possible to burn coal containing 15 per cent. or more of moisture. Ignition is first effected by the use of a torch. The heat stored in the incandescent brick lining is sufficient to restart the fire after a temporary stop. The fuel consumption may be regulated in exact proportion to the demands made on the boiler, the air supply adjusted closely to the amount theoretically required, and the production of smoke reduced to a minimum. A very small stack will suffice, and steam can be raised very quickly—an advantage in taking care of peak loads.

Specifications for the Purchase of Coal for Use in Steam Power Plants. Following are extracts from the more important stipulations embodied in the form of specifications and contract devised by the U. S. Bureau of Mines.

Sampling. Samples to be regularly and systematically collected in increments of from 10 to 30 lb. (5 to 10 lb. may be taken for slack and small sizes of anthracite), so regulated that the gross sample shall not be less than 1000 lb. If coal contains an unusual amount of impurities, or slate, or the pieces of such impurities are very large, gross sample to be 1500 lb. or more. For slack and small sizes of anthracite without impurities in abnormal quantities or in pieces larger than ¾ in., a 500-lb. gross sample will be sufficient.

Gross sample to be crushed, mixed and reduced in quantity to convenient size for transmissal to laboratory. Crushing, by mechanical crusher or by hand tamping on smooth, tight floor (or on a heavy canvas). Mixing and reduction, by hand with a shovel, or by means of riffles and sampling machines. When prepared by hand, coal to be crushed to following approx. sizes before each reduction:

Weight of sample, lb.	1000 or more	500	250	125	60
Size, in.	1	¾	½	⅜	¼

The 60-lb. sample to be reduced to about 15 lb. by quartering or by use of riffling and sampling machines and divided into three 5-lb. parts, each placed in air-tight containers, one going to laboratory agreed upon, one to coal company and one to consumer, each part bearing an unbroken seal.

If moisture content is desired a separate special moisture sample must be taken. This sample, of approximately 100 lb., is to be accumulated by placing in a waterproof receptacle with a tight-fitting and waterproof lid small parts of the gross sample as collected, or it may be collected independently of the gross sample. The moisture sample is to be immediately crushed and reduced mechanically or by hand to about a 5-lb. quantity, which is to be immediately placed in a container and sealed air-tight. If prepared by hand, it should be rapidly crushed so that no pieces of coal or impurities are larger than ½ in., and it should be rapidly reduced by the "quartering" method on a canvas to the 5-lb. quantity.

Description of Coal Offered. The description of the coal should include the percentage content of moisture in the coal "as received," volatile matter in "dry coal," ash in "dry coal," sulphur in "dry coal," and the B.t.u. per lb. in "dry coal." The source of the coal should be indicated by giving the name of mine or mines and their location; the name or other designation of coal bed; the name of operator of mine or mines; the commercial name of coal; and the railroad on which mine or mines are located.

Award of Contract. Bids may be rejected from further consideration offering coals on which the consumer has information as possessing physical characteristics or volatile matter or sulphur or ash content, or because of clinkering or excessive refuse, or as having failed to meet the requirements of city smoke ordinances, or for other cause which would indicate them to be of a character or quality which the consumer considers unsuited for use in his storage space or in his power-plant furnace equipment.

In order to compare bids as to the quality of the coal offered, all proposals shall be adjusted to a common basis. The method used is to merge the four variables—ash content, moisture content, heating value, and price bid per ton—into one figure, the cost of 1,000,000 B.t.u. as follows:

(*a*) All bids are adjusted to the same ash percentage by selecting as the standard the proposal that offers coal containing the lowest percentage of ash. The difference in ash content between any given bid and this standard is divided by 2 and the price quoted in such bid multiplied by the quotient. The result is added to the price bid.

(*b*) The price as determined under (*a*) above is divided by the difference between 100 per cent. and the percentage of moisture guaranteed, the result being computed to the nearest tenth of a cent.

(*c*) The price as determined under (*b*) is multiplied by 1,000,000 and the result divided by the product of 2240 (or 2000) multiplied by the number of B.t.u. guaranteed.

After elimination of undesirable bids, the selection of the lowest bid of those remaining on the basis of the cost per 1,000,000 B.t.u. may be considered by the consumer as a tentative award, the consumer reserving the right to have practical service test or tests to determine the final award of contract.

Causes for Rejection. Coal containing 3 per cent. more moisture, or 4 per cent. more ash, or 3 per cent. more volatile matter, or 1 per cent. more sulphur, or 4 per cent. fewer B.t.u. than the specified guarantees or coal furnished from a mine or from mines other than those specified by the company, unless upon the written permission of the consumer, shall be considered subject to rejection, and the consumer may, at his option either accept or reject the same.

Price. The price named is to be adjusted as follows for variations in heating value, ash content, and moisture content from the standards guaranteed:

(a) When the coal is considered on a "dry-coal" basis, no adjustment in price shall be made for variations of 2 per cent. or less in the number of B.t.u. from the guaranteed standard. When the variation in heat units exceeds 2 per cent. of the guaranteed standard, the adjustment shall be proportional.

(b) No adjustment in price shall be made for variations of 2 per cent., or less, below or above the guaranteed percentage of ash on the "dry-coal" basis. When the variation exceeds 2 per cent. the adjustment in price shall be determined as follows: The difference between the ash content by analysis and the ash content guaranteed shall be divided by 2 and the quotient multiplied by the bid price and the result added to or deducted from the price adjusted for B.t.u. according to whether the ash content by analysis is below or above the percentage guaranteed. Adjustment to be figured to the nearest tenth of a cent. As an example, consider a coal delivered under a contract guaranteeing 10 per cent. ash at a bid price of $3 per ton. If the coal shows by analysis an ash content of 13.26 per cent. the adjustment in price would be $[(0.1326 - 0.10)/2] \times \$3 = 4.9$ cents per ton (deduction).

(c) The price shall be further adjusted for moisture content in excess of the amount guaranteed by the contractor, the adjustment being determined by multiplying the price bid by the percentage of moisture in excess of the amount guaranteed. *E.g.*, if a coal delivered under a contract guaranteeing a moisture content of 3 per cent., the price bid being $3 per ton, shows on analysis 4.58 per cent. moisture, the bid price should be multiplied by 1.58 (representing excess moisture), giving 4.7 cents as the deduction per ton.

Coke

Coke is the solid substance left after bituminous coal has been deprived of its volatile constituents by distillation. Distilled in a beehive oven the product has a long columnar structure, while from closed retorts (as in the by-product process) the structure is short and blocky, friable and large-celled. Both are used for metallurgical purposes. The theoretical **yield** of coke is the sum of the fixed carbon and ash of the coal, the actual yield averaging 64.7 per cent. for beehive and 75.1 per cent. for by-product coke. The average **weight** of coke is 28 lb. per cu. ft., *i.e.*, approximately 71 cu. ft. per short ton. About 58 per cent. of the sulphur in the coal is found in the coke. From 12 to 20 boiler h.p. can be generated from the heat from each beehive oven.

Cokes differ greatly in appearance and properties. They may be dull gray, light gray, silvery and occasionally iridescent. Coke is generally rough-surfaced, but that from near the walls of the oven is often smooth and glassy. Color is not a safe indication of quality. The structure may vary from porous to dense and heavy. For metallurgical purposes it should be hard and not easily crushed or broken, giving a clear, ringing sound when struck. Some cokes are soft, brittle, easily broken and give a soft, punky sound when struck. The ease of ignition varies widely. The cellular structure is what gives to coke its great advantage as a metallurgical fuel. Other things being equal, within certain limits, the more porous the coke the better the fuel. The limit to this advantage of porosity is reached when the strength of the cell walls is too greatly lessened due to the enlargement. Generally speaking, dense cokes are also soft, and porous cokes hard. The real **specific gravity** of coke is the specific gravity of the coke substance; the apparent specific gravity is the relation between the whole mass and an equal volume of water. Laboratory tests to determine the physical qualities of cokes are not very satisfactory. Shatter tests are probably of more value than crushing tests.

Coke made in beehive ovens from Connellsville coal is the **standard** with which all other cokes in the United States are compared. Average analyses of this coal and the coke produced from it are given in Table 3. Analyses of beehive and by-product cokes from various regions are given in Tables 4 and 5.

Table 3. Average Analyses of Connellsville Coal and Coke

Peat

Peat is a mixture of water (85 to 95 per cent.) and partly decayed vegetable matter that is exceedingly friable and variable in quality. Color, from yellowish to brown and black; dry weight, from 7 to 60 lb. per cu. ft. Air-dried peat is from 8 to 18 times as bulky as coal, is easily kindled, burns freely, gives quick, intense heat, is clean—without soot or dust—and is liked for domestic use. Illuminating gas, producer gas and a variety of valuable by-products can be made from peat (for various uses, see Bulletin No. 16, U. S. Bureau of Mines). Table 6 gives percentage analyses and calorific values of peat from various localities.

Table 6. Analyses and Calorific Values of Air-dried Peat
(U S. Bureau of Mines)

Kind of peat	Locality	Water	Ash	Sulphur	Calorific value		
					Calories	B.t.u.

Wood

The fuel values of different woods are nearly proportional to their dry weights, except that resinous woods give higher values. Ordinary dry cord wood contains about 25 per cent. of moisture. The weight and ash content of dry wood are given in Table 7 (see also p. 454). The proximate percentage analysis

Table 7. Weight and Ash Content of Dry Wood
(Wood dried to a constant weight at 212 deg. fahr.)

Name of wood	Ash, per cent.	Weight, lb. per cu. ft.	Name of wood	Ash, per cent.	Weight, lb. per cu. ft.
Ash, black	0.72	39	Hickory, pignut	0.99	56
Ash, white	0.42	39	Hickory, shagbark	0.73	51

of oak wood made by the U. S. Bureau of Mines, the samples being obtained by sawing across the sticks, is as follows: Moisture, 10.3; volatile matter, 77.6; fixed carbon, 11.2; ash, 0.9; sulphur, 0.03. B.t.u. as received, 7589; in dry wood, 8460. Ultimate analysis shows that about 50 per cent. of the weight of wood is carbon, and about 6 per cent. hydrogen. Analyses, by Gottlieb, of different woods (dry) are given in Table 8.

Table 8. Analyses of Various Woods (Dry)

Name	C	H	N	O	Ash	Calories	B.t.u.
Oak	50.16	6.02	0.09	43.36	0.37	4620	8316
Ash	49.18	6.27	0.07	43.91	0.57	4711	8480

Pine	50.31	6.20	0.04	43.08	0.37	5085	9153

A small house-heating boiler in which a variety of fuels were burned evaporated 15,345 lb. of water from and at 212 deg. fahr. with amounts of fuel approximately as follows:

1 cord of dry oak wood,	1700 lb. of anthracite coal,
$1\frac{1}{8}$ cords of yellow pine,	1800 lb. of semi-bituminous coal,
$1\frac{1}{2}$ cords of spruce or birch,	2300 lb. of bituminous coal,
$1\frac{3}{4}$ cords of poplar, white pine, or cottonwood,	2800 lb. of sub-bituminous coal,
	3500 lb. of lignite.

Charcoal

Beech, birch and maple produce about 46 bushels of excellent charcoal per cord. Charcoal absorbs moisture rapidly up to 10 to 15 per cent., an average piece containing 84 per cent. carbon, 12 per cent. water, 3 per cent. ash and 1 per cent. hydrogen. Incomplete distillation leaves as much as 10 per cent. of volatile matter in some charcoal. The heating value is about 12,850 B.t.u. per lb.

Other Solid Fuels

Sawmill Refuse, consisting of saw dust, "hogged" or shredded wood, chips, etc., contains from 40 to 60 per cent. of moisture. The calorific value of redwood, pine, fir, hemlock, spruce and cedar refuse is practically 9000 B.t.u. per lb. of dry fuel.

Straw from which grain has been threshed has a calorific value of from 5000 to 6500 B.t.u. per lb., depending on its degree of dryness. **Corn** (shelled), sometimes used as an emergency fuel in the grain-growing states west of the Mississippi, has a calorific value of from 7800 to 8500 (dry) B.t.u. per lb.

Tan Bark, or the fibrous portion of oak bark remaining after it has been used in the tanning industry, contains about 66 per cent. moisture. The available heat per lb. is approximately 2700 B.t.u. The spent tan resulting from 1 lb. of dry ground bark used will produce an available heat of about 5700 B.t.u. In burning tan bark it is necessary to have a large combustion space, large areas of heated brickwork radiating to the fuel bed, and draft sufficient for high combustion rates. According to D. M. Meyers, from 1.5 to 2.08 h.p. may be developed from 1 sq. ft. of grate surface in horizontal return-tubular boilers.

Bagasse is sugar cane from which the juice has been extracted by pressure between the rolls of a mill. Its moisture content ranges from 42 to 53 per cent. Dry bagasse contains 43–47 per cent. C., 5.4–6.6 per cent. H, 45–49 per cent. O, and 1.5–3 per cent. ash, its calorific value ranging from 8000 to 8700 B.t.u. per lb. Porto Rico bagasse contains 0.4 per cent. N. The fuel value of green mill bagasse, according to "Steam," is approximately as follows, allowance being made for the heat required to evaporate its moisture and superheat the resulting steam to the stack-gas temperature:

Per cent. of extraction of weight of cane	Per cent. moisture in bagasse		B.t.u. available for steam generation		Lb. bagasse equivalent to 1 lb. of 14,000-B.t.u. coal	
	(a)	(b)	(a)	(b)	(a)	(b)
75	42.64	51.00	4139	3294	3.38	4.25
77	39.22	48.07	4475	3630	3.13	3.86
79	35.15	44.52	4874	3976	2.87	3.52
81	30.21	40.18	5359	4392	2.61	3.19
83	24.12	35.00	5958	5005	2.35	2.80
85	16.20	28.33	6716	5558	2.08	2.52

(a) Based upon tropical cane of 12 per cent. fiber and juice containing 18 per cent. of solid matter. (b) Based upon Louisiana cane of 10 per cent. fiber and juice containing 15 per cent. of solid matter.

LIQUID FUELS

Crude Oils and Their Distillates. Petroleum is a mineral oil composed of a series of hydrocarbons in various proportions. **Fuel oil** is either crude oil or the residue after the lighter oils have been removed. There is available for fuel 2 or 3 per cent. of the product from the Pennsylvania and Ohio fields; an amount from Ohio, Indiana and Oklahoma depending on a low price that will compete with coal, most of the California oil, and practically all from the Texas field. Crude oils from various fields show somewhat different compositions. As a rule, the specific gravity lies between 0.80 and 0.97, the flash point between 76 and 93 deg. fahr., and the composition by weight is 84 to 88 per cent. carbon and 11.5 to 14.5 per cent. hydrogen, with a small per cent. of impurities. Tables 9 and 10 give data on crude oils from various fields, and on their distillates. W. Inchley (*The Engineer*, vol. III, p. 155) finds that the higher heating value of liquid fuels is given very closely by the empirical expression

$$13{,}500\ C + 60{,}890\ H,$$

in which C and H denote respectively the parts by weight of carbon and hydrogen in the fuel. The last column of Table 10 (due to Mr. Inchley) gives values calculated from this formula. The heating value may also be roughly estimated by the formula: B.t.u. per lb. = 18,650 + 40 × (Baumé reading − 10).

Oil is sold by the barrel of 42 gal. The A. T. & S. F. R. R. Co. found the evaporative value of coal and oil the same when the price of coal in tons was three and a half times the price of oil in barrels. Most experience falls within the limits of 3 to 4½ bbl. of oil as the equivalent of one long ton of coal.

Tests of 17 burners by the U. S. Naval Board showed the water evaporated from and at 212 deg. per lb. of oil to vary from 11.48 to 13.96 lb. Tests of stationary plants show equivalent evaporations of 14 to 16 lb. Fuel oil may be too viscous to flow in cold weather, and steam-heating devices are used to raise the temperature to about 150 deg. Reliable temperature control is necessary for successful handling as well as for economical use. Noxious and explosive gases that are heavier than air evolve from fuel oil, requiring the ventilation of containers and isolation from ignition sources.

Coal Tar, a by-product of the manufacture of coal gas and of coke, is a black, viscous liquid composed largely of aromatic hydrocarbons, 100 lb. of gas coal yielding from 4 to 5 lb. of tar weighing from 9.2 to 10.5 lb. per gal. (sp. gr., 1.10 to 1.26). It has a low flash point, and its lower calorific value is about 15,000 B.t.u. per lb. (higher, about 16,500). It can be burnt as a fuel in any furnace suitable for crude oil, by preheating to make it sufficiently fluid. It should pass through a strainer before reaching the burners.

Tar Oils (creosote oil, anthracene, etc.), resulting from the distillation of tar, have been used as Diesel-engine fuels in Germany. Specific gravity, 0.97 to 1.11; mean lower calorific value, about 16,000 B.t.u. per lb.

Gasoline. The average percentage composition of gasoline used in motors is carbon, 83.5 to 85; hydrogen, 15.5 to 15; nitrogen, oxygen, sulphur, etc., 1.0 to 0. The higher heating value lies between 19,000 and 21,000 B.t.u. per lb. From Inchley's formula it should be 20,710 B.t.u., but calorimetric determinations frequently show lower values. Specific gravity, 0.67 to 0.73. For the combustion of 1 lb. of gasoline the weight of air required is about 15 lb., or the volume of air at 62 deg. fahr. is approximately 200 cu. ft. When gasoline is used as a fuel for internal-combustion motors the liquid is vaporized and the vapor mixed with a suitable amount of air. Levin gives the following data regarding carbureted gasoline: One pound of gasoline vapor at 62 deg. fahr. and atmospheric presssure has a volume of

4.2 cu. ft. With 15 per cent. excess, 1 cu. ft. of vapor requires 54.2 cu. ft. of air, and taking 18,500 B.t.u. as the lower heating value per lb., the heating value per cu. ft. of the normal charge is 69.3 B.t.u. Approximate heating value, B.t.u per lb. = 18,320 + 40 (Bé. − 10).

Kerosene. The average composition is C = 84.5, H = 15.5, per cent. by weight; higher heating value, 20,000 to 23,000 B.t.u. per lb. Volume of 1 lb. of kerosene vapor at 62 deg. fahr., about 2.5 cu. ft.; and with 15 per cent. excess, 87.5 cu. ft. of air must be supplied per cu. ft. of kerosene vapor. The lower heating value per cu. ft. of normal charge (Levin) is 64.4 B.t.u. Approximate heating value, B.t.u. per lb. = 18,440 + 40 (Bé. − 10).

Benzol, obtained from by-product coke ovens, is used for denaturing and enriching alcohol. The specific gravity is 0.88 and the higher heating value about 18,000 B.t.u. per lb. (lower, 17,300 B.t.u.). Benzol has the chemical formula C_6H_6; hence 13.32 lb. of air are required for complete combustion of 1 lb. of benzol. 1 cu. ft. of benzol vapor at 62 deg. fahr. requires 36 cu. ft. of air for combustion and gives up 3700–3880 B.t.u.

Alcohol. See p. 621. The laws of the United States and France require that alcohol used as fuel must be **denatured.** It is required that: "To 100 volumes of ethyl or grain alcohol of strength of not less than 90 per cent. there must be added 10 volumes of methyl or wood alcohol and ½ volume of benzine; or 2 volumes of wood alcohol and ½ volume of pyridine bases." Commercial alcohol always contains water. Table 11, by Schöttler, gives the specific gravity and heating value of various mixtures of alcohol and water.

Table 11. Specific Gravity and Heating Value of Various Mixtures of Alcohol and Water

Per cent. of alcohol in mixture by volume	Per cent. of alcohol in mixture by weight	Specific gravity	Lower heating value per lb., B.t.u.
95	93.8	0.805	10,880
90	87.8	0.815	10,080
85	81.8	0.826	9,360
80	76.1	0.836	8,630
75	70.5	0.846	7,920
70	65.0	0.856	7,200

The equation of complete combustion of alcohol is:

$$C_2H_6O + 3O_2 = 2CO_2 + 3H_2O$$

1 cu. ft. of alcohol vapor at 62 deg. fahr. requires 14.5 cu. ft. of air for combustion. If the combustion is incomplete, according to the equation

$$C_2H_6O + O_2 = C_2H_4O_2 + H_2O,$$
